dysfunction.[21] In a study of patients with coronary artery disease, the administration of 4 g powdered ginger daily for 3 months did not affect ADP- and epinephrine-induced platelet aggregation, fibrinolytic activity, or plasma fibrinogen concentration.[22] However, a single dose of 10 g powdered ginger administered produced a significant reduction in platelet aggregation induced by the ADP and epinephrine. *In vitro* studies suggest that ginger may produce anti-inflammatory effects by inhibiting arachidonic acid metabolism, cyclooxygenase, and lipoxygenase pathways.[23] *In vitro* studies also indicate that gingerol compounds are novel capsaicin-activated VR1 (vanilloid) receptor agonists.[24]

Mechanism of Toxicity

Potential active antiemetic agents in the rhizome of ginger include shogaol and gingerol. Some of the antiemetic activity may result from the presence of gingerols, 6-shogaol, and galanolactone, which inhibit 5-HT_3 receptor function. *In vitro* studies indicate that these compounds are not competitive antagonists at the 5-HT_3 receptor, and the anti-emetic effect probably results from the binding of these compounds to a modulatory site distinct from serotonin.[25]

DOSE RESPONSE

The typical daily dose of fresh ginger is about 2–4 g (1.0 in./2.5 cm rhizome) or 0.5–1.0 g powdered dry rhizome in 3–4 divided doses. There are few data on the toxicity of ginger following the ingestion of doses of ginger exceeding typical therapeutic amounts. A clinical trial used a single dose of 10 g powdered ginger administered to patients with coronary artery disease, but the study did not report adverse effects.[22]

TOXICOKINETICS

Absorption

Based on *in vitro* studies, the dehydrated product (i.e., shogaol) undergoes almost complete reversion to gingerol in the acidic conditions of the stomach at body temperature (37.0 °C/98.6 °F).[19] Consequently, the dehydration of gingerol to shogaol may not reduce the bioavailability of gingerol.

Biotransformation

In rats, 6-gingerol undergoes conjugation, ω-1 oxidation and β-oxidation at the phenolic side chain.[26] The bile contains about 48% of an orally administered dose of 6-gingerol for over 60 hours, whereas about 12% appears in the urine as multiple metabolites (e.g., vanillic acid, ferulic acid, 9-OH-6-gingerol) and (S)-(+)-6-gingerol. There are few pharmacokinetic data on gingerol in humans.

Drug Interactions

Theoretically, ginger may increase the risk of bleeding when ingested with other drugs or herbs that affect coagulation. Because ginger can inhibit thromboxane formation and platelet aggregation, concomitant use with anticoagulants is not usually recommended. However, there is no clear evidence that these potential effects are clinically relevant. In an open-label, three-way crossover study of 12 healthy volunteers receiving pretreatment for 7 days with standard doses of ginger, there was no significant effect on clotting parameters or the pharmacokinetics of warfarin.[27] Outcomes included measurement of platelet aggregation, international normalized ratio (INR), warfarin protein binding, plasma warfarin concentrations, and S-7-hydroxywarfarin concentrations in the urine. A case report of a 76-year-old woman on long-term phenprocoumon therapy associated the development of an elevated INR (>10) and epistaxis with the use of ginger and tea from ginger powder.[28] Prior to the use of ginger, she had a stable INR, and her INR returned to the normal therapeutic range at the same phenprocoumon dose after cessation of ginger use. Other potential drug interactions include an increased effect of hypoglycemics and antihypertensive agents, and decreased efficacy of histamine$_2$-blockers (e.g., ranitidine) and proton-pump inhibitors (e.g., lansoprazole).

CLINICAL RESPONSE

There are few reports of toxicity associated with the use of ginger. Exposure to ginger is one of the most common contact allergens among spices based on patch testing.[29] Consumption of excessive amounts of ginger may cause sedation. Adverse effects of ginger during clinical trials include headache, diarrhea, abdominal discomfort, esophageal reflux, and drowsiness.[30] Although the number of subjects was limited, follow-up of randomized clinical trails on the use of ginger during pregnancy did not demonstrate an increased incidence of spontaneous abortions, stillbirths, neonatal deaths, low birth weight, or congenital abnormalities, when compared with the placebo group.[31,32] Ginger Jake paralysis was a peripheral neuropathy that was associated with the consumption of an alcoholic ginger extract, Jamaica ginger. This neurological condition resulted from contamination of this beverage with triorthocresyl phosphate rather than any constituent in ginger.

DIAGNOSTIC TESTING

The combination of high performance liquid chromatography (HPLC) with UV photodiode array detection and electrospray mass spectrometry allows the detection of constituents of ginger and ginger extracts. HPLC with mass spectrometry or nuclear magnetic resonance spectroscopy provides rapid determination of ginger constituents without sample purification or synthetic standards.[33] Thermal degradation and dehydration of gingerol compounds can occur during gas chromatographic analysis, resulting in the formation of aliphatic aldehydes, zingerones, and the corresponding shogaol compounds. Liquid chromatography/electrospray ionization/tandem mass spectrometry coupled with diode array detection identification is an alternative to GC/MS for the analysis of gingerol-related compounds, especially for thermally labile constituents.[34] At least during short-term storage, gingerol and shogaol are relatively stable at room temperature in the absence of strong acids or bases.[19] Aged essential oil of ginger contains relatively high amounts of α-curcumene and smaller amounts of zingiberene.[2]

TREATMENT

There are few data on the toxicity associated with excessive amounts of ginger. Treatment is supportive.

Chapter 69

GINKGO TREE
(*Ginkgo biloba* L.)

HISTORY

The seeds and fruits of *Ginkgo biloba* have been part of traditional Chinese medicine for approximately three millennia before the birth of Christ, particularly for the treatment of asthma, indigestion, cough, and chilblains (i.e., pedal edema related to cold exposure).[1] In the 16th century, the Chinese *Materia Medica* described herbs from *Ginkgo biloba* as a treatment for senility in the royal families.[2] Gingko seed poisoning has been annotated in old Japanese scripture ("Yamato-honzo") at least since the early 18th century.[3] In 1881, the first case reports of gingko seed poisoning appeared in the Japanese medical literature.[4] During food shortages in Japan from 1930–1960, gingko seeds were an important source of food; there were numerous case reports of gingko seed poisoning (Gin-nan food poisoning).[5] In recent decades, medicinal uses for the extract of *Ginkgo biloba* include Alzheimer's disease, dementia, memory loss, cerebral ischemia, premenstrual syndrome, and altitude sickness.

BOTANICAL DESCRIPTION

The ginkgo tree is the last remaining species in the Ginkgoaceae family, which dates back at least 180–200 million years. Plants from the Ginkgoaceae family dominated the landscape 130 million years ago, but modern angiosperm seed plants gradually replaced all species in the Ginkgoaceae family except *Ginkgo biloba*. All other species in this family are now extinct. The ginkgo tree is a long-lived species (i.e., up to 1000 years) that is a popular ornamental tree worldwide. In Japanese, *ginkyo* describes the ginkgo nut as "silver apricot."

Common Name: Ginkgo, Ginkgo Tree, Maidenhair Tree

Scientific Name: *Ginkgo biloba* L.

Botanical Family: Ginkgoaceae

Physical Description: This well-branched, deciduous tree grows up to 40 m (~130 ft) in height after reaching maturity in 25 years. Male and female plants grow separately. The bark is usually light gray-brown with irregular ridges that eventually become deeply furrowed. Young twigs are light reddish-brown that become gray with numerous and obvious spur shoots. The reddish-brown buds are broadly conical to dome-shaped. Alternate, simple, fan-shaped leaves reach up to 5–8 cm (~2–3 in.) in length and width with parallel, fan-like venation. The light green leaves have long petioles with two or three irregular lobes and broad or undulating edges. Male flowers are very small and green, and these flowers appear on slim, cylindrical, leafless clusters (catkins) about 1 in. (2.5 cm) long. The female are "cones" on 4–5 cm (~1.5–2 in.) peduncles bearing one or two ovules. The fruit is a naked seed about 2.5 cm (~1 in.) long with a fleshy covering. After dropping off the tree, the fruit develops a strong, unpleasant odor. The inner hard seed of the mature fruit is edible after the first frost in the fall.

Distribution and Ecology: Gingko is a native species in China. However, this ornamental shade tree has been introduced into Australia, Southeast Asia, Europe, Japan, and the United States. Commercial cultivation of the gingko tree occurs in both the United States and France.

EXPOSURE

Sources

The most commonly used form of *Ginkgo biloba* is the aqueous acetone extract of the dried and milled leaves. Ginkgo leaf extract is standardized to contain 24% ginkgo-flavone glycosides and 6% terpenoids. EGb761 is a standardized extract of the leaves of *Ginkgo biloba* that contains 5–7% terpene trilactones (ginkgolides, bilobalide), 22–24% flavonoids (isorhamnetin, kaempferol, quercetin), 0.5–1% organic acids (acetic acid, ascorbic acid, *p*-hydroxybenzoic acid, kynurenic acid, shikimic acid, vanillic acid), and <5 ppm ginkgolic acids (anacardic acids).[6] Most commercial preparations contain about 40 mg of *Ginkgo biloba* extract. The leaves of the *Gingko biloba* tree are harvested from July to September, dried, and then extracted with aqueous acetone. Drying of the extract results in the formation of one part extract from 50 parts raw leaves. Commercial trade names for this extract include BioGinkgo® (Pharmanex, Provo, UT), Flordis™ (Crow's Nest, New South Wales, Australia), Rökan® (Spitzner Arzneimittel, Ettlingen, Germany), Tavonin™ (Dr. Willmar Schwabe GmbH, Karlsruhe, Germany), Tanakan® (Beaufour Ipsen Pharma, Paris, France), and Tanamin® (YuYu, Inc., Seoul, Korea). Folium ginkgo consists of the dried whole leaf of *Ginkgo biloba* L.

Medicinal Uses

Traditional

The ginkgo nut is a culinary delicacy in China and Japan. Uses for ginkgo in traditional Chinese medicine include the treatment of asthma, cough, arthritis, edema, enuresis, and skin infections.

Current

The use of ginkgo primarily involves the use of this dietary supplement to improve cerebral and peripheral blood flow. The use of herbal extracts of ginkgo include the treatment of dementia, memory impairment, cerebral ischemia, peripheral vascular disorders, sexual dysfunction associated with selective serotonin reuptake inhibitors, asthma, bronchitis, stress, and hearing loss. Numerous studies suggest that the administration of ginkgo extract causes small improvements in claudication symptoms.[7,8] However, ginkgo may not be as efficacious as exercise therapy or prescription drugs. Overall, the scientific literature suggests that ginkgo (120–240 mg daily) modestly improves memory function in the early stage of Alzheimer's disease and multi-infarct dementia,[9,10] but recent evidence on the efficacy of gingko extract remains inconsistent.[11,12] The effects on attention and memory in healthy and older adults appear short-lived as a result of tolerance developing with 6 weeks of treatment. In a placebo-controlled double-blind study of 52 students, a single dose of ginkgo (120 mg standardized extract) modestly improved performance on a sustained-attention task and a pattern-recognition (episodic) memory task.[13] However, there were no statistically significant differences on any cognitive test, when baseline and posttreatment (6 weeks) scores were compared. Tests in this study measured sustained attention, episodic and working memory, mental flexibility, planning, and mood. There was no statistically significant difference in scores on eight tests of episodic and semantic memory between a group of 40 healthy subjects (age 35–80 years) using gingko supplements for 2 years and a control group.[14] In a group of 202 subjects over 60 years old without cognitive impairment, a 6-week randomized, double-blind, placebo-controlled, parallel-group trial did not demonstrate a statistically significant difference between the treatment (120 mg gingko extract daily) and placebo groups on standard neuropsychological tests of learning, memory, attention, concentration, and verbal fluency.[15] Furthermore, there were no significant differences in self-reported memory function or global ratings by spouses or relatives.

There is little scientific evidence to support the use of ginkgo extracts for sexual dysfunction associated with selective serotonin reuptake inhibitors, stroke, postmenopausal syndrome, cocaine addiction, tinnitus, vertigo, depression, or the sustained enhancement of memory in healthy subjects. One week of gingko treatment in postmenopausal women improved attention, memory, and mental flexibility, but by 6 weeks of treatment these improvements disappeared except for mental flexibility in the older, poorer performing subjects.[16]

Regulatory Status

Gingko is a dietary supplement in the United States. Approved uses of gingko by the German Commission E include treatment of memory loss, poor concentration, dementia, depression, dizziness, vertigo, intermittent claudication, and headache.

PRINCIPAL INGREDIENTS

Chemical Composition

Constituents of the leaves of *Ginkgo biloba* include dimeric flavones (bilobetin, ginkgetin, isoginkgetin, sciadopitysin), flavonols (kaempferol, quercetin), proanthocyanidins, terpenoids (bilobalide, ginkgolides A, B, C, J, M), and amino acids. Ginkgolide J occurs only in the leaves of *Ginkgo biloba*, whereas the other ginkgolides are found primarily in the root bark.[2] The main active ingredients in ginkgo are probably bilobalide and ginkgolides.

Ginkgolides are diterpene compounds with a cage skeleton consisting of six 5-membered rings. Bilobalide (CAS RN: 33570-04-6) is a sesquiterpenoid compound with a molecular formula of $C_{15}H_{18}O_8$. Most of the flavonoid compounds (flavonols, flavones) are attached to sugars (glycosides), although occasionally they occur as aglycones. Analysis of 26 commercial ginkgo products indicates that there are severalfold variations in the composition and relative concentrations of ginkgolides and bilobalide in herbal products[17,18] as well as ginkgolic acids (i.e., <500 to 90,000 ppm).[19] Figure 69.1 and Figure 69.2 display the chemical structures of the main flavonoid and terpene trilactone compounds in the extract of *Gingko biloba*. The seeds of *Gingko biloba* contain the alkaloid, ginkgotoxin (4′-*O*-methylpyridoxine),[20] phenols, and cyanogenic glycosides as well as a 5′-glycoside of ginkgotoxin.[21] Although used as a medicinal herb, ginkgotoxin occurs in smaller concentrations in gingko leaves compared with gingko seeds. Figure 69.3 displays the chemical structure of ginkgotoxin. Gingko seeds contain variable amounts of the pyridoxine antagonist and convulsant, 4′-*O*-methylpyridoxine (ginkgotoxin). Analysis of the aqueous extract of ginkgo seeds by liquid chromatography with fluorescence detection demonstrated a mean free ginkgotoxin concentration of 179 μg/g and total ginkgotoxin concentration of 308 μg/g after β-glucosidase treatment.[21] Canned

FIGURE 69.2. Chemical structures of terpene trilactone compounds (ginkgolides, bilobalide) in ginkgo biloba.

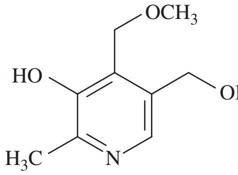

FIGURE 69.3. Chemical structure of ginkgotoxin.

ginkgo seeds contained no water-extractable ginkgotoxin, whereas water extracts of ginkgo capsules contained variable concentrations of ginkgotoxin ranging up to 457 g/g. In a study of 10 ginkgo natural health products, the ginkgotoxin concentration ranged between 3 μg/g (dry weight) in canned seeds and 181 μg/g (dry weight) in tablets, as measured by liquid chromatography with UV or fluorescence detection.[22] Although boiled Japanese ginkgo food may contain ginkgotoxin, the concentration of ginkgotoxin is generally below the concentration likely to cause toxicity. Concentrations of ginkgolides and ginkgotoxin in leaves and seeds are highest in late summer and early autumn. Analysis of fresh ginkgo seed albumin demonstrated approximately 105 μg ginkgotoxin (4′-*O*-methylpyridoxine)/g dry weight compared with 1.32 μg ginkgotoxin/dry weight in boiled seed albumin from canned Japanese food.[23] Ginkgolic acid and related alkylphenols are major components of the lipid fraction of the fruit pods of *Ginkgo biloba* L., but the aqueous extracts contain minimal amounts (<5 ppm) of these allergens.[24] Ginkgotoxin is not a unique compound in *Ginkgo biloba*, as this compound also occurs in the paperbark albizia (*Albizia tanganyicensis* Baker f.).[25]

Physiochemical Properties

All ginkgolides are acid-stable, bitter tasting solids without reported melting points. Glycine and $GABA_A$ receptors are members of the ligand-gated ion channel superfamily that mediate inhibitory synaptic transmission in the adult central nervous system. *In vitro* studies indicate that most of the ginkgolides are selective and potent antagonists of the glycine receptor.[26] Bilobalide is a less potent glycine receptor antagonist than ginkgolides, but bilobalide is a more potent inhibitor of the $GABA_A$ receptors than ginkgolides. Platelet-activating factor is a phospholipid synthesized in a variety of cells throughout the body for a variety of diverse physiological and pathological functions, particularly in the central nervous system. Ginkgolide B is a potent antagonist of the platelet-activating factor receptor, which is a 39 kDa G-protein coupled receptor.[27] Ginkgo extract also potentially inhibits platelet aggregation by increasing the concentrations of endothelium-derived thrombolytic agents (e.g., nitric oxide, prostacyclin) by inhibiting the synthesis of thromboxane B_2.[28,29] 4′-*O*-Methylpyridoxine is heat stable, and cooking does not detoxify gingko seeds.

Mechanism of Toxicity

The active ingredient of ginkgo extract has not been identified. However, the extracts are standardized to total flavonoid glycosides and terpenoid content, and the most clinically important compounds are these flavonoids (kaempferol, quercetin, isorhamnetin) and terpenoids (ginkgolides A/B, bilobalide).[30] Consumption of gingko seeds containing 4′-*O*-methylpyridoxine inhibits the formation of GABA and increases the formation of glutamate, resulting in the occurrence of seizures. Glutamate decarboxylase catalyzes the formation of γ-aminobutyric acid (GABA) from glutamate. Pyridoxal phosphate is a coenzyme of glutamate decarboxylase, and 4′-*O*-methylpyridoxine is a competitive antagonist of this coenzyme. Treatment of these seizures with pyridoxine (vitamin B6) terminates these seizures and prevents the development of status epilepticus.[31] Animal studies indicate that the main allergens in extracts of *Ginkgo biloba* are ginkgolic acids.[32]

DOSE RESPONSE

Medicinal Use

The usual daily dose of ginkgo extract is 80 to 240 milligrams in 2 to 3 divided doses of a 50 : 1 standardized leaf extract (standardized to 24–25% ginkgo flavone glycosides and 6% terpene lactones). Other dosage forms include the use of a tea (e.g., 30 mg extract/bag) or 3–6 mL of a 40 mg/mL extract daily in three divided doses.

Toxicity

Japanese adults typically ingest 5–10 ginkgo seeds during a meal, and boiled seed usually have small concentrations (i.e., ≤1 ppm) of ginkgotoxin (4′-*O*-methylpyridoxine). The ingestion of 50–60 raw ginkgo seeds by a 2-year-old was associated with the development of vomiting, diarrhea, irritability, and seizures.[3] The child recovered after receiving intravenous administration of vitamin B_6. A 36-year-old woman developed two generalized seizures and two episodes of vomiting within 24 hours after ingesting 70–80 gingko seeds cooked in a microwave.[33]

TOXICOKINETICS

Absorption

The bioavailability of bilobalide and ginkgolide A and B is relatively high (>75–80%), whereas the bioavailability of ginkgolide C is low.[34] Volunteer studies indicate that maximum plasma concentrations of free terpenoid compounds (ginkgolides A and B, bilobalide) occurs about 1–2 hours after ingestion by fasting volunteers.[35,36] The concomitant ingestion of the extract with food slightly delays (i.e., about 1 hour) the peak ginkgolide and bilobalide plasma concentration. In general, the bioavailability of flavonols (isorhamnetin, kaempferol, quercetin) is low.[37] In a study of 10 volunteers receiving a single dose of six gingko extract tablets, the bioavailability of kaempferol and quercetin was low (i.e., <1–2%).[38] P-glycoprotein is an ATP-driven efflux pump capable of transporting a wide variety of diverse compounds from the cell interior to the extracellular space. *In vitro* studies suggest that the P-glycoprotein type efflux pump limits the bioavailability of ginkgo flavonols.[39]

Distribution

The volumes of distribution of bilobalide and ginkgolide A and B are approximately 80–200 L, 40–60 L, and 60–100 L, respectively.[30,40]

Biotransformation

The biotransformation of flavonoids (flavonol glycosides, biflavones) in ginkgo extract is more extensive in humans than rats with urinary metabolites accounting for <30% of the flavonoid dose.[41] In contrast to rats, the major urinary metabolites are conjugated and free substituted benzoic acids (4-hydroxybenzoic acid, 3-methoxy-4-hydroxyhippuric acid, 3,4-dihydroxybenozoic acid, hippuric acid, vanillic acid) with little to no detectable phenylalkyl acids being present.

Elimination

The plasma elimination half-life of terpenoid compounds (ginkgolides A, B, bilobalide) is approximately 4–6 hours, depending on the specific terpenoid, the dose, and route of administration. In a study of healthy volunteers receiving a single dose of 240 mg EGb 761 extract, the mean elimination half-lives for ginkgolide A, ginkgolide B, and bilobalide were 5.1 ± 1.4 hours, 9.9 ± 2.0 hours, and 4.9 ± 2.5 hours, respectively.[40] The kidney excretes quercetin and kaempferol in the urine primarily as glucuronides, and there are relatively minor amounts of free quercetin and kaempferol in the urine after consumption of ginkgo extract.[42] In a study of 10 adult volunteers receiving a single oral dose of quercetin and kaempferol in ginkgo extract, approximately 0.17% and 0.22% of the oral dose was recovered in the urine.[38] All these compounds were present as glucuronides as reflected in the fact that neither of these compounds was detectable without hydrolysis. The plasma elimination half-life of these flavonoid compounds is about 1–4 hours.[38,40]

Drug Interactions

In vitro animal and *in vivo* clinical studies on the effect of ginkgo extracts on platelet aggregation, coagulation, and various cytochrome P450 isoenzymes are conflicting. Case reports suggest a *possible* adverse effect on bleeding after the use of gingko extract and aspirin, ibuprofen, or warfarin.[43,44] However, in an open-label, three-way crossover study of 12 healthy volunteers receiving pretreatment for 7 days with standard doses of ginkgo extract, there was no significant effect on clotting parameters or the pharmacokinetics of warfarin.[45] Outcomes assessed included measurement of platelet aggregation, international normalized ratio (INR) of prothrombin time, warfarin protein binding, plasma warfarin concentrations, and S-7-hydroxywarfarin concentrations in the urine.

In vitro studies indicate that ginkgolic acids I and II inhibit cytochrome P450 isoenzymes, CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4.[46] An *in vitro* study of human cytochrome P450 enzymes indicated the flavonoid fraction of ginkgo extract (EGb761) contains inhibitors of CYP2C9 and, to a lesser extent, CYP1A2 and CYP3A4.[47] However, a study of 12 volunteers receiving 120 mg gingko extract (EGb761) did not detect a statistically significant difference between baseline and posttreatment concentrations of dextromethorphan metabolite ratios (CYP2D6 activity) or alprazolam (CYP3A4 activity) metabolic ratios.[48] The plasma concentration *versus* time curve for alprazolam decreased 17%, but the unchanged elimination half-life of alprazolam indicated the there was no significant hepatic

induction of CYP3A4. Using drug probes, a study of 12 healthy volunteers receiving a 28-day course of gingko extract did not detect any significant effect on CYP1A2, CYP2D6, CYP2E1, or CYP3A4 activity, when comparing baseline and posttreatment ratios of drug probes and their metabolites.[49] In a study of 18 healthy Chinese subjects, the administration of a 12-day course of 140mg ginkgo extract twice daily induced CYP2C19 activity. This interaction could reduce the effect of drugs (e.g., omeprazole) metabolized by this enzyme.[50] However, the clinical significance of the interactions of ginkgo extract with cytochrome P450 isoenzymes remains undetermined.

CLINICAL RESPONSE

Adverse Reactions

The most common adverse effects associated with the use of ginkgo are diarrhea, flatulence, headache, dizziness, and palpitations. Cross-reactivity to urushiols (mango, sumac, poison ivy, poison oak, cashews) may occur in patients allergic to ginkgo. Rarely, case reports describe the use of ginkgo extract with isolated seizures, but a causal relationship between the use of ginkgo and the development of seizures has not been firmly established.[51] A case report associated the development of seizures in two epileptic patients stabilized on valproic acid. Seizures developed within 2 weeks of initiating treatment with ginkgo extract, and good control of the seizures returned following the cessation of ginkgo extract use.[52] Published case reports suggest a possible causal relationship between the use of gingko extract and the development of spontaneous bleeding including postoperative bleeding,[53] vitreous hemorrhage,[54] subarachnoid hemorrhage,[55] and intracranial hemorrhage.[56] Most of these case reports involve serious hemorrhage, but the timing of the bleeding event in relation to prolonged gingko exposure (i.e., months) do not suggest a strong causal association. However, bleeding did not recur in these case reports, which included evaluation following cessation of gingko use. The bleeding times were prolonged in the four case reports where bleeding times were measured, but other coagulation factors were normal.[57] Most large clinical trials do not report an increased incidence of spontaneous bleeding or other adverse effects in patients treated with gingko extract.[11]

Acute Effects

The ingestion of large amounts of gingko seeds is associated with the development of protracted nausea, vomiting, diarrhea, and seizures.[58] The gastrointestinal irritation begins with a few hours after the ingestion of ginkgotoxin, followed by the development of seizures. The convulsions are usually single, tonic-clonic seizures. Although status epilepticus does not typically develop, several seizures may occur during intoxication. Four hours after the ingestion of approximately 70–80 seeds, a 36-year-old woman developed a seizure.[33] She was transferred to the emergency department, where she had another episode of vomiting along with another seizure. Symptoms typically resolve within 24 hours without sequelae.

DIAGNOSTIC TESTING

Analytical Methods

Ginkgolides are difficult to separate because of similar solubilities and chromatographic behavior.[59] Analytical methods for the detection of ginkgotoxin include liquid chromatography with fluorescence detection, high performance liquid chromatography/electrospray ionization tandem mass spectrometry,[60] and gas chromatography/mass spectrometry (GC/MS) with solid-phase extraction (limit of detection = 50pg).[61] Analysis of ginkgotoxin by ion-pair HPLC has greater speed and superior analytical sensitivity (i.e., limit of detection 5pg) compared with conventional analytical methods using solid-phase extraction.[62]

Biomarkers

Serum concentrations of 4′-*O*-methylpyridoxine drawn near the time of seizure activity typically exceed 90ng/mL. Approximately 9 hours after ingesting gingko seeds, a 2-year-old girl developed a tonic-clonic seizure. At that time, the serum 4′-*O*-methylpyridoxine concentration was 360ng/mL.[3] Ten hours later, the serum 4′-*O*-methylpyridoxine concentration was below the limit of detection (15ng/mL). However, the concentration of 4′-*O*-methylpyridoxine was 37ng/mL in an admission serum sample from a 2-year-old child, who ingested 50 gingko nuts 4 hours prior to admission.[63] The child developed a second afebrile convulsion 30 minutes after admission, and 8 hours later the serum 4′-*O*-methylpyridoxine concentration was 157ng/mL, as measured by HPLC. Eight hours after the ingestion of 10 pan-fried ginkgo seeds by a 17-month old girl, the serum 4′-*O*-methylpyridoxine concentration was 100ng/mL, as measured by GC/MS.[61] She had a seizure 5 hours after ingestion that lasted about 10 minutes.

Abnormalities

Routine laboratory tests and electroencephalograms are typically normal after the ingestion of gingko seeds.

Transient hyperglycemia occurred in a 2-year old girl, who developed seizures following the ingestion of roasted ginkgo seeds.[3]

TREATMENT

Allergic reactions occasionally occur after the use of ginkgo, and the treatment is supportive. The most serious reactions occur with the ingestion of raw ginkgo seeds. Patients with suspected ginkgo seed poisoning and protracted vomiting should be evaluated for fluid and electrolyte imbalance as well as observed closely for the development of seizures and aspiration pneumonia. All of these patients should be placed under seizure precautions including intravenous access for the administration of anticonvulsants as needed. The seizures associated with gingko seed poisoning result from the competitive antagonist action of 4′-*O*-methylpyridoxine on GABA synthesis. Pyridoxine (vitamin B_6) is a suggested antidote for seizures caused by the ingestion of gingko seeds. There are few clinical data on the appropriate dose of intravenous pyridoxine following the ingestion of gingko seeds. A recommended dose of intravenous pyridoxal phosphate (i.e., nearly equivalent to pyridoxine hydrochloride) is one-fourth of the estimated ingestion of 4′-*O*-methylpyridoxine (i.e., based on 80 µg/seed).[3] When the amount of ingested seeds is unknown, the standard dose of pyridoxine hydrochloride for isoniazid (INH) intoxication in adults and children (70 mg/kg up to 2–5 g, intravenously) can be used. Patients with active seizures should always receive an intravenous dose of benzodiazepine (lorazepam, diazepam) in addition to the pyridoxine and supportive care (oxygen, observation for prevention of aspiration and trauma).

Chapter 70

GINSENG

HISTORY

Ginseng is a popular Chinese herb that has been used for several thousand years as a panacea for promoting longevity.[1] Father Petrus Jartoux, a Jesuit missionary to northern China, was the first European to describe the herbal uses of ginseng, when he sent a letter to the Procurator General of the Missions of India and China from Peking in 1711.[2] American ginseng has been known in the United States since colonial times. George Washington mentioned the gathering of this plant in his diary; the American frontiersman and explorer, Daniel Boone, was active in the ginseng trade.[3]

BOTANICAL DESCRIPTION

Ginseng species from East Asia, Central Asia and North America include *Panax bipinnatifidus* Seem, *P. ginseng* C.A. May, *P. notoginseng* (Burkill) F.H. Chen, *P. omeiensis* J. Wen, *P. pseudoginseng* Wallich, *P. japonicus* (T. Nees) C.A. Meyer, *P. quinquefolius* L., *P. stipuleanatus* H.T. Tsai and K.M. Feng, *P. trifolius* L., *P. wangianus* S. C. Sun, *P. vietnamensis* Ha & Grushv., and *P. zingiberensis* C.Y. Wu and K.M. Feng. Most studies on the effects of ginseng involve American ginseng (*P. quinquefolius*), Asian or Chinese ginseng (*P. ginseng*), or Japanese ginseng (*P. japonicus*). The term ginseng often applies to herbal plants with similar appearance and uses as Asian or American ginseng, but some of these other types of "ginseng" belong to other plant families. Table 70.1 lists the names and origin of herbs commonly called ginseng.

Common Name: American Ginseng

Scientific Name: *Panax quinquefolius* L.

Botanical Family: Araliaceae (ginseng)

Description: This plant is a smooth perennial herb, with a large, fleshy, very slow-growing, spindle-shaped root, which typically reaches 5–7 cm (~2–3 in.) in length and 1–2 cm (~0.4–0.8 in.) in diameter. The root has a round apex with a slight terminal, projecting point. Occasionally, a small branch appears in the fork formed near the curved end of the root. Some small rootlets exist upon the lower portion of the root. The color ranges from a pale yellow to a brownish colour. The stem is simple and erect with three leaves, which are divided into five finely-toothed leaflets. A single, terminal umbel has a few small, yellowish flowers that produce a cluster of bright red berries.

Distribution and Ecology: *P. quinquefolius* is a native perennial herb of shady hardwood forests of central and eastern United States and Canada, particularly in the mountains from Ontario and Quebec to Georgia. Commercial growth of this herb occurs in Canada (British Columbia, Ontario) and the United States (Wisconsin).

Common Name: Asian Ginseng, Chinese Ginseng, Korean Ginseng, Red or White Ginseng

Scientific Name: *Panax ginseng*

Botanical Family: Araliaceae (ginseng)

Description: This species is similar in appearance to American ginseng. Chinese ginseng has a thick, spindle-like brown-yellow root that is usually

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

TABLE 70.1. Herbs Commonly Called Ginseng

Common Name	Scientific Name	Family	Origin
Asian, Chinese, or Korean ginseng	*Panax ginseng* C.A. Meyer	Araliaceae	Korea, China, Japan, Russia
American ginseng	*Panax quinquefolius* L.	Araliaceae	United States, Southern Canada
Brazilian ginseng	*Pfaffia paniculata* (Mart.) Kuntze	Amaranthaceae	
Dwarf ginseng	*Panax trifolius* L.	Araliaceae	United States
Ginger ginseng	*Panax zingiberensis* C.Y. Wu and K.M. Feng	Araliaceae	China
Himalayan ginseng	*Panax pseudoginseng* Wallich		China, Himalayas
Indian ginseng	*Withania somnifera* (L.) Dunal	Solanaceae	Australia, East Asia, Africa
Japanese or Chikutsu ginseng	*Panax japonicus* C.A. Meyer		Japan, China
Notoginseng or Yunnan ginseng	*Panax notoginseng* (Burkill) F.H. Chen	Araliaceae	China
San-chi or Feather-leaf ginseng	*Panax bipinnatifidus* Seem	Araliaceae	Nepal, Eastern Himalayas
Siberian or Russian ginseng	*Eleutherococcus senticosus* (Rupr. & Maxim.) Maxim.	Araliaceae	Russia, China, Korea
Vietnamese or Bamboo ginseng	*Panax vietnamensis* Ha & Grushv.	Araliaceae	Vietnam

divided on the end. The simple, smooth (glabrous) stem forms a whorl of three or five palmately compound leaves consisting of five oblong-ovate, finely double-serrate leaflets. A single umbel of greenish-yellow flowers appears from June to August that produces small, pale red, fleshy berries (drupe) each with a solitary seed.

Distribution and Ecology: *P. ginseng* grows naturally in Korea, far-eastern Siberia, and northeastern China, but this species of Asian ginseng is rare now and the other Asian species of ginseng (e.g., *P. pseudoginseng* Wallich) are much more common.

EXPOSURE

Sources

Although ginsenosides are present in all parts of the plant, the fresh root is the main source of ginseng. Typically, the ginseng root is harvested after about 4–6 years of cultivation. Ginseng appears in the *Pharmacopoeias* of several countries including China, Japan, United Kingdom, Germany, Austria, and France as a treatment to restore well-being (adaptogenic). The two commercial forms of ginseng are called red and white ginseng. The latter preparation consists of dried, peeled roots of ginseng, whereas the former preparation is produced from the steaming of fresh, whole ginseng root prior to drying. Radix ginseng is the dried root of *Panax ginseng* C.A. Meyer. Forms of ginseng include crude plant material, capsules and tablets of [P1]powdered drugs, extracts, tonic drinks, teas, wines, and lozenges.

Medicinal Uses

In general, decoctions of the root of *Panax ginseng* and other *Panax* species are distributed as panaceas and as tonics for the restoration of strength. Ginseng is a traditional treatment for a variety of clinical conditions including cardiovascular collapse, edema, fatigue, sexual dysfunction, immune deficiencies, cardiac disease, Addison's disease, dyspepsia, neurosis, cancer, anemia, and leukopenia.[4] Animal studies suggest that ginseng contains a variety of active ingredients including anti-inflammatory compounds,[5] antioxidants,[1] antineoplastic agents,[6] memory aids,[7] and anxiolytics.[8] Although ginseng is a relatively safe herbal remedy,[9] there is little evidence from randomized clinical trials to document the efficacy of ginseng for any of these conditions,[10] including overall improvement in vitality[11] or the long-term enhancement of memory in healthy adult volunteers.[12] A randomized clinical trial of night-shift nurses did not demonstrate the improvement of mood or sense of well-being during the daily use of 1–2 g of Korean ginseng.[13] As measured by the Positive Affect-Negative Affect Scale and the Profile of Mood States Inventory, a double-blind, placebo-controlled study of 83 adults did not demonstrate a statistically significant difference in scores between controls and subjects receiving daily doses of 200 mg and 400 mg *Panax ginseng*.[14] There is no conclusive evidence in humans that the chronic administration of ginseng reduces cancer mortality.[15]

Regulatory Status

In the United States, ginseng is regulated as a dietary supplement. The German Commission E approves the

use of *Panax ginseng* as an over-the-counter tonic for the treatment of fatigue, poor concentration, reduced work capacity, and general debility.

PRINCIPAL INGREDIENTS

Chemical Composition

The major active ingredients of ginseng are a diverse group of over 20 steroidal saponins, which primarily are tetracyclic triterpene dammarane compounds (ginsenosides) subdivided into (20S)-protopanaxadiol ($Ra_{1–3}$, $Rb_{1–3}$, Rc, Rc_2, Rd, Rd_2, Rh_2), (20S)-protopanaxatriol (Re_2, Re_a, Rf, Rg_1, Rg_2, Rh_1) along with an oleanolic acid ginsenoside (Ro) as demonstrated in Figure 70.1.[1,16] Ginsenoside Ro is a nonsteroidal saponin (i.e., oleanic acid). The ginsenoside content of ginseng varies substantially (i.e., 2–20%) depending on species, plant part, cultural conditions, age, and season with a typical range of 1–4%.[17,18] American ginseng contains at least 30 different ginsenoside compounds with the main functional group at the 3-OH and 17-OH positions. The major ginsenoside compounds include Rb_1 Rb_2, Rc, Rd, Rf, Rg_1, Rg_2, mRb_1, mRb_2, mRc, and the glycoside of Rc with Rb_1, Rb_2, and Rg_1 usually being the most abundant.[19] There are no estrogen compounds in ginseng. Additionally, commercial ginseng preparations contain variable amounts of ginsenosides.[20] In a study of 50 commercial ginseng preparations from 11 countries, the concentration of ginsenosides varied from 1.9–9% (weight/weight) as measured by gas chromatography/mass spectrometry (GC/MS).[21] Six samples sold in the United States, Sweden, and the United Kingdom did not contain detectable amounts of ginsenosides. Other compounds present in ginseng include fatty acids, peptides, polysaccharides, and polyacetylenic alcohols.

In a study of plant parts from *Panax ginseng* cultivated in China, the total saponin content of the main root, lateral root, rhizome, and fresh leaf averaged approximately 2%, 7%, 6%, and 5.5%, respectively.[22] Drying procedures during the processing of white ginseng do not alter the ratio of panaxadiol (Rb_1, Rb_2, Rc, Rd) and panaxatriol (Rg_1, Rg_2, Re, Rf) compounds. Typically, leaves contain Rd, Re, and Rg_1 ginsenosides. The ginsenoside Rg_1 content is relatively high in the root of Chinese ginseng (*Panax ginseng*) compared with American ginseng (*Panax quinquefolius*), which has a relatively low Rg to Rb ratio.[23] Although Siberian

FIGURE 70.1. The chemical structures of ginsenoside compounds including panaxadiols, panaxatriols, and ginsenoside R_0.

ginseng (*Eleutherococcus senticosus*) contains a variety of biologically active substances (e.g., sesamin, hederasaponin B, isofraxidin, β-sitosterol), most commercially available extracts of Siberian ginseng are standardized to the content of eleutheroside B (syringing 4-β-D-glucoside) and eleutheroside E (syringaresinol 4,4′-β-D-diglucoside).

Physiochemical Properties

The taste of the root is somewhat bitter with a hint of sweetness similar to liquorice, and there is little or no odor. Ginsenoside compounds are glycosylated steroids that contain four *trans*-ring rigid steroid skeletons with modification at the C20-side chain. These saponins are prone to hydrolysis under heat and acid conditions. Malonic esters of ginsenosides are present in substantial concentrations in ginseng root. The malonyl-ginsenosides are particularly unstable during heating in acidic conditions; consequently, the red form of Asian ginseng produced from the steaming and drying of the roots of *P. ginseng* contains substantially lower concentrations of malonyl-ginsenosides than does the white form.[24]

DOSE RESPONSE

The recommended, short-term dose for general stimulatory effects from Chinese ginseng is 2–3 g with doses up to 50 g producing insomnia, depression, and anxiety.[25] The estimated mean dose of ginseng (*P. ginseng, P. quinquefolius*) was 3 g with adverse effects (depression, depersonalization, confusion) more common with a 15 g dose. Headache, chest tightness, and gastrointestinal (GI) distress were associated with the ingestion of 25 g *Panax ginseng*.[26]

TOXICOKINETICS

Kinetics

Because ginseng contains over 20 structurally similar ginsenoside compounds, the toxicokinetic profile of ginseng is highly complex with limited data on individual ginsenosides. Animal studies suggest that the absorption of some ginsenoside compounds is relatively low (<1–2%) and some ginsenosides (e.g., Rg_1) undergo hydrolysis in the acidic milieu of the stomach.[27] During an experimental study, the absorption of orally administered ginsenosides Rb_1 and Rg_1 by rats was rapid with peak serum concentrations occurring about 30 minutes after oral administration.[28] The amount of ginsenoside Rg_1 appearing in the urine was about 1.9% with biliary excretion accounting for most of the elimination of this ginsenoside compound. Animal studies indicate that ginsenoside Rb_1 is poorly absorbed from the GI tract, and biliary excretion is not a significant route of elimination.[29] In a study of a single subject, the elimination half-lives of 20(S)-protopanaxadiol and 20(S)-protopanaxatriol extended over 13–17 hours.[30] Urinary excretion of these substances accounted for 0.24% and 1.2%, respectively, of the total dose of ginsenoside compounds. Metabolites of ginsenosides in humans include the protopanaxadiol-type ginsenoside G-Rh_1 and G-Rb_1, protopanaxatriol-type G-F_1, and compound K.[31]

Drug Interactions

Case reports suggest possible drug reactions between ginseng and ethanol, warfarin, and phenelzine,[32] but the clinical significance of these potential interactions is unclear. An open-label, nonrandomized clinical study of 14 healthy volunteers suggested that the administration of Chinese ginseng (*Panax ginseng*) reduces blood ethanol concentrations by increasing ethanol clearance.[33] The blood ethanol concentration at 40 minutes postingestion in most subjects decreased about 30–50% following the simultaneous administration of 3 g *P. ginseng* extract/65 kg body weight, when compared with controls (same subjects without ginseng). However, there was no statistical analysis of the data. Animal studies suggest that ginseng and/or ginsenosides reduce blood ethanol concentrations by delaying gastric emptying.[34] Case reports suggest that the simultaneous use of ginseng and warfarin reduces the anticoagulant effect of warfarin. Following the administration of 3 capsules Ginsana® (Pharmaton, Lugano, Switzerland; proprietary *P. ginseng* extract, G115) daily for 2 weeks, the international normalized ratio (INR) of a 47-year-old man decreased from 3.3 to 1.5; the INR normalized in therapeutic concentrations after the cessation of ginseng.[35] A randomized, double-blind, placebo-controlled trial of 20 healthy volunteers demonstrated that American ginseng (*Panax quinquefolius*) reduced the anticoagulant effect of warfarin (–0.19, 95% CI: –0.36 to –0.07, $P = 0.0012$).[36] However, the administration of Korean ginseng (3 g *P. ginseng* root daily) to 12 healthy subjects for 7 days did not alter coagulation parameters of a 25-mg dose of warfarin, when compared with controls (same volunteers without ginseng).[37] The clinical significance of a ginseng-warfarin drug interaction remains unclear.

Siberian ginseng probably does not significantly induce CYP2D6 and CYP3A4 isoenzymes.[38] Ginseng contains digoxin-like substances, which can interfere with digoxin immunoassays, but there is no clear pharmacokinetic or pharmacodynamic interaction between ginseng and digoxin.

CLINICAL RESPONSE

In general, adverse effects (e.g., indigestion, fatigue) during clinical trials involving ginseng are uncommon, mild, and transient.[39] The most common adverse effects are sleep disturbances, anxiety, fatigue, headache, and GI distress (diarrhea, nausea).[2] Although case reports associate the use of ginseng with psychological and ephedrine-like effects, the lack of biomarkers and analytical data limit conclusions regarding causality, particularly in patients taking multiple drugs and herbs. A case series associated the chronic use of ginseng with nervousness, generalized edema, hypertension, insomnia, skin eruptions, and morning diarrhea in 14 of the 133 subjects.[25] Chronic daily ingestion of high doses (≥15 g ginseng) was associated with increasing CNS effects (depression, confusion, depersonalization), but effect of ginseng was not well defined because of the variety of ingested preparations and the lack of analysis of herbal products. Several case reports document the development of manic symptoms (restlessness, insomnia, agitation irritability, pressured speech, and tangential thinking). These psychiatric abnormalities occurred in patients with[40–42] and without[43] prior psychiatric illness. A case report associated the onset of cerebral arteritis (severe headache, nausea, vomiting) with the ingestion of approximately 25 g ginseng root.[44] The clinical and angiographic features of this case report were similar to the cerebral arteritis associated with abuse of sympathomimetic drugs, but the patient denied drug use (the report did not document a urine drug screen). Other adverse effects associated with ginseng use include vaginal bleeding[45] and mastalgias.[46]

DIAGNOSTIC TESTING

Analytical Methods

The use of high performance thin-layer chromatography fingerprint analysis separates the various types of ginseng based on differences in the content of major ginsenosides (Rb_1, Re, Rg_1).[47] The most common analytical method for the quantitation of ginsenosides in herbal preparations is high performance liquid chromatography (HPLC) with UV absorbance detection at 205 nm. Other methods for the detection of ginsenosides include thin layer chromatography,[48] gas chromatography,[49] and HPLC with negative ion electrospray mass spectrometry.[50] The latter method allows the detection of minor ginsenosides as well as malonyl ginsenosides and hydrolysis products. Additionally, HPLC with positive mode electrospray mass spectrometry allows the separation of Asian ginseng (*P. ginseng*) from American ginseng (*P. quinquefolius*) by determining the presence of the acetylated form of ginsenoside Rb_1 (quinquenoside R_1) and the ratio of ginsenosides Rg_1 to Re.[51] In contrast to Asian ginseng, American ginseng contains the acetylated form of ginsenoside Rb_1 and a lower ratio of Rb_1 to Re. For quantitation of low concentrations of ginsenoside compounds, the limits of detection with GC/MS methods are a few ng/mL.[30] Mass spectral analyses of ginsenosides include electron impact MS, liquid secondary ion MS, LC/MS, and LC/MS/MS with nebulizer gas-assisted electrospray.[52] The latter technique has limits of detection for ginsenosides of about 2 pg. Electrospray ionization with HPLC/MS are most appropriate for polar thermo-labile ginseng compounds, whereas the use of atmospheric pressure chemical ionization is applicable with HPLC/MS to the analysis of weakly polar and stable ginsenosides.[53] Although there are no regulatory standards for ginseng, typically ginseng should contain at least 1.5% ginsenosides calculated as ginsenoside Rg_1 (D-glucopyranosyl-6β-glucopyranosyl-20S-protopanaxatriol, relative molecular mass 800).

Abnormalities

Ginseng contains digoxin-like immunoreactive substances, which can interfere with some digoxin immunoassays. Case reports suggest that the ingestion of ginseng by patients on digoxin may cause false elevation of digoxin concentrations depending on the reactivity of the individual immunoassay. An *in vitro* study examined the potential interference of Brazilian, Indian, Siberian, Asian, and North American ginseng with the following three digoxin immunoassays: fluorescence polarization (FPIA), microparticle enzyme (MEIA), and Tina-quant® (Roche Diagnostics, Indianapolis, IN).[54] Analysis of aliquots of serum pools prepared from patients receiving digoxin and supplemented with all ginsengs except Brazilian ginseng indicated that the addition of ginseng falsely elevated digoxin values with FPIA and falsely decreased digoxin values (negative interference) with MEIA. There was no interference of ginseng with digoxin as analyzed by Tina-quant®.

TREATMENT

Most adverse reactions to ginseng involve nonspecific complaints, such as headache, anxiety, and GI distress. Treatment is supportive.

Chapter 71

GOLDENSEAL
(*Hydrastis canadensis* L.)

HISTORY

Goldenseal has a long history of use by Native Americans, especially by the Cherokee for the treatment of gastrointestinal (GI) and skin disorders. The Iroquois also used this herb for the treatment of diarrhea and whooping cough. Goldenseal use was popular among European settlers during the mid-19th century, and this herb was listed in the *United States Pharmacopeia*. By the beginning of the 20th century, supplies of goldenseal were dwindling as a result of excessive harvesting and loss of habitat. Wild goldenseal is now rare. This herb was officially recognized as an endangered species in 1991, and goldenseal now is listed in the Convention on International Trade in Endangered Species of Wild Fauna and Flora with associated trade restrictions.

BOTANICAL DESCRIPTION

As result of limitations in the supply of goldenseal, some herbal preparations of goldenseal may contain adulterants. These adulterants include Japanese goldthread [*Coptis japonica* (Thunb.)Makino.], Oregon grape [*Mahonia aquifolium* (Pursh) Nutt.], celandine (*Chelidonium majus* L.), barberry (*Berberis vulgaris* L.), and yellow root (*Xanthorhiza simplicissima* Marsh.). Berberine is a constituent of other herbs including *Berberis aristata* DC. (tree turmeric, Indian barberry), and *Coptis chinensis* Franch. (coptis root, Huang Lian).

Common Name: Goldenseal, Eye Root, Yellow Indian Plant, Turmeric Root, Yellow Paint Root, Orange Root, Goldenroot

Although synonyms for goldenseal include Indian turmeric and curcuma, this herb should not be confused with turmeric (*Curcuma longa* L.).

Scientific Name: *Hydrastis canadensis* L.

Botanical Family: Ranunculaceae (buttercups)

Physical Description: This plant is a small perennial herb with a horizontal, irregularly knotted, bright yellow root-stock, which produces a 6–12 in. (~15–30 cm) high, hairy flowering stem in early spring. Each stem has two dark green, hairy leaves with 5–7 lobes and irregular, finely toothed margins. The small, solitary flowers with three small greenish-white sepals appear in April. By July small, oblong, crimson berries develop, but these fruits are not edible.

Distribution and Ecology: Goldenseal is a native North American species, found primarily in the rich shady forests of the eastern United States and Canada. However, the range of goldenseal is shrinking due to deforestation and urbanization.

EXPOSURE

Sources

The root of goldenseal is the main portion of the plant used for herbal medicines, primarily as a tea. Goldenseal is a popular herbal component of dietary supplements, cold/cough/flu preparations, allergy remedies, eardrops, feminine hygiene products, laxatives, and digestive aids. The limited supply of goldenseal combined with high

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

demand for this herb results in the adulteration of goldenseal preparations with other berberine-containing herbs [e.g., Chinese goldthread (*Coptis chinensis* Franch.)], and Oregon grape [*Mahonia aquifolium* (Pursh) Nutt.].[1] Berberine can be synthetically converted to hydrastine by a chemical process involving oxidation, hydration, *N*-alkylation, and reduction.[2]

Medicinal Uses

Traditional

Traditional uses for goldenseal rhizomes and roots (orange root, yellow root, tumeric root, goldenroot) include treatment of GI disturbances, anorexia, urinary symptoms, inflammation, and infections of the skin, mouth, respiratory tract, and eye. The root of goldenseal was also used as a clothing dye by Native Americans. In traditional Chinese medicine, goldenseal is an antimicrobial herb used for the treatment of dysentery and infectious diarrhea.

Current

Goldenseal tea is one of the most popular herbal preparations, particularly as an herbal supplement to improve immune function.[3] Purported uses for goldenseal include anorexia, cancer, cirrhosis, colitis, infectious diarrhea, diabetes, congestive heart failure, edema, fever, infections (colds, trachoma, conjunctivitis, malaria), and menorrhagia. Most clinical studies administer the alkaloids (e.g., berberine, hydrastine) rather than an extract of the goldenseal herb. Although goldenseal is one of the top-selling herbs in the United States, there is an absence of information from randomized, controlled clinical trials to support the medicinal use of this herb. Goldenseal is often formulated in herbal preparations with echinacea for the treatment of upper respiratory infections based in part on animal studies that suggested that the use of these two herbs increases immunoglobulin production in rats.[4] However, there is a lack of scientific evidence in humans that this combination prevents or improves upper respiratory tract infections.

Regulatory Status

In the United States, goldenseal is listed as a dietary supplement. Goldenseal is not generally recognized as safe or effective by the US Food and Drug Administration (FDA), and the use of this herb is not approved by the FDA in over-the-counter products. Specifically, the FDA does not approve the use of goldenseal as a blood purifier, herbal antibiotic, aphrodisiac, or decongestant.

PRINCIPAL INGREDIENTS

Chemical Composition

The principal compounds in goldenseal are the isoquinoline alkaloids, hydrastine (1.5–4%), berberine (0.5–6%), and canadine (tetrahydroberberine, CAS RN: 522-97-4).[1] The concentrations of these alkaloids vary by plant part with the roots and rhizomes of goldenseal containing the highest concentrations of hydrastine and berberine. The mean concentrations of these alkaloids in three samples of goldenseal from New Zealand are listed in Table 71.1.[5] Tetrahydroberberastine, berberastine (CAS RN: 2435-73-6), canadaline are minor alkaloids. Goldenseal does not contain detectable amounts of jatrorrhizine, coptisine, or palmatine. Figure 71.1 displays the chemical structure of hydrastine (CAS RN: 118-08-1, $C_{21}H_{21}NO_6$).

The typical ratio of berberine to hydrastine is about 3:2. However, the content of hydrastine and berberine

TABLE 71.2. Physiochemical Properties of Hydrastine

Physical Property	Value
Melting Point	132 °C/~270 °F
pKa	7.8
log P (Octanol-Water)	1.890
Water Solubility	30 mg/L (20 °C/68 °F)
Vapor Pressure	6.01E-11 mmHg (25 °C/77 °F)
Henry's Law Constant	1.34E-15 atm-m³/mole (25 °C/77 °F)
Atmospheric OH Rate Constant	2.03E-10 cm³/molecule-second (25 °C/77 °F)

TABLE 71.3. Physiochemical Properties of Berberine

Physical Property	Value
Melting Point	145 °C/~293 °F
pKa	2.47
log P (octanol-water)	2.080
Atmospheric OH Rate Constant	2.09E-10 cm³/molecule-second (25 °C/77 °F)

in herbal products is highly variable. In a study of 20 samples of goldenseal herbal products purchased from Michigan pharmacies and health food stores, the mean hydrastine and berberine content were 1.57% (range: 0–2.93%) and 2.79% (range: 0.82–5.86%), respectively.[6] Figure 71.2 displays the chemical structure of berberine (CAS RN: 2086-83-1, $C_{20}H_{18}NO_4$). Berberine is found in several other plant species including *Mahonia aquifolium* (Oregon grape), *Berberis aristata* (tree turmeric), *Berberis vulgaris* (barberry), and *Coptis chinensis* (coptis or Chinese goldthread).

Physiochemical Properties

Goldenseal powder is dark yellow to moderate green-yellow in color. Both hydrastine and berberine are ionized, minimally water-soluble compounds. Table 71.2 and Table 71.3 list some physiochemical properties of hydrastine and berberine.

In vitro studies indicate that (+)-hydrastine is a $GABA_A$ receptor antagonist. This action is stereoselective with (+)-hydrastine being 180 times more potent than (−)-hydrastine. As measured by stimulation of [^{3}H]-diazepam binding to GABA receptors in rat brain membranes, the affinity of (+)-hydrastine for the $GABA_A$ receptor is five times greater than the competitive $GABA_A$ antagonist, bicuculline.[7]

Mechanism of Toxicity

In vitro studies suggest that berberine has positive inotropic effects as well as some antiarrhythmic actions by the blockade of delayed rectifier K^+ or K_{ATP} channels and increases in the effective refractory period.[8] Berberine-containing botanicals may cause QTc prolongation in patients with severe underlying heart disease, but there are few human data to confirm the clinical significance of this potential effect following the consumption of goldenseal.

DOSE RESPONSE

The typical oral doses of goldenseal are 0.5–1 gram tablets or capsules, 0.3–1 mL of liquid/fluid extract (1 : 1 in 60% ethanol), 0.5–1 gram as a decoction, or 2–4 mL as a tincture (1 : 10 in 60% ethanol) 3 times daily. Typical doses of berberine for the treatment of infectious diarrhea are 100–200 mg capsules 2–4 times or one 400 mg tablet daily. There few dose-response data for humans following consumption of goldenseal.

TOXICOKINETICS

Kinetics

The relatively high subcutaneous toxicity (LD_{50} 104 mg/kg) of berberine in animal studies compared with much lower oral toxicity suggests that the GI absorption of berberine is low.[9] Rodent studies also indicate that the oral bioavailabilities of the alkaloids, hydrastine and berberine, are relatively low.[10] Animal studies suggest that P-glycoprotein contributes to the poor intestinal absorption of berberine.[11] Based on animal studies, the kidneys excrete small amounts (i.e., 1%) of a berberine dose unchanged in the urine.[12]

Drug Interactions

Goldenseal strongly inhibits CYP2D6 and CYP3A4/5 activity *in vivo* and *in vitro*.[13] A study of 12 healthy volunteers used single-time point phenotypic metabolic ratios to determine the effect of 28 days of goldenseal supplementation on cytochrome P450 isoenzyme activities. The use of goldenseal resulted in an approximate 40% inhibition of CYP2D6 and CYP3A4/5 activity

when compared with activities prior to supplementation.[14] There was no significant effect on CYP1A2 or CYP2E1 activity *in vivo*. The clinical significance of this potential drug interaction remains undetermined. There was no significance difference in the peak concentration or oral clearance of a single dose of 800 mg indinavir before and after 14 days of supplementation with 2,280 mg goldenseal daily.[15] The relatively high oral bioavailability of indinavir limits the effectiveness of this drug as a probe for testing CYP3A4/5 interactions. *In vitro* studies suggest that the major alkaloids responsible for inhibition of these two enzymes are hydrastine (CYP3A4) and berberine (CYP2D6).[16]

CLINICAL RESPONSE

Adverse effects of goldenseal are typically GI disturbances (e.g., nausea, vomiting). There are few human data on the acute toxicity of goldenseal. Based on animal studies with berberine, seizures and dysrhythmias are potential complications of excessive doses of goldenseal, but there are no human data to confirm these clinical effects. Although there are few human data, *in vitro* studies suggest that berberine and goldenseal extract can produce photosensitization following topical applications.[17]

In traditional Chinese medicine, the use of goldenseal is contraindicated during pregnancy. Some animal studies suggest adverse effects on maternal body weight and embryonic development at very high doses of goldenseal. In a study of CD-1® mice exposed to golden-seal root powder in feed (0, 3125, 12,500, or 50,000 ppm) from gestational day 6 to 17, a statistically significant (i.e., about 8%) reduction in average fetal body weight per litter occurred at the high dose only.[18] The calculated developmental toxicity NOAEL was 12,500 ppm and the LOAEL was 50,000 ppm. This dose represents about 300 times the estimated human intake from dietary supplements (26 mg/kg/d). Other animal studies using doses of goldenseal that did not produce maternal toxicity did not cause adverse fetal effects. A study of female Sprague-Dawley rats receiving 1.86 g goldenseal extract/kg (i.e., 65 times the daily human dose) during the preorganogenic period (gestational day 1–8) and during the organogenic and early fetal period (gestational day 8–15) did not demonstrate reproductive abnormalities in the offspring.[19] There was no significant change in fetal body weights, increased implantation losses, or a statistically significant increase in fetal malformations in the treated group, when compared with the control group. The control group received the same dose of ethanol as the treatment group received in the goldenseal extract.

DIAGNOSTIC TESTING

Analytical Methods

Methods to analyze the alkaloid content (hydrastine, berberine) of goldenseal include colorimetry,[20] spectrophotometry,[21] thin layer chromatography with UV spectrophotometry,[22] gas chromatography/mass spectrometry (GS/MS),[23] capillary electrophoresis/mass spectrometry,[24] enzyme-linked immunosorbent assay (ELISA),[25] and high performance liquid chromatography (HPLC).[26] The presence of certain other alkaloids (e.g., jatrorrhizine, coptisine, palmatine) in goldenseal samples indicates adulteration of the sample by other plants.[23] Limits of detection and quantitation for berberine and hydrastine with the capillary zone electrophoresis method were 1 µg/mL and 2.5 µg/mL, respectively,[27] whereas these values for a HPLC with photodiode array detection method were 0.1 µg/mL and 0.4 µg/mL.[28] Isocratic liquid chromatography with UV detection is a rapid screening method for isoquinoline alkaloids in goldenseal that can be easily confirmed with LC/MS.[29] This procedure allows the quantitation of goldenseal alkaloids (berberine, berberastine, tetrahydroberberastine, canadine, canadaline, hydrastine) as well as non-goldenseal alkaloids (coptisine, jatrorrhizine, palmatine). The limits of quantitation were 1.65 µg/mL (berberine), 0.207 µg/mL (hydrastine), 0.122 µg/mL (canadine), and 0.27 (palmatine).

Biomarkers

Ingestion of large volumes of goldenseal tea is a popular method for concealing illicit drug use by causing darkening of the urine sample.[30] However, use of this tea probably does not alter the sensitivity or detection times of urine drug screens (e.g., marijuana, cocaine) other than the dilutional effect secondary to excessive fluids, when the tea is consumed with sufficient water to produce dilute urine specimens (creatinine <20 mg/mL, specific gravity <1.003).[31,32]

Abnormalities

In vitro studies indicate that berberine displaces bilirubin on a molar basis. The daily intraperitoneal administration of berberine (10 and 20 µg/g) for 1 week to adult rats produced a significant decrease in mean bilirubin–serum protein binding and an elevation in steady-state serum concentrations of unbound and total bilirubin.[33] Potentially, the ingestion of goldenseal can cause an exacerbation of hyperbilirubinemia in neonates or other diseases associated with hyperbilirubinemia depending on the concentration of berberine; however, there are

inadequate data to determine the clinical importance of this potential interaction.

TREATMENT

The treatment of toxicity associated with goldenseal is supportive. There are few human data to guide management of potential complications of goldenseal use.

Chapter 72

HAWTHORN
(*Crataegus* Species)

HISTORY

Chemical analysis of organic compounds absorbed into pottery jars from the early Neolithic village of Jiahu in Henan Province in China suggests that fermented beverages of rice, honey, and fruit were consumed by ancient Chinese as early as the seventh millennium before Christ (BC).[1] A potential source, other than grapes, for the tartaric acid in the Jiahu samples is the Chinese hawthorn (*Crataegus pinnatifida* Bunge, *Crataegus cuneata* Siebold & Zucc.). These plants contain four times the amount of tartaric acid in grapes. Dioscorides mentioned the use of hawthorn as a medicinal herb in the 1st century AD. Herbal use in traditional Chinese medicine dates back at least to 659 AD, when hawthorn was listed in the official Chinese pharmacopoeia, *Tang Ben Cao*.[2] Although treatment of heart disease with hawthorn began in Europe during the late 1800s, large clinical trials examining the efficacy of hawthorn extract for the treatment of congestive heart failure did not begin until the 1980s.

BOTANICAL DESCRIPTION

Hawthorn is the common name for plant species in the genus *Crataegus*. These plants are distributed throughout the world. Of the approximately 20 species of hawthorn used as herbs, the most common species used for medicinal purposes are *C. laevigata* (Poir.) DC. and *C. monogyna* Jacq.(*C. oxyacantha* auct. non L.). Chinese species include *Crataegus pinnatifida* and *Crataegus cuneata*, whereas European species of hawthorn include *Crataegus monogyna* Jacq., *C. pentagyna* Waldst. & Kit. ex Willd., *C. nigra* Waldst. & Kit., and *C. azarolus* L.

Common Name: Hawthorn, Aubépines

Scientific Name: *Crataegus* spp.

Botanical Family: Rosaceae (rose)

Physical Description: The dull gray stems of this thorny shrub have small, bright green, three- to five-lobed leaves with short, distinct stalks. Flat clusters of white flowers appear in spring with pink stamen, which turn brown and discharge pollen. The flower produces bright red berries.

Distribution and Ecology: There are over 280 species of hawthorn (*Crataegus* spp.) occurring primarily over northern temperate zones of East Asia, Europe, and eastern North America.

EXPOSURE

Sources

The medicinal parts of the hawthorn plant are the leaves, flowers, and fruits. The hawthorn fruit is also used as a foodstuff (e.g., jam, jelly, canned fruit, beverage, wine).

Medicinal Uses

Traditional

Hawthorn is a Chinese and European herb with a long history of use in traditional medicine, primarily as a digestive aid. In traditional Chinese medicine, hawthorn

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

stimulates digestion, promotes the blood circulation, and reduces blood stasis. Herbal uses involve the treatment of diarrhea, indigestion, abdominal pain, hyperlipidemia, hypertension, and amenorrhea. In Europe, hawthorn extract is a treatment for fluid overload, hypertension, hyperlipidemia, congestive heart failure, and colic.

Current

Experimental studies suggest that hawthorn extract has positive inotropic, negative chronotropic, and coronary artery vasodilatory properties similar to phosphodiesterase inhibitors (amrinone, milrinone), but there is no clear incremental benefit of adding hawthorn extract to standard regimens for congestive heart failure.[3,4] Typically, hawthorn is an adjunct to the conventional treatment (angiotensin-converting enzyme inhibitors, calcium antagonists, diuretics) for mild forms of chronic congestive heart failure. A meta-analysis of eight clinical trials (632 patients with chronic heart failure NYHA class I-III) demonstrated a statistically significant improvement in maximal workload along with reduced fatigue and dyspnea, when comparing hawthorn extract to placebo.[5] The weighted mean difference was 7 watts (95% CI: 3–11, $P < 0.01$). Seven of the eight trials used the hawthorn extract WS 1442 (standardized to 18.8% oligomeric). However, the number of patients in these trials is small, the follow-up period was short, and the improvement in maximal workload for the addition of hawthorn extract was small (9%) compared with angiotensin-converting enzymes alone (19%).[6]

An herbal preparation (Sympathyl, Laboratorier Innotech Internation, Arcueil, France) is an extract of hawthorn (*C. monogyna* Jacq. or *Crataegus oxyacantha*) and California poppy (*Eschscholzia californica* Cham.) that is used in France as a treatment for insomnia and anxiety.[7]

Regulatory Status

In Germany, hawthorn extract is a prescription medication. The German Commission E approved the use of hawthorn extract (leaves, flowers) for the treatment of patients with New York Heart Association (NYHA) class II symptoms.

PRINCIPAL INGREDIENTS

Chemical Composition

The main compounds in hawthorn (leaves, flowers, berries) are flavonoids (catechin, oligomeric procyanidin, quercetin, quercitrin, rutin), triterpene saponins (crataegus acid, oleanolic acid, ursolic acid), organic acids (caffeic acid, chlorogenic acid), and amines (acetylcholine, β-phenethylamine, tyramine). Approximate amounts of these compounds in hawthorn include the following: oligomeric proanthocyanidins (1–3%, fruits or leaves with flowers), triterpene acids (0.5–1.4%, fruits), organic acids (2–6%), sterols, and trace amounts of cardioactive amines.[2] Ursolic and oleanolic acids account for about 90% of the pentacyclic triterpene compounds.[8] Flavonoids are naturally occurring antioxidants present in many fruits, vegetables, and beverages. This group of compounds is composed of five subclasses as follows: flavanols (catechin, epicatechin, procyanidins), flavanones (hesperidin, naringin), isoflavanones, flavones (apigenin, luteolin, vitexin), flavonols (quercetin, rutin, hyperoside), and anthocyanidins.[9] Figure 72.1 displays some representative flavones and flavonols in hawthorn.

The main flavonoid compounds in hawthorn are flavonols (i.e., oligomeric procyanidins).[10] The flavan-3-ols, (−)-epicatechin and (+)-catechin, occur extensively in foodstuffs (e.g., cocoa, peanuts) along with their related oligomers (dimers, trimers), the procyanidins. Figure 72.2 displays the chemical structure of procyanidin (CAS RN: 4852-22-6, $C_{30}H_{26}O_{13}$). In general, aqueous extracts of hawthorn contain lower and more variable concentrations of procyanidins, total flavonoids, and total phenols compared with alcohol (methanol, ethanol) extracts, but the concentrations of total vitexins are similar in these two types of extracts.[11]

Physiochemical Properties

Procyanidins are antioxidants that protect bilayer membranes by decreasing membrane fluidity.[12]

Mechanism of Toxicity

The mechanism of action of hawthorn is not well defined, but most authorities believe that the active ingredients in hawthorn extracts are flavanoid compounds. The trace amounts of amines in hawthorn extract are probably not absorbed by the gastrointestinal (GI) tract in clinically significant amounts.

DOSE RESPONSE

European clinical studies used daily doses of hawthorn extract from 160–900 mg that were standardized to 2.2% flavonoids or 18.75% oligomeric proanthocyanidins.[2] In China, typical doses of dried hawthorn fruit are 9–12 g 2 to 3 times daily.

FIGURE 72.1. Representative flavones and flavonols in hawthorn.

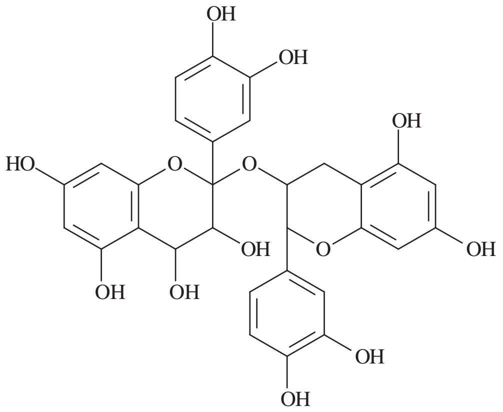

FIGURE 72.2. Chemical structure of procyanidin.

TOXICOKINETICS

Kinetics

There are few data on the pharmacokinetics of flavonoid compounds following ingestion by humans. Animal studies suggest that the oral bioavailability of epicatechin is low, while the GI absorption of other components of hawthorn extract (chlorogenic acid, hyperoside, isoquercitrin) is very low. In a study of rats, the bioavailability of epicatechin from hawthorn extract was about 10%, whereas the GI absorption of chlorogenic acid, hyperoside, and isoquercitrin was only about 1–2%.[13]

Drug Interactions

P-glycoprotein is a transmembrane protein that functions as an efflux transporter and is found in high concentrations in the gut and the kidney. The ingestion of hawthorn extract causes mild induction of P-glycoprotein activity, but this induction does not necessarily result in decreased absorption of P-glycoprotein dependent substrates, such as digoxin. A randomized, crossover trial with eight healthy volunteers did not detect a statistically significant difference in pharmacokinetic parameters (area under the concentration-time curve, maximum concentration, half-life, renal clearance) of digoxin, when comparing three weeks of daily hawthorn extract (WS 1442) to baseline.[14]

CLINICAL RESPONSE

Adverse effects associated with clinical trials using hawthorn extract at therapeutic doses are typically minor.[15] These effects include headache, dizziness, vertigo, rash, diaphoresis, palpitations, agitation, drowsiness, and GI disturbances. Larger doses of hawthorn extract in animals produce sedation, hypotension, and dysrhythmias.[16] There are few data on human toxicity associated with the ingestion of hawthorn extract. Based on animal data, potential toxic effects of hawthorn intoxication include cardiac abnormalities (hypotension, dysrhythmias). Rare case reports associate exposure to the fruits and leaves with contact dermatitis.[17] The concealed thorns on hawthorn stems can produce corneal abrasions and lacerations.

DIAGNOSTIC TESTING

Methods to determine the flavonoid content of hawthorn extract include high performance liquid chromatography and gas chromatography/mass spectrometry.[18,19] Separation of flavonoid compounds with capillary zone electrophoresis allowed detection limits of 0.35 µg/mL, 0.30 µg/mL, 0.40 µg/mL, and 0.29 µg/mL for vitexin-2′-rhamnoside, hyperoside, rutin, and vitexin, respectively.[20]

TREATMENT

Treatment is supportive. There are few clinical data on the toxicity of hawthorn extract to guide treatment.

Chapter 73

IMPILA, PINE THISTLE, and ATRACTYLOSIDE

HISTORY

The properties of pine thistle have been known at least since the first century AD, when the Greek pharmacologist and physician Pedanius Dioscorides of Anazarbos described the plant and its properties.[1] During the Renaissance, the plant was known as *chameleone*, and the use of this plant was suggested as an antidote for snake envenomation and other poisons, as well as urinary retention, somnolence, and dental pain. In 1867, Lefranc extracted a toxin from the rhizome of pine thistle that he named atractylic acid (atractyline), and later the compound was termed atractylate of potassium.[2] Stanislas and Vignais discovered a structurally related, more potent toxin called carboxy-atractyloside in 1956.[3] Brookes et al. isolated the main toxin, atractyloside, from the tubers of *C. laureola* in 1983.[4] *Callilepis laureola* (impila) is a popular traditional remedy in South Africa that was administered during the 1930s in low doses for whooping cough.[5]

BOTANICAL DESCRIPTION

Pine thistle (*Atractylis gummifera* L.) has been known since antiquity under a variety of names including ixia, chameleon leukos, chardon á glu (France), edded (North Africa), mascarida (Sardinia), and masticogna (Sicily).[6] This plant is often confused with the nontoxic plant, *Atractylis acaulis* Pers.

Common Name: Pine Thistle, Glue or Mediterranean Thistle, Blue Thistle, Birdlime, Chameleon

Scientific Name: *Atractylis gummifera* L.

Botanical Family: Asteraceae (sunflower)

Physical Description: This long-lived herbaceous plant has an aerial part (i.e., fern-like leaves, pink flowers, fruits) and a subterranean part (i.e., long, large rhizome of variable color depending on the season). The leaves are deeply divided into prickly lobes and grouped into rosettes.

Distribution and Ecology: *Atractylis gummifera* is a native of the Mediterranean region, particularly in dry areas of Tunisia, Morocco, Algeria, Spain, Italy, and Greece. Although this thistle is distributed worldwide, this plant is especially abundant in northern Africa and southern Europe.

Common Name: Ox-eye Daisy

Scientific Name: *Callilepis laureola* DC.

Botanical Family: Asteraceae (sunflower)

Physical Description: This woody tuber has a bulbous shape and a pungent odor.

Distribution and Ecology: *Callilepis* species are perennial, herbaceous plants that grow in the grassland of eastern South Africa.

EXPOSURE

Uses

In the Zulu culture, the tuber of *C. laureola* is a multipurpose remedy in the Kwa Zulu-Natal region of northeastern South Africa.[7] After boiling the powder of the

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

root in water for 30 minutes, the decoction (i.e., impila) is administered orally or rectally. Traditional uses for this plant include stomach problems, constipation, tape worm infections, cough, induction of fertility in young women, and impotence.[8] Peoples of this region adhere to the magical belief that decoctions from this plant provide "protective powers" that ward off evil spirits. In Arab countries, the dried rhizome is burned as an incense to avoid bad fates. Tubers of *C. laureola* are harvested in the winter and processed into a dry powder. Alternatively, a piece of fresh material is cut and scraped from the tuber. Traditional uses of pine thistle include the treatment of syphilitic ulcers, intestinal parasites, syncope, drowsiness, abscesses, and discolored teeth, as well as an abortifacient, suicidal agent, and homicidal agent.[1,9] There are no approved medicinal uses of *C. laureola* (impila) or atractyloside.

PRINCIPAL INGREDIENTS

Chemical Composition

The two major toxic compounds in *C. laureola* are the diterpenoid glycosides, atractyloside and carboxy-atractyloside (gummiferin).[6] Atractyloside compounds also occur in other plant species including the pine thistle (*Atractylis gummifera*),[10] aerial parts of Asian *Atractylis* species *(A. carduus, A. lancea)*, the South American herb *Pascalia glauca* Ortega (*Wedelia glauca)*,[11] the Australia plant *Wedelia asperrima* (Decne.) Benth., and the common cocklebur (*Xanthium strumarium* L.).[12] Atractyloside and carboxy-atractyloside are the main toxic constituents of *Iphiona aucheri* (Boiss.) A. Anderberg, which has been used to poison racing camels in the Middle East.[13] *Atractylis acaulis* does not contain toxicologically significant amounts of atractyloside or carboxy-atractyloside.[9] Atractyloside may be a constituent of green and roasted coffee beans from *Coffea arabica* L.[14] Carboxy-atractyloside undergoes decomposition to atractyloside.[15] The concentration of atractyloside compounds varies with season, plant species, and environmental conditions; however all underground parts contain these two diterpenoid glucosides.[16] The green beans of *Coffea arabica* also contain substantial amounts of atractyloside, but the dry roasting process significantly decreases the content of atractyloside available in coffee extracts.[17]

Physiochemical Properties

Atractyloside consists of a relatively nontoxic aglycone with a perhydrophenanthrene structure and a glycoside moiety composed of glucose, sulfate, and isovalerate.[14] Figure 73.1 demonstrates the chemical structure of

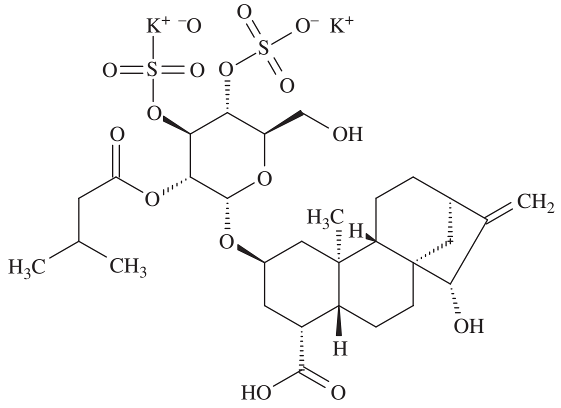

FIGURE 73.1. Chemical structure of atractyloside.

atractyloside. Carboxy-atractyloside occurs only in fresh roots because of the decarboxylation of this diterpenoid compound to atractyloside, particularly during heating and drying.[18] Other potential toxins in *Atractylis* species include carboxy-atractyloside, apoatractyloside, atractylgenine, and carboxy-atractylgenine.[6] Reduction of the carboxyl group on C4 of the diterpene ring to the corresponding alcohol produces a nontoxic compound (atractylitriol).[19]

Mechanism of Toxicity

Animal studies indicate that atractyloside and carboxy-atractyloside in *Atractylis* species inhibit mitochondrial oxidative phosphorylation and block the conversion of ADP to ATP by interacting with the adenine nucleotide translocator involved with the ATP/ADP antiport and mitochondrial membrane permeabilization.[20] Extracts of *C. laureola* probably contain both a liver toxin and a renal toxin (atractyloside), which cause hepatic necrosis and renal failure as a result of the inhibition of mitochondrial phosphorylation.[21] In experimental animals, atractyloside produces hypoglycemia and acute renal tubular necrosis, but the administration of this compound does not cause the centrilobular liver necrosis associated with impila.[17,22] Both atractyloside and carboxy-atractyloside bind selectively to phosphoryl transferase (nucleoside mono phosphokinase) in the outer mitochondria membranes resulting in the blockade of oxidative phosphorylation.[23] By binding to the adenine nucleotide translocator on the mitochondrial membrane, atractyloside and carboxy-atractyloside competitively inhibit the transport of ADP across the mitochondrial membrane. The result is a reduction in the synthesis of ATP and fatty acid oxidation, inhibition of gluconeogenesis, and acceleration of anaerobic glycolysis and glycogenolysis. The mechanism or mechanisms by which these compounds cause apoptosis of

hepatocytes remain unclear, and the toxic effects of atractyloside involve mechanisms other than the blockade of oxidative phosphorylation.[14] *In vitro* studies indicate that aqueous extracts of *C. laureola* cause apoptosis via the caspase cascade and destruction of cytoplasmic tubulin architecture in human hepatocytes.[5,24] The histological features of hepatic damage are not consistent with lipid peroxidation and free radical formation.[9]

DOSE RESPONSE

The toxicity of decoctions from the tubers of *C. laureola* depends on variation of the toxic principals with season, climate, soil conditions, and plant part as well as on the sensitivity of individual patients (e.g., malnutrition).[25]

TOXICOKINETICS

There are few data on the toxicokinetics of atractyloside. Some unchanged atractyloside appears in the urine based on analyses of blood and urine samples from patients poisoned by atractyloside-containing herbs.[14]

CLINICAL RESPONSE

The classical presentation of toxicity following exposure to atractyloside-containing substances (impila, pine thistle) involves the sudden onset of abdominal pain, vomiting, diarrhea, altered consciousness, and fulminant hepatorenal failure.[26,27] In a retrospective review of admissions to a toxicology intensive care unit in Tunisia, ingestion of *Atractylis gummifera* accounted for about one-third of the cases.[28] Symptoms typically begin 6–36 hours after ingestion of the extract of *Atractylis gummifera* rhizome.[29] Convulsions occur in a substantial number of seriously poisoned patients. Although renal dysfunction usually occurs with substantial hepatic necrosis, case reports document the occurrence of early renal failure without prominent liver damage.[30] There are few data on the chronic toxicity of low doses of atractyloside. The differential diagnosis of atractyloside-induced hepatic dysfunction includes Jamaican vomiting sickness, Reye's syndrome, viral hepatitis, and sepsis.

DIAGNOSTIC TESTING

Analytical Methods

Thin layer chromatographic and enzyme-linked immunosorbent assay (ELISA) methods are screening procedures for the detection of amounts of atractyloside exceeding 0.5 μg.[31,32] These screening tests confirm exposure to atractyloside, but there are inadequate data to correlate atractyloside concentrations with clinical effects. Gas chromatography/mass spectrometry techniques are available to confirm the presence of atractyloside compounds.[33]

Abnormalities

The most common laboratory abnormalities in patients with severe atractyloside toxicity include hypoglycemia, metabolic acidosis, hypoprothrombinemia, and elevated serum hepatic aminotransferases. Other common laboratory abnormalities include leucocytosis, hyperkalemia, hyponatremia, and hypernatremia.[26] Jaundice is relatively mild compared with the severity of the liver disease, in part because of the rapid progression of liver failure.[31] Diagnosis is confirmed by liver biopsy demonstrating centrilobular necrosis of the liver.[34] Postmortem findings beside centrilobular liver necrosis include congestion of the renal cortex, acute tubular necrosis of the proximal convoluted tubules and the loops of Henle, and hemorrhage of the lungs and gastrointestinal tract.

TREATMENT

Treatment of atractyloside poisoning is supportive. Because of the frequency of hypoglycemia, all patients should be screened with rapid blood glucose tests and treated promptly if hypoglycemia is present. There are no clinical data to guide the treatment of hepatorenal failure other than the standard methods of treatment (i.e., fluid and electrolyte replacement, cardiorespiratory support, seizure control) and support of hepatorenal function.

Chapter 74

JIN BU HUAN and TETRAHYDROPALMATINE

HISTORY

Jin bu huan is a popular Chinese herb that has been used for over 1,000 years. In 1993, public health and healthcare providers in Colorado reported the development of central nervous system and respiratory depression in three children accidentally ingesting jin bu huan anodyne tablets.[1] All of these children recovered after receiving intensive supportive care. Subsequent analyses of these tablets indicated that they contained high concentrations of a compound, *l*-tetrahydropalmatine, which was not previously found in jin bu huan. Later that year, several cases of acute hepatitis were associated with the ingestion of these tablets over several months.[2] Subsequently, federal agencies in the United States and Canada banned the use jin bu huan in their respective countries.

BOTANICAL DESCRIPTION

Jin bu huan is an ancient Chinese herb with multiple herbal sources, including *Aristolochia yunnanensis* Franch, *Asystasiella neesiana* (Wallich) Lindau, *Huperzia serrata* var. *serrata* (Thunb. ex Murr.) Trevisan (*Lycopodium serratum*), *Panax pseudoginseng* Wallich, *Polygala chinensis* Hook L., *Rumex madaio* Makino, *Rumex patientia* L., *Selaginella involvens* (Swartz) Spring, *Stephania delavayi* Diels, and *Stephania sinica* Diels.[3] Of these plant species, only *Stephania* species contain the toxic ingredient (tetrahydropalmatine) in the jin bu huan anodyne tablets associated with central nervous system (CNS) and hepatic toxicity.

EXPOSURE

Sources

The jin bu huan anodyne tablets associated with hepatic and CNS toxicity were an herbal product purportedly containing *Polygala chinensis* L. (Chinese milkwort) imported from Kwangsi, China by the Kwangsi Pai Se Pharmaceutical Company. These tablets were sold as a sedative, analgesic, and sleeping tablet for individuals with nocturnal pain. Subsequent analysis of these tablets indicated that the sole active ingredient was *l*-tetrahydropalmatine (i.e., about 34–36% weight/weight), which is not present in detectable quantities in *Polygala chinensis*.[4] The suspected origin of tetrahydropalmatine in these tablets was probably a standard pharmaceutic source.[5]

Medicinal Uses

Jin bu huan is a traditional Chinese herbal product used as a sedative, antispasmodic, analgesic and decongestant. Tetrahydropalmatine (rotundine) is a pharmaceutical product in China.

PRINCIPAL INGREDIENTS

Chemical Composition

Analysis of tetrahydropalmatine-containing jin bu huan anodyne tablets indicated that the tetrahydropalmatine concentration in these tablets was approximately 34–

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

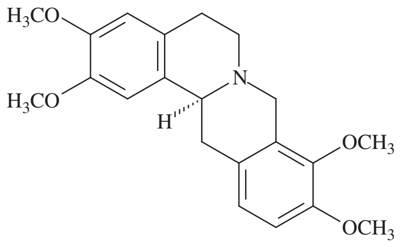

FIGURE 74.1. Chemical structure of tetrahydropalmatine.

36% weight/weight compared with 1.5% in herbs, which naturally contain this alkaloid.[6] The rest of the tablets contained starch, and there were no other plant alkaloids or pharmaceutical products detected. Figure 74.1 displays the chemical structure of tetrahydropalmatine (CAS RN: 10097-84-4, $C_{21}H_{25}NO_4$), which is similar to the structure of berberine. The latter compound has been associated with kernicterus and displacement of bilirubin in preterm neonates.[7]

Physiochemical Properties

Although tetrahydropalmatine in extractions of herbal plants (e.g., *Corydalis* spp., *Stephania* spp.) typically contain racemic mixtures (*d*,*l*-tetrahydropalmatine), rodent studies indicate that only the *l*-enantiomer is pharmacologically active.[8] In animal models, tetrahydropalmatine has reserpine-like properties resulting in the depletion of neurotransmitters (dopamine > norepinephrine > serotonin).[9] Rodent studies indicate that *l*-tetrahydropalmatine acts as a dopaminergic D_2 antagonist in nigro-striatal neurons, resulting in the blockage of both pre- and postsynaptic dopamine receptors.[10,11] This compound has little affinity for opioid receptors.[12]

Mechanism of Toxicity

The exact mechanism of hepatotoxicity associated with tetrahydropalmatine-adulterated jin bu huan remains unclear. Potential mechanisms include hypersensitivity reactions, idiosyncratic reactions, or direct toxicity from active metabolites. The abrupt recrudescence of hepatitis following reintroduction of jin bu huan anodyne tablets to 2 patients suggests a hypersensitivity reaction.[4] However, the significant decrease in serum hepatic aminotransferase following continuation of a reduced dosage of jin bu huan suggests a direct toxic effect. The clinical course of some of these patients is also consistent with an idiosyncratic reaction.

DOSE RESPONSE

The recommended adult dose of jin bu huan anodyne tablets was 2–4 tablets 1–3 times daily. The ingestion of 17 tetrahydropalmatine-adulterated jin bu huan anodyne tablets (28.8 mg *l*-tetrahydropalmatine/tablet) by a $2^1/_2$-year-old girl resulted in lethargy, respiratory depression requiring intubation, and bradycardia. The ingestion of 60 tablets by a 13-month-old boy caused lethargy, hypotonia, and transient bradycardia. Both children survived without sequelae after supportive care.[6]

TOXICOKINETICS

There are few data on the kinetics of tetrahydropalmatine in humans. The relatively rapid onset of symptoms in children ingesting tetrahydropalmatine-adulterated jin bu huan anodyne tablets suggests that the absorption of tetrahydropalmatine is rapid. The resolution of symptoms within 10 hours of a large overdose also suggests rapid elimination. Analysis of serum and urine from patients poisoned by tetrahydropalmatine suggests that biotransformation of this compound occurs by *O*-demethylation and elimination by excretion of glucuronide metabolites in the urine.[13]

CLINICAL RESPONSE

Acute Effects

Case reports associate the acute ingestion of tetrahydropalmatine in adulterated jin bu huan anodyne tablets by young children and the intentional overdose of tetrahydropalmatine-containing sleeping pills by adults with CNS depression. The clinical features of a case series of three young children ingesting 7–60 tablets included lethargy, hypotonia, bradycardia, dysconjugate gaze, and respiratory depression requiring intubation.[6] The children recovered within approximately 3–10 hours. A case series of 9 adult patients associated the intentional ingestion of up to 75 herbal sleeping pills containing 26 mg tetrahydropalmatine/tablet with disorientation, lethargy, and coma.[13] All patients were released within 1–3 days after supportive care.

Chronic Effects

Several case reports associate the development of acute hepatitis with the chronic ingestion of tetrahydropalmatine-adulterated jin bu huan anodyne tablets.[1,14] In a case series of 7 patients, the mean onset of acute hepatitis after beginning these tablets was 20 weeks (range: 7–52 weeks) and resolution occurred in 6 patients within 2–30 weeks (Mean: 8 weeks).[4] The seventh patient was

recovering during the time the article was published. The clinical features of this illness included fever, fatigue, nausea, pruritus, abdominal pain, jaundice, and hepatomegaly. Liver biopsy in one patient suggested a drug reaction (i.e., eosinophilia), while other pathological abnormalities included focal hepatocellular necrosis, mixed periportal infiltrates, microvesicular steatosis, and moderate fibrosis. Although these biopsies occasionally demonstrate the presence of moderate fibrosis,[15] these patients usually recover without clinical or biochemical evidence of liver damage.

DIAGNOSTIC TESTING

Older methods for the detection of tetrahydropalmatine include thin layer chromatography (TLC) and reverse-phase high performance liquid chromatography (RP/HPLC). However, TLC has poor reproducibility and analysis of basic drugs by RP/HPLC is limited by excessive retention and poor column efficiency. The use of an unmodified silica column with reversed-phase eluents improves the speed and precision of HPLC.[16] Screening of urine or serum samples with uniform solid-phase extraction and HPLC with diode-array detection allows the detection of tetrahydropalmatine and metabolites.[13] The treatment of biological samples with hydrolysis or glucuronidase improves the yield, particularly in urine samples. Gas chromatography/mass spectrometry (GC/MS) confirms the presence of tetrahydropalmatine and specific metabolites.

Serum abnormalities associated with the consumption of tetrahydropalmatine-adulterated jin bu huan tablets include elevated serum hepatic aminotransferases and serum bilirubin.[17] The serum alkaline phosphatase concentration may be within the normal range, and the prothrombin time is usually normal unless the hepatitis is severe enough to alter synthesis of clotting factors by the liver. These abnormalities usually resolve within several months of cessation of the use of these tablets.

TREATMENT

The occurrence of respiratory depression requiring intubation and bradycardia indicates that symptomatic intoxications with tetrahydropalmatine-adulterated jin bu huan should be evaluated and monitored carefully for the adequacy of ventilation including pulse oximetry and cardiac monitoring.[6] The onset of symptoms is typically rapid (i.e., within 1 hour). Bradycardia in these cases was responsive to atropine. If the patient presents to the emergency department within 1 hour of ingestion, the use of activated charcoal is appropriate. The use of syrup of ipecac is contraindicated because of the rapid onset of CNS depression. Case reports indicate that the CNS toxicity associated with the acute ingestion of tetrahydropalmatine-adulterated jin bu huan anodyne tablets is not responsive to intravenous naloxone administration.[6] The treatment of acute hepatitis associated with tetrahydropalmatine-adulterated jin bu huan is supportive. Most of these cases respond to cessation of jin bu huan use.

Chapter 75

JUNIPER
(*Juniper communis* L.)

HISTORY

The use of juniper berries dates back at least to the ancient Greeks and Egyptians. The Greeks used these berries for medicinal purposes. Ancient Egyptian tombs, including the tomb of Tutankhamen, contained *Juniperus oxycedrus* berries even though this plant was not native to Egypt. The Romans used juniper berries as a domestic substitute for the expensive black pepper imported from India; Pliny the Elder mentioned the use of juniper berries in his book, *Historia Naturalis*. Extracts of juniper berries have a long history of use as flavoring agents, including as an additive to gin.

BOTANICAL DESCRIPTION

Common Name: Common Juniper, Dwarf Juniper, Genévrier Commun

Scientific Name: *Juniper communis* L.

Botanical Family: Cupressaceae (cypress, redwood)

Physical Description: This slow-growing coniferous evergreen shrub or a small columnar tree is usually decumbent or rarely upright. The height of juniper varies with the variety with shrub reaching 4 m (~13 ft) and trees reaching up to 10 m (~33 ft). The thin, fibrous, brown bark exfoliates in thin strips. The firm, green, simple leaves have a pungent odor and are arranged in whorls of three. The fruits are berrylike seed cones, and each cone contains 2–3 small (3–4 mm/~0.1–0.2 in.) seeds.

Distribution and Ecology: The genus *Juniperus* comprises about 70 species distributed throughout the North America, Europe, and Asia. These species include *Juniperus virginiana* L. (eastern red cedar from the eastern United States), *Juniperus ashei* Buchh. (Ashe juniper), *Juniperus phoenicea* L. (Phoenician cedar from the Mediterranean coast), and *Juniperus oxycedrus* L. (prickly or cade juniper from southwest Europe to northwest Africa).

EXPOSURE

Sources

Juniper oils are steam distillates of juniper berries or wood; these oils are fragrance ingredients in some cosmetics. The berries from the juniper tree contain about 0.5–1.5% essential oil.[1] The source of *Juniperus communis* extract (CAS RN: 84603-69-0) is the extract of the mature fruit of *J. communis*, whereas *Juniperus communis* oil (RN: 8002-68-4, juniper berry oil) is the volatile oil from the berries of *J. communis*. The destructive distillation of branches and wood from *Juniperus oxycedrus* L. is the source of cade oil (CAS RN: 8013-10-3, juniper tar). The concentration of juniper extract and juniper tar in cosmetics ranges from about 0.1–1% and 1–5%, respectively.[1] The chief flavoring agent in distilled liquor, gin, is the highly aromatic, blue-green berry of the juniper (*Juniperus* spp.), which is grown commercially in the United States, Canada, northern Italy, and Croatia.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Medicinal Uses

TRADITIONAL

Cade oil is a traditional treatment for skin diseases (e.g., atopic dermatitis, chronic eczema) in humans and animals based on keratolytic, antipruritic, and antimicrobial properties. Other herbal uses of juniper include the treatment of diabetes mellitus, fluid overload (diuretic), and bronchopulmonary diseases.

CURRENT

Rectified cade oil is a fragrance in soaps, creams, lotions, detergents, and perfumes.

REGULATORY STATUS

Most countries do not regulate the use of juniper oil.

PRINCIPAL INGREDIENTS

Chemical Composition

Juniper oils are complex mixtures containing many monoterpene, sesquiterpene, oxygenated monoterpene, and oxygenated sesquiterpene hydrocarbons.[2] Essential oils from *Juniperus* species contain about 85–95% monoterpenes and approximately 0.1–12% alcohols. The major compounds in essential oils from *Juniperus* species are α-pinene, β-pinene, δ-3-carene, sabinene, myrcene, β-phellandrene, limonene, and D-germacrene.[3] Analysis of the essential oil from dried juniper berries (*J. communis*) by gas chromatography/mass spectrometry demonstrated the following approximate yield: α-pinene (29%), β-pinene (18%), sabinene (14%), limonene (6%), and myrcene (0.3%).[4] However, there are substantial quantitative and qualitative differences in the essential oils between different *Juniperus* species and between different plant parts. The main component in the leaf essential oil from *Juniperus communis* was sabinene (about 61%), whereas α-pinene (about 52%) was the main ingredient in the essential oil from the berries.[3] The yield of leaf essential oil from *Juniperus oxycedrus* is about 0.27%.[5] The major constituents are α-pinene (about 40%) and the diterpene, manoyl oxide (about 10%). The yield of berry essential oil is higher (i.e., 1.14%). α-Pinene is also the major constituent (about 65%) of berry essential oil with smaller amounts of myrcene (about 4%), limonene, β-pinene, manoyl oxide, and γ-muurolene.

The leaves of the eastern red cedar (*Juniperus virginiana* L.) contain podophyllotoxin. The leaves from the mature plants have about 1–2.5 mg podophyllotoxin/g material, but this concentration is much less than leaves from the American mayapple (*Podophyllum peltatum* L.).[6] The average podophyllotoxin content of juvenile plants was approximately 40% of the concentration in immature and mature specimens of *J. virginiana*.

Physiochemical Properties

Juniper berry oil is a yellowish, alcohol-soluble liquid with a density of 0.865 g/mL and a boiling point of 120 °C (248 °F).

Mechanism of Toxicity

Most adverse effects associated with exposure to juniper oil are hypersensitivity reactions.

DOSE RESPONSE

Toxic doses of juniper oil are not well defined. Many reactions to juniper oil involve hypersensitivity responses; therefore most of these reactions are not dose-related. A typical herbal dose of juniper oil is 100 mL of a 1:20 dilution in boiled water.

TOXICOKINETICS

There are few human or animal data on the toxicokinetics of constituents of juniper oil.

CLINICAL RESPONSE

In general, animal studies and clinical trails indicate that juniper oils produce little skin irritation or sensitization, although some sensitization can occur to juniper tar (cade oil).[1] Species in the Cupressaceae family, including the genus *Juniperus* (e.g., *Juniperus ashei* J. Buchholz, *J. virginiana*), are common causes of allergic rhinitis, particularly in the winter and early spring.[7] In a New York study of 102 patients with asthma and/or rhinitis as well as evidence of sensitivity to trees, grass, or ragweed pollens, 51% (52 patients) were sensitive to the eastern red cedar (*Juniperus virginiana*) or white cedar (*Thuja occidentalis* L.).[8] There is substantial cross-reactivity within juniper species and between juniper species and other cedar trees [*Libocedrus decurrens* Torr., *Chamaecyparis lawsoniana* (A. Murray bis) Parl., *Cryptomeria japonica* (Thunb. ex L. f.) D. Don or Japanese cedar] and cypress trees (*Cupressus arizonica* Greene).[9] However, there is little cross-reactivity with pines and angiosperms.

A case report associated the ingestion of a spoonful of homemade cade oil (juniper tar) by a 32-year old man with the development of fever, hypotension, gross

hematuria, renal failure, white desquamated facial burns, thrombocytopenia, and elevated serum creatine phosphokinase concentrations.[10] His vital signs and hepatorenal function returned to normal after 8 days. These effects were attributed to phenol (carbolic acid) in the cade oil, but there was no chemical analysis of the cade oil. Although essential oils from *Juniperus* species contain phenolic compounds, phenol (carbolic acid) is not a major constituent of essential oils from *Juniperus* species, and the facial burns suggested exposure to phenol.

DIAGNOSTIC TESTING

Methods to analyze the components of juniper oil include high-performance liquid chromatography with UV detection,[11] capillary gas chromatography with flame ionization and mass spectrometry.[2]

TREATMENT

Treatment is supportive.

Chapter 76

KAVA
(*Piper methysticum* Forster)

HISTORY

For several thousand years, South Pacific Islanders used the aqueous extracts of dried Kava roots for ceremonial and social purposes.[1] The use of this intoxicating beverage spread to Europe in the 1700s after two Swedish botanists described the plant on the first expedition (1768–1771) of Captain Cook. During his second voyage (1772–1775), botanist, Johann Georg Forster, named the plant *Piper methysticum* (intoxicating pepper). German colonists brought kava to Europe during the following century.[2] The kava rhizome appeared in the *British Pharmacopoeia* in 1914 and in the *US Dispensary* in 1950. Kava was listed as a treatment for gonorrhea in the *German Pharmacopoeia* prior to the discovery of penicillin. During the early 1980s, the recreational use of this beverage spread to Aboriginal communities in Australia, where heavy consumption of this beverage frequently occurred with ethanol. Since the 1990s, kava extracts prepared from nonaqueous solvents appeared in commercial markets of the United States and Europe as dietary supplements for the treatment of stress, insomnia, and anxiety. Case reports in the early 1990s associated the use of kava extracts with the development of hepatitis, cirrhosis, and fulminant liver failure. Consequently, several European countries and Canada banned the use of kava extracts.

BOTANICAL DESCRIPTION

Common Name: Kava, Kava Kava, Kawa-kawa, Yati, Yagona, Yangona

Scientific Name: *Piper methysticum* Forster

Botanical Family: Piperaceae (pepper)

Physical Description: This perennial shrub reaches 3 m (~10 ft) in height with long (15–20 cm/~6–8 in.), bright green, heart-shaped leaves about 15–20 cm (~6–8 in.) long. Small flowers appear in spikes, but these flowers do not produce fruit or seeds. The thick, succulent-like stems have prominent nodes.

Distribution and Ecology: Kava is a perennial shrub native to the South Pacific including Melanesia (Fiji, Papua New Guinea, the Solomon Islands and Vanuatu), Micronesia, and Polynesia. This shrub prefers well-drained, rich soil in the sun when mature.

EXPOSURE

Sources

Kava rhizomes undergo extraction using water, ethanol, or acetone. The aqueous extract of the kava plant (*Piper methysticum* Forster) is a traditional drink used by South Pacific Islanders for soporific and psychotropic effects.[3] This drink is an infusion of ground kava rhizomes (1–1.5 g) in cold water (100–150 mL) or in coconut milk. The kava root is pulverized by mastication for narcotic-like effects in some parts of Vanuatu and Papua New Guinea. Dried powdered kava imported from Fiji or Tonga is mixed with water by Aborigines in Arnhem Land, Australia. In Western cultures, commercial caplets of kava are used rather than the traditional kava rhizome infusion. The difference between the aqueous extraction

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

method for the traditional drink and the acetone or alcohol extraction methods for commercial caplets results in substantial variation in the chemical composition of these extracts. The traditional aqueous beverage contains glutathione, which potentially provides some protection against hepatotoxicity in comparison to the more lipophilic acetone extracts of kava plant.[4] The commercial, acetone kava extract WS®1490 is a 90–110 mg extract of dry kava rhizome (11–20:1) that corresponds to about 70 mg kavalactones. The dried extracts are pressed into caplets or tablets for commercial use.

Medicinal Uses

Traditional

Traditional uses for kava include the treatment of asthma, rheumatism, urological problems, menopausal symptoms, gonorrhea, vaginitis, nocturnal incontinence, weight loss, and insomnia. As a traditional social beverage, ingestion of aqueous extracts of kava roots produces mild euphoria characterized by loquaciousness, increased sociability, and increased sensitivity to sounds. Kava is an important part of the Pacific Island societies as manifest by the use of kava in social processes, ceremonies, ritual practices, and the invocation of the supernatural.[5]

Current

Although the effect is small, several studies suggest that kava extract is an effective treatment for anxiety for 1–4 weeks.[6] A meta-analysis of seven double-blind, random clinical trials (380 patients) on kava extract suggested a significant reduction in total scores on the Hamilton Anxiety Scale in patients receiving kava extract, when compared with placebo (mean difference 3.9, 95% CI: 0.1–7.7, $P = 0.05$).[7] Limitations of these studies included the small size of the effect and the short duration of use. An Internet-based, double-blind, placebo-controlled study of 391 subjects did not detect a statistically significant difference in scores on the State-Trait Anxiety Inventory State subtest (anxiety) or the Insomnia Severity Index (insomnia), when comparing kava treatment and placebo groups.[8] The kava treatment group received 100 mg total kavalactones 3 times daily in kava extract for 28 days. Kava is present in some chocolates and beverages as a flavoring agent, but the kavalactone content in these products is low per serving (<10–12 mg) in most of these products compared with dietary supplements.[9]

Regulatory Status

The US Food and Drug Administration (FDA) issued a warning to consumers and physicians in 2002 regarding the hepatotoxicity of kava extracts, but this product is still available in the United States. However, Germany, the United Kingdom, France, Switzerland, and Australia banned the use of herbal products containing kava extracts during the early 2000s. These bans are being reevaluated in several countries (e.g., Germany).

PRINCIPAL INGREDIENTS

Chemical Composition

Commercial kava rhizomes typically contain about 3.5–8% kavalactones (kavapyrones) calculated as kavain (kawain), while kava extracts contain approximately 30–70% kavalactones. The actual content of kavalactones in kava rhizomes varies with the plant, cultivars, cultivation techniques, season, weather, and plant part sampled.[1] Kava lactone content decreases in higher plant parts being highest in the roots and smallest in the leaves. The major kavalactones in the leaves are dihydrokavain and dihydromethysticin, whereas kavain and methysticin are the major kavalactones in the roots and rhizomes. Although both aqueous and acetone/alcohol extracts contain similar kavalactones, the efficiency of the aqueous extracts using traditional methods is about 5–10% of direct extraction by organic solvents (acetone, ethanol, methanol).[10] Furthermore, the aqueous kava root extract contains the lower proportions of kavalactones (e.g., yangonin) compared with acetone/alcohol extracts because of the low water solubility of the kavalactones.[11] The latter extracts contain relatively small amounts of highly polar constituents present in the aqueous extracts. There are at least 18 kavalactones and three chalcones in alcohol/acetone extracts of kava rhizomes.[12] Six kavalactones account for approximately 96% of the total kavalactones in extracts of the kava plant. These kavalactones contain a 4-methoxy-2-pyrone ring system. Figure 76.1 displays the chemical structure of these six kavalactones. Water extraction methods (e.g., teas from kava) produce lower concentrations of kavalactones and higher variation in individual kavalactone content, when compared with methanol extracts of kava rhizomes.[13] Ethanol extracts of kava rhizomes also contain minor amounts (i.e., about 1% by weight) of the chalcones, flavokavins A–C.[14]

Physiochemical Properties

The water solubility of kavalactones is low. Animal studies indicate that kavalactones increase the number of $GABA_A$ receptor binding sites in the brains of rats, particularly in the hippocampus and the amygdala.[15] These findings suggest that $GABA_A$ receptor binding is a potential mechanism for the sedative effects of kava

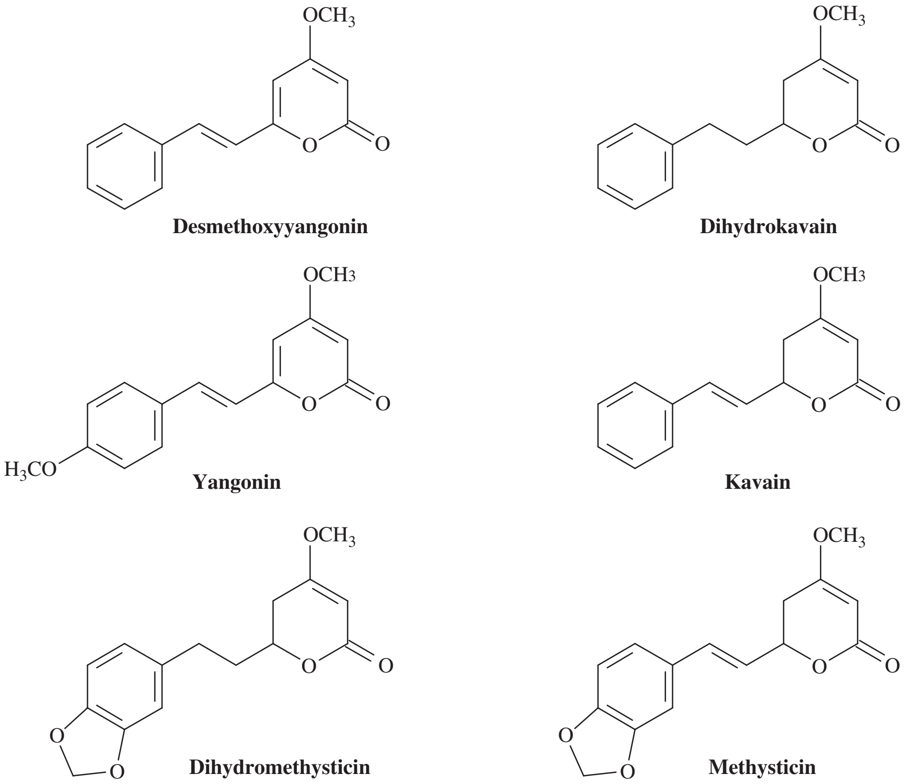

FIGURE 76.1. Chemical structures of the six common kavalactones in kava root.

extract. However, other rodent studies indicate that the binding of kavalactones to the $GABA_A$ receptor is weak; therefore, the mechanism of action of kava probably involves other paths.[16]

Mechanism of Toxicity

The exact mechanism of kava toxicity is unclear. Animal studies suggest that the anxiolytic action of kavalactones and dihydrokavain may result from $GABA_A$ receptor binding.[17] These studies also suggest that kavalactones directly alter neuronal excitability through voltage-dependent ion channels (e.g., sodium), resulting in a reduction of muscle tension.[18] The cause of the hepatotoxicity associated primarily with commercial kava extracts is unknown. Potential mechanisms of toxicity include immune-mediated idiosyncratic reaction, reduction of liver glutathione content, and drug interactions mediated by inhibition of cytochrome P450 enzymes.[19] Most case reports of hepatotoxicity involve the ingestion of multiple drugs rather than kava alone.

DOSE RESPONSE

Medicinal Use

Although kava extracts typically are standardized to 30% kavalactones, there is substantial variation between herbal preparations containing kava root extract. Many commercial herbal brands of kava use WS1490 as the ingredient of kava. The typical daily dose of kavalactones is up to about 250 mg. Doses up to 800 mg daily were tolerated over a short period without serious adverse effects.[20]

Toxicity

The mean weekly consumption of 11 very heavy users of kava beverages in Australian Aboriginal communities was about 440 g.[21] Observational studies indicate that the ingestion of large doses of aqueous kava extract (200 g powder over 14 hours) causes cerebellar dysfunction with significant reduction in cognitive abilities.[22] The rare association of kava use with hepatotoxicity suggests an idiopathic reaction that is not necessarily dose-related. However, most of the case reports of kava-associated hepatotoxicity occur in adults 20–60 years of age taking daily doses of 120–240 mg kavalactones from acetone or alcohol extracts over 4–16 weeks.[23] Liver failure requiring transplantation occurred in a 14-year old girl after the consumption of kava extract for 3 months,[24] and in another 14-year-old girl after the ingestion of an herbal preparation containing 200 mg commercial kava extract for 4 months.[25] Hepatotoxicity has been associated with the chronic consumption of kava beverages very rarely.[26]

TOXICOKINETICS

Absorption

In rodent studies, the gastrointestinal tract absorbs the kava lactone, kawain (kavain), quite well including rapid uptake of kawain and dihydrokawain by the brain.[27,28] Compared with the administration of kawain alone, the coadministration of kava extract increases the absorption of kawain two- to three-fold. In a human study (n = unreported), a single oral dose of 800 mg kavain produced peak serum free kavain concentration of 40 ng/mL within 30–60 minutes after ingestion.[29]

Biotransformation

In rats, the 5,6-dihydro-α-pyrones (dihydrokawain, kawain, methysticin) undergo variable amounts of hydroxylation, scission of the 5,6-dihydro-α-pyrone ring, and demethylenation, whereas biotransformation of the α-pyrones, 7,8-dihyroyangonin and yangonin, results from *o*-demethylation.[30] In a study of volunteers ingesting kava prepared by traditional aqueous methods, the urine contained all six major and some minor kavalactones.[31] Metabolites typically resulted from reduction of the 3,4-double bond and/or demethylation of the 4-methoxy group of the α-pyrone ring system. In contrast to rats, there were no dihydroxylated metabolites of the kavalactones in human urine as measured by methane chemical ionization gas chromatography/mass spectrometry. The main human metabolites of kavain are *p*-hydroxykavain, *p*-hydroxy-5,6-dehydrokavain and *p*-hydroxy-7,8-dihydrokavain.[29]

Elimination

Human studies suggest that the kidney excretes little unchanged kavain in the urine. *p*-Hydroxykavain is the main metabolite of kavain that is present in urine in both the free and conjugated (glucuronide, sulfate) forms.[29] 5,6-Dehydrokavain, *p*-hydroxy-5,6-dehydrokavain, and *o*-desmethyl-hydroxy-5,6-dehydrokavain are minor urinary metabolites.

Drug Interactions

In vitro studies indicate that the administration of kava extract inhibits CYP2C9, CYP2C19, CYP2D6, and CYP3A4 activity as well as the efflux transporter, P-glycoprotein, primarily as the result of the effects of kavalactones.[27,32] However, the results between *in vitro* and *in vivo* studies are somewhat inconsistent. Furthermore, the interaction varies between individual kavalactones with dihydromethysticin, methysticin, and desmethoxyyangonin demonstrating the greatest effect. Kawain and dihydrokawain had little effect on these CYP isoenzyme activities at concentrations up to 10 μM. IC_{50} is the concentration required to inhibit metabolism of surrogate substrates by 50%, and an IC_{50} <10 μM indicates potent inhibition of the particular CYP P450 isoenzyme. For *in vitro* studies the most potent kava lactone causing inhibition of CYP P450 isoenzymes was as follows: CYP1A2, desmethoxyyangonin (IC_{50} = 1.7 μM); CYP2C19, dihydromethysticin (IC_{50} = 0.43 μM); and CYP3A4, methysticin (IC_{50} = 1.49 μM).[33] In general, *in vitro* studies suggest that kavalactones do not affect the activities of CYP2E1, CYP2C8, or CYP2A6. However, an *in vivo* study of 12 healthy volunteers using single-time-point phenotypic metabolic ratios suggested that 28-day supplementation with kava root extract (1 g twice daily with no standardization claim) inhibited CYP2E1 activity approximately 40% when comparing ratios before and after supplementation.[34] This study did not detect changes in the activities of CYP1A2, CYP3A4, or CYP2D6. There are few data on the clinical significance of these potential drug interactions at usual doses of kava extracts. The action of kava may potentiate the effect of sedative-hypnotic drugs, alcohol, and barbiturates,[35] but there are no data to determine the clinical effect of standard herbal dose of kava with these drugs.

CLINICAL RESPONSE

Adverse Reactions

Adverse reactions associated with the use of commercial kava extracts include headache, malaise, rash, and stomach discomfort.[2] Case reports associate several dermatologic reactions with the use of kava extract including photosensitivity reactions, flushing, and urticaria. A 70-year-old man developed pruritic, erythematous papules and plaques on the face and trunk after sun exposure following the use of kava extracts for 3 weeks.[36] Biopsies of these plaques demonstrated lymphocytic infiltration and destruction of the associated sebaceous glands. Other reactions include delayed hypersensitivity reactions[37] and acute eczema.[38] Clinical features of acute kava intoxication include ataxia, euphoria, muscle weakness, hypoesthesias of the skin and mouth, sedation, and tremors. Although case reports associate the use of kava with sudden death in the Aboriginal community, a cross-sectional study did not demonstrate an increased risk of cardiovascular events when comparing kava and non-kava users in this population.[39] Some heavy kava drinkers develop a peculiar, dry, scaly skin eruption, which is reversible after cessation of kava use. This ichthyosiform eruption is called kava dermopathy.[40] In a non-

random study of heavy kava drinkers, about 15% had the clinical features of kava dermopathy.[41]

Acute Effects

The ingestion of large doses of kava powder produces a state of intoxication in kava drinkers, characterized by ataxia, tremors, sedation, and blepharospasm.[22] Neuropsychological testing during this state of intoxication indicates that there is a reduction in coordination and visual attention, but performance of complex cognitive functions remains normal. A 37-year-old man developed ataxia, diaphoresis, mydriasis, severe vertigo, generalized muscle weakness, and vomiting after ingestion of a strong tea made from kava.[42] He recovered without sequelae within 4 hours after ingestion, and his serum hepatic aminotransferases remained normal.

Chronic Effects

Case reports associate the consumption of commercial kava caplets with hepatotoxicity. These reports include a few cases of acute fulminant hepatitis with extensive centrilobular necrosis and hepatic failure requiring liver transplant.[24,43] The development of hepatotoxicity has not been reported in clinical trials or following chronic use of the traditional infusion of kava roots. In a study of over 7,000 patients administered kava extract equivalent to 105–240 mg kavalactones daily over 5–7 weeks, there were no cases of hepatotoxicity.[44]

DIAGNOSTIC TESTING

Analytical Methods

Thin-layer chromatographic methods with UV spectroscopy are available for the determination of kavalactones, but these methods lack precision with recoveries in the range of 80–95%.[45] Methods for the quantitation of kavalactones in kava extracts include gas chromatography (GC) and high performance liquid chromatography (HPLC), but each method has some limitations.[46] GC methods do not usually separate methysticin and yangonin, and the high injection port temperatures cause decomposition of methysticin. Normal-phase HPLC allows more rapid and better separation of constituents compared with reverse-phase HPLC, but the latter method is more sensitive. Limits of detection for kavalactones with ultrasonic extraction and isocratic reversed-phase liquid chromatography range from about 0.1–0.25 μg/g.[13] HPLC detection methods for kavalactones assays include UV (240 nm and 254 nm) with secondary detection by mass spectrometry or fluorescence spectroscopy. The UV detection of yangonin occurs at 355–360 nm. Chiral active HPLC columns can separate enantiomers of kavalactones.[47] Reliable methods for the rapid detection of major kavalactones include near-infrared reflectance spectroscopy with partial least-squares regression.[48]

Abnormalities

Rarely, mild, subclinical elevation of serum hepatic aminotransferases occurs in some clinical studies of commercial kava extracts.[2] Elevated serum gamma glutamyl transferase, serum alkaline phosphatase, and mild elevations of serum hepatic aminotransferases occur in chronic consumers of aqueous kava drinks, in part as a result of the induction of cytochrome P450 isoenzymes.[26,49] These abnormalities resolve after 1–2 months of abstinence, and clinically significant liver damage does not usually occur.[50] Very rarely, case reports have associated the development of significant hyperbilirubinemia and markedly elevated serum hepatic aminotransferases with chronic use of aqueous kava extracts by kava drinkers.[26]

Neuropsychological testing of persons receiving kava suggest that consumption of usual doses (e.g., 1 g/kg body weight) of kava powder does not produce significant impairment on test scores on short-term memory, reaction times (simple, choice), or attention (visual tracking, divided attention).[51] However, the use of kava with ethanol does modestly increase the deficits associated with blood ethanol concentrations near 100 mg/dL, particularly in divided attention tasks.[52] These effects are not consistent among test subjects.

TREATMENT

The treatment of adverse reactions associated with the use of kava is supportive.

Chapter 77

LAVENDER
(*Lavandula* Species)

HISTORY

In ancient Greece and Rome, lavender was an antiseptic and a fragrance for baths and cleansing agents. The ancient Egyptians used linen soaked in asphalt and oil of lavender to wrap mummies before drying the casts in the sun.[1]

BOTANICAL DESCRIPTION

For cosmetic and medicinal purposes, the most common variety is *L. angustifolia*. Other species of lavender include *Lavandula burmanni* Benth., *L. dentata* L., *L. dhofarensis* A.G. Miller, *L. lanata* Boiss., *L. latifolia* Medikus (broadleafed lavender), *Lavandula X intermedia* Emeric ex Lois. (lavandin), and *L. stoechas* L. (French lavender). Lavandin is a sterile hybrid of English lavender (*L. angustifolia*) and broadleafed lavender (*L. latifolia*). Currently, the two most common cultivars in the French lavender industry are Grosso and Super.

Common Name: English Lavender

Scientific Name: *Lavandula angustifolia* P. Miller (*L. officinalis, L. vera*)

Botanical Family: Lamiaceae (menthes, mints)

Physical Description: English lavender is an evergreen plant with a round, compact shape and opposite leaves that reach 2 in. (5 cm) in length. Small, fragrant, purple flowers appear in summer as interrupted spikes.

Distribution and Ecology: Although lavender (*Lavandula* spp.) is a native plant of the Mediterranean region, the Arabian Peninsula, Africa, and Russia, this plant is cultivated throughout the warm areas of the northern hemisphere.

EXPOSURE

Sources

Typically, lavender oil is a steam distillation product of the leaves and flowers of lavender species (*L. angustifolia, L. latifolia, L. stoechas, L. x intermedia*). For medicinal purposes, the flower is the most commonly used part of the lavender plant because the essential oil from this part of the plant is sweeter and more aromatic than the oil from other plant parts. Perfumes and cosmetic products with lavender usually contain essential oils of *Lavender* species (e.g., *L. angustifolia*) with relatively low camphor and high linalyl acetate content, whereas insect repellants with lavender typically contain essential oils from *Lavender* species (e.g., *L. stoechas*) with relative high camphor content. The constituents in Lavender products are not standardized in the United States.

Medicinal Uses

Traditional

Lavender has a long history of use as a fragrance and medicinal herb. Linen bags containing lavender were placed in pillows for soporific effects. Traditionally, this herb has been used as an expectorant, an antidepressant, carminative (smooth muscle relaxant), anti-

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

spasmodic, sedative, antimicrobial agent, and healing agent for burns, insect bites, and other wounds.

Current

The essential oils of lavender are common fragrances in a variety of products including soaps, candles, perfumes, shampoos, massage oils, colognes, and lotions. In food manufacturing, these essential oils are flavoring agents in ice cream, candy, beverages, chewing gum, and baked goods. Medicinal applications of lavender oil include use as anxiolytic agent (aromatherapy),[2] soporific agent (aromatherapy),[3,4] oral antispasmodic, topical antibiotic,[5] soothing agent for perineal discomfort after childbirth, adjunctive therapy for mild depression,[6] treatment for alopecia,[7] and chemotherapeutic agent.[8] There are few well-controlled clinical trials supporting the use of lavender for these indications. The weight of the evidence suggests a small positive effect of lavender aromatherapy for relaxation,[9] but the studies are not well designed and the strength of the evidence is weak.[1] A small, preliminary (phase I) trial suggested that a constituent of lavender (perillyl alcohol) is a safe chemotherapeutic drug in doses up to 1200 mg/m^2 4 times daily, but the efficacy of this compound as a chemotherapeutic agent remains unproven.[10]

Regulatory Status

In the United States, lavender is regulated as a dietary supplement with GRAS (generally recognized as safe) status, when used in recommended amounts. Linalool, a constituent in lavender, is approved as a food additive (GRAS). This compound is used in fragrances, soaps, perfumes, beverages, ice cream, candy, gelatins, and chewing gum.

PRINCIPAL INGREDIENTS

Chemical Composition

Lavender contains over 100 compounds, including linalool, linalyl acetate, camphor limonene, tannins, triterpenes, cyclic monoterpenes (cineole, perillyl alcohol), hydroxycoumarins, and flavonoids. The main components of lavender oil are linalool (CAS RN: 78-70-6, 3,7-dimethyl-1,6-octadien-3-ol), linalyl acetate, 1,8-cineole (eucalyptol), β-ocimene, terpinen-4-ol, and camphor.[11] Figure 77.1 displays the chemical structure of linalyl acetate (CAS RN: 115-95-7, $C_{12}H_{20}O_2$). In a study of nine Australian samples of lavender essential oil derived from steam distillation, the approximate concentrations of the main components were as follows: linalool (23–57%), linalyl acetate (4–35%), 1,8-cineole (0.1–20%), β-ocimene (27%), terpinen-4-ol (0.1–3%), and camphor (0.1–7%).[12] Major *volatile* components of the leaves and flowers of *Lavandula* species include camphor, 1,8-cineole, and compounds with a necrodane structure, as measured by direct thermal desorption/gas chromatography/mass spectrometry.[13]

The chemical composition and fragrance of lavender essential oil depends on the extraction process, the cultivars, cultural practices, growing conditions, harvesting season, and species. Table 77.1 demonstrates the variability in linalyl acetate, linalool, camphor, and cineol content in four *Lavandula* species. Analysis of a sample of *L. angustifolia* essential oil by solid-phase trapping solvent extraction demonstrated linalyl acetate concentrations of 35.44% compared with 4.04% for reduced pressure steam distillation and 2.63% for simultaneous steam distillation-solvent extraction.[14] For linalool, the yields for these three extraction methods were 18.7%, 36.8%, and 43.5%, respectively. Analysis of a Turkish sample of lavender essential oil (*L. stoechas*) demonstrated the following major constituents: pulegone

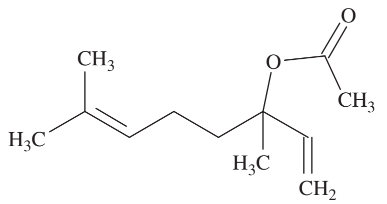

FIGURE 77.1. Chemical structure of linalyl acetate.

TABLE 77.1. Concentration of Major Components in Four Lavandula Species as Determined by Solid-Phase Trapping Solvent Extraction and Gas Chromatography/Mass Spectrometry

Chemical	*L. stoechas*[a]	*L. dentate*[a]	*L. angustifolia*[a]	*L. heterophylla*[a]
Linalyl acetate	0.5 ± 1.6	ND	35.4 ± 3.7	ND
Linalool	0.1 ± 1.8	4.4 ± 2.7	18.7 ± 2.1	1.4 ± 2.0
Camphor	53.4 ± 2.9	5.7 ± 4.1	0.5 ± 5.3	20.4 ± 9.5
Cineol	12.5 ± 1.9	47 ± 0.6	5.9 ± 6.3	50.1 ± 2.5

Source: From Ref 14.
[a]Normalized peak area (%) ± relative standard deviation (RSD) for three samples by solid-phase trapping solvent extraction for each *Lavandula* species; ND, not detected.

(40.4%), menthol (18.1%), and menthone (12.6%).[15] Typically, oils derived *L. lanata* and *L. stoechas* have higher camphor and lower terpene (e.g., β-phellandrene) and sesquiterpene (e.g., caryophyllene) concentrations than oils derived from *L. angustifolia* or *L. dentata*.[16] The concentrations of linalool and linalyl acetate are higher in the essential oil than in volatile fraction of lavender, whereas sesquiterpene compounds are higher in the volatile fraction than in the essential oils.

Physiochemical Properties

In studies on rats, constituents (e.g., cineole, perillyl alcohol) in lavender essential oil reduced cholesterol synthesis.[17] Linalool, linalyl acetate, and *L. angustifolia* essential oil (0.25% volume/volume) are cytotoxic to human skin cells (endothelial cells, fibroblasts) *in vitro*.[18] Table 77.2 lists some of the physical properties of linalyl acetate.

Mechanism of Toxicity

The active ingredient and mechanism of action of lavender oil is not well defined. Lavender essential oil has some spasmolytic activity on guinea pig ileum and rat uterus *in vitro* along with reduction in skeletal muscle tone in phrenic nerve-diaphragm preparations.[19] However, the clinical significance and mechanism of action remain poorly defined.

DOSE RESPONSE

Recommended adult doses of lavender include the following: tea, steeping 10 g (10 mL) of the leaves in 250 mL boiling water for 15 minutes; aromatherapy, inhalation of the vapors from 2–4 drops in 2–3 cups boiling water; message therapy, 1–4 drops per 15 mL of base oil; bath additive, 6 drops of lavender oil in bath.[1] In refractory cancer patients receiving perillyl alcohol as a chemotherapeutic agent, the maximum tolerated dose was 1200 mg/m^2 4 times daily.[8] Gastrointestinal toxicity (nausea, vomiting, satiety, eructation) was the dose-limiting factor.

TABLE 77.2. Physical Properties of Linalyl Acetate

Physical Property	Value
Melting Point	<25 °C/77 °F
Boiling Point	220 °C/428 °F
log P (Octanol-Water)	3.93
Water Solubility	8.200 mg/L (25 °C/77 °F)
Henry's Law Constant	1.74E-03 atm-m^3/mole (25 °C/77 °F)
Atmospheric OH Rate Constant	1.16E-10 cm^3/molecule-second (25 °C/77 °F)

TOXICOKINETICS

Lavender contains a variety of compounds, and the active ingredients have not been identified. Animal studies suggest that linalool is rapidly absorbed through the gastrointestinal tract and undergoes excretion in the bile and in the urine after metabolism.[20] The absorption of perillyl alcohol is relatively rapid with peak plasma concentrations occurring within 2 hours following ingestion.[21] Metabolites of limonene and perillyl alcohol include perillic acid, *cis*-dihydroperillic acid, and *trans*-dihydroperillic acid. In clinical trials using doses of perillyl alcohol up to 1600 mg/m^2 4 times daily, the major metabolite was perillic acid and <1% of the dose of perillyl alcohol appeared in the urine unchanged.[8] Lavender contains a variety of coumarin compounds, and theoretically these compounds could increase the effect of anticoagulants, but the clinical significance of this potential interaction remains unclear. Theoretically, lavender oil or aromatherapy could increase drowsiness caused by some drugs (e.g., benzodiazepines, narcotics, ethanol), but the clinical significance of this potential interaction is also undetermined.

CLINICAL RESPONSE

Side effects of the use of lavender oil include headache, nausea, vomiting, anorexia, constipation, chills, drowsiness, and confusion. Occasional case reports indicate that sensitization to lavender can occur after the use of lavender as a soporific agent on pillows (acute contact dermatitis, eczema),[22] as a shampoo by hairdressers,[23] or as aromatherapy (allergic airborne contact dermatitis).[24] Clinical features of these allergic reactions include erythema, lichenification, eczema, vesiculation, and local irritation.[25,26] Case reports also associate the chronic use of lavender oil with photosensitization[27] and alteration of skin pigments.[28] In general, local allergic reactions to lavender oil is relatively rare. However, a Japanese review of the positivity rate of patch tests to lavender oil indicated that this rate increased as lavender aromatherapy became more popular.[29]

DIAGNOSTIC TESTING

Extraction techniques for the determination of constituents in lavender essential oil include hydrodistillation, supercritical-fluid extraction, headspace solid-phase microextraction, solid-phase trapping solvent extraction, reduced pressure steam distillation, and simultane-

ous steam distillation-solvent extraction. Solid-phase trapping solvent extraction is a superior extraction technique because of effectiveness of this technique for the determination of linalyl acetate, which is an important measure of the quality of lavender essential oil.[14] Quantitation of constituents of lavender oil typically involves gas chromatography/mass spectrometry (GC/MS).[13,14] The use of multidimensional GC allows the qualitative and quantitative determination of enantiomers of various constituents in lavender.[12]

TREATMENT

Treatment of adverse reactions to lavender oil is supportive.

Chapter 78

LICORICE
(*Glycyrrhiza* Species)

HISTORY

The root of *Glycyrrhiza glabra* has been used at least for three millennia.[1] The Tomb of King Tut contained substantial amounts of licorice root. In ancient Egypt, a sweet licorice drink (mai sus) was prepared as part of a ritual ceremony to honor the spirits of the pharaohs. The army of Alexander the Great used licorice root as means to quench thirst, and Hippocrates used this root to heal wounds and sore throats. Theophrastus, the successor of Aristotle in the Peripatetic school, promoted the use of licorice root during the 4th–3rd century BC for the treatment of nonproductive cough, asthma, and other respiratory diseases, as well as to quench thirst.[2] His medical writing had a substantial impact on the practice of Medieval medicine. In the *Naturalis Historia*, Pliny the Elder mentioned the use of licorice in reducing hunger and thirst as well as treating asthma and sterility in women.[3] Celsus used licorice root to treat renal calculi, whereas the Latin medical writer, Marcellus Empiricus (5th century AD, Roman Gaul) used this herb for a variety of stomach, pulmonary, intestinal, renal, and back ailments. The first Chinese dispensary, Shen Nong Ben Cao Jing, contained references to the herbal use of licorice. During the Middle Ages, licorice root was a treatment for hypotension. In 1946, the Dutch physician F. E. Revers used the crude extract of licorice for the treatment of stomach ulcers. At that time, he noted that some of the treated patients developed pedal edema and weight gain.[4]

BOTANICAL DESCRIPTION

There are approximately 30 species of the genus *Glycyrrhiza* with many of these species inhabiting China. The *Glycyrrhiza* species commonly used for herbal therapy include cultivated licorice (*Glycyrrhiza glabra* L.) and Chinese licorice (*Glycyrrhiza uralensis* Fisch.). *G. lepidota* Pursh is another North American licorice species, which inhabits the Great Plains and western United States.

Common Name: Common Licorice, Cultivated Licorice, Sweetwood, Sweet Root

Scientific Name: *Glycyrrhiza glabra* L. (*Liquiritae officinalis*)

Botanical Family: Fabaceae (pea)

Physical Description: This shrub grows to 4–5 ft (~1.0–1.5 m) in height with oval leaflets, white-purplish flowers in clusters, and flat pods. The main taproot is yellow, soft and fibrous.

Distribution and Ecology: *G. glabra* is native species of southwest Asia and the Mediterranean region. In Europe (Spain, Italy, France), this species has been cultivated since at least the 16th century.

Common Name: Chinese Licorice, Gan Cao

Scientific Name: *Glycyrrhiza uralensis* Fisch.

Botanical Family: Fabaceae (Pea)

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Physical Description: This plant forms large clumps up to 4 ft (~1 m) in height with clusters of small lilac flowers that produce reddish pods. The flowers appear June to August, and the seeds ripen from July to October.

Distribution and Ecology: *G. uralensis* is a native of central Asia, China, and Japan.

EXPOSURE

Sources

Radix Glycyrrhizae consists of the dried roots and rhizomes of varieties of *Glycyrrhiza glabra* L. (common licorice) or of *Glycyrrhiza uralensis* Fisch. (Chinese licorice). The dried roots of *Glycyrrhiza* species are collected in autumn, and the fluid and dry extracts are prepared from powdered and finely cut licorice roots. Licorice contains glycyrrhizic acid, which is a sweet tasting glycoside used as a food additive and an herbal medicine. Various types of consumer products containing licorice include some sweets, chewing gum, cigarettes, chewing tobacco, and some alcoholic beverages, but the majority of the licorice in consumer items now occurs in tobacco products.[5] The flavoring agent in most licorice candies currently is anise oil. The licorice used in the manufacture of confectionery products is a semisolid extract obtained by treating dried roots of *Glycyrrhiza glabra* with boiling water and drying the extract. Herbal sources of licorice include laxatives, licorice tea, and Chinese medicines.

Medicinal Uses

Traditional

Chinese licorice (*G. uralensis*) is one of the most common herbs in traditional Chinese medicine that is frequently administered with other herbs.[6] Uses of Chinese licorice include anti-inflammatory agent, expectorant, carminative, and the treatment of skin eruptions (atopic dermatitis, pruritus, cysts, eczema) and allergies.[7] Other uses include the treatment of ulcers in the gastrointestinal tract, abdominal pain, Addison's disease, and a variety of infections (pharyngitis, malaria, tuberculosis, abscesses). In Ayurvedic medicine, licorice was a remedy for constipation, stomach ulcers, arthritis, and ocular diseases.

Current

Intravenous glycyrrhizic acid is an experimental treatment for reducing serum hepatic aminotransferases and the risk of progression to hepatocellular carcinoma in patient with chronic hepatitis C.[8] Previously, licorice had undergone clinical trials as a treatment for stomach ulcers. However, there is no clear evidence that licorice promotes the healing of stomach ulcers. In a randomized, placebo-controlled clinical trial of 96 patients with gastric ulcers, there were no differences in the healing rates between the treatment group (deglycyrrhizinated licorice) and the placebo group over 4 weeks.[9]

Regulatory Status

In the United States, licorice is used as flavoring and sweetening agents in food products, and the use of licorice is controlled as a food supplement. The US Food and Drug Administration (FDA) approved the use of licorice as a food additive (GRAS, generally recognized as safe).[10] The German Commission E approved the use of licorice for the treatment of peptic ulcers in daily doses of 200–600 mg glycyrrhizic acid. Treatment is limited to 5 weeks, and the use of licorice by patients with cardiovascular or renal disease is discouraged unless closely supervised by a physician.

PRINCIPAL INGREDIENTS

Chemical Composition

Licorice root contains triterpenes (glycyrrhizic acid), flavonoids (glabridin, glabrene, hispaglabridin A and B), polyamines, coumarins, polysaccharides, volatile oils, bitter principles, sterol, phytoestrogens, and vitamins.[11] The typical concentration of glycyrrhizic acid (glycyrrhizin) in licorice root is about 2–5%, but the amount of this compound can range up to approximately 15% depending on the plant species, climate, season, and location. In 1-year-old roots, the glycyrrhizic acid content increased substantially from October to November, but there was little change in this compound during May to August in 3-year-old plants.[12] The concentration of glycyrrhizic acid in licorice root and licorice extract is typically about 40 times higher than the pharmacologically active metabolite, glycyrrhetinic acid.[13] Polyphenol compounds account for about 1–5% of the dried licorice root with the main phenolic compounds being liquiritin (liquiritoside) and liquiritigenin and their chalcone-type derivatives, isoliquiritin and isoliquiritigenin.[14] In a study of nine samples of Italian licorice (*Glycyrrhiza glabra*), the yield of glycyrrhizic acid in methanol extracts of licorice ranged from 0.425–2.08%, whereas the yield of isoliquiritigenin ranged from 0.138–0.316%.[15] The active toxicological ingredient in licorice is the procompound, glycyrrhizic acid, which undergoes hydrolysis to the pharmacologically active compound, glycyrrhetinic acid (glycyrrhetic acid). The concentration of glycyrrhi-

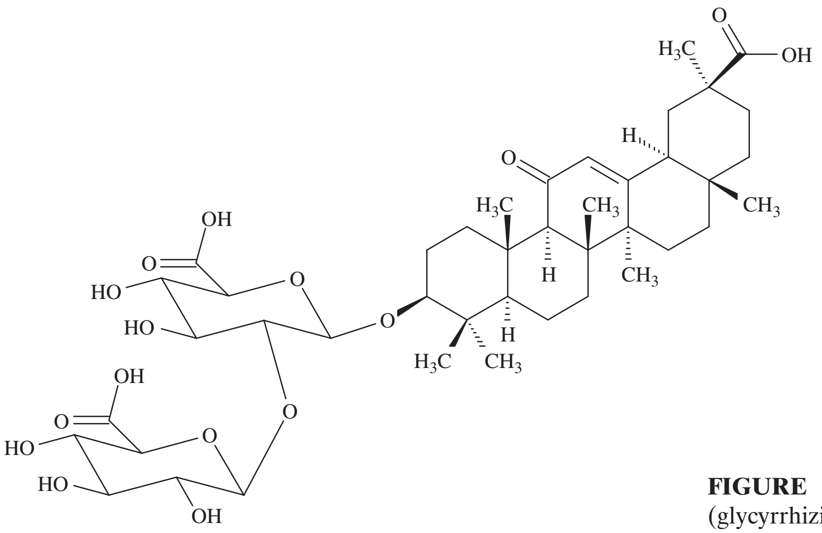

FIGURE 78.1. Chemical structure of glycyrrhizic acid (glycyrrhizin).

zic acid in the confectionary products ranged from 0.26 mg/g to 7.9 mg/g in a study of the glycyrrhizic acid (glycyrrhizin) content in 42 samples of English licorice-containing confectionery, health products, and raw materials, as measured by high performance liquid chromatography (HPLC).[16] The glycyrrhizic acid in health care products ranged from 0.3 mg/g to 47.1 mg/g in the throat pearls. The glycyrrhizic acid (glycyrrhizin) concentration in six samples of licorice root ranged from 22.2 mg/g to 32.3 mg/g. The highest glycyrrhizic acid concentrations occurred in samples of licorice extract powder (79 mg/g to 113 mg/g). Figure 78.1 displays the chemical structure of glycyrrhizic acid (CAS RN: 1405-86-3, $C_{42}H_{62}O_{16}$). Presystemic hydrolysis of glycyrrhizic acid by intestinal bacteria produces glycyrrhetinic acid, which has mineralocorticoid properties. Figure 78.2 displays the chemical structure of glycyrrhetinic acid (CAS RN: 471-53-4, $C_{30}H_{46}O_4$).

Physiochemical Properties

Glycyrrhizic acid accounts for the sweet taste of licorice, being about 50–170 times sweeter than sugar.[17] Table 78.1 lists some of the physical properties of glycyrrhizic acid.

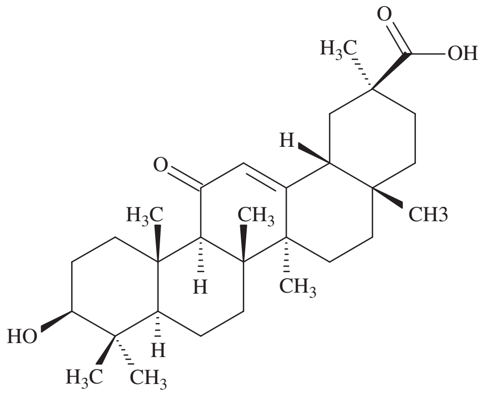

FIGURE 78.2. Chemical structure of glycyrrhetinic acid.

TABLE 78.1. Physical Properties of Glycyrrhizic Acid

Physical Property	Value
Melting Point	220 °C/428 °F
log P (Octanol-Water)	2.8
Water Solubility	0.053 mg/L (25 °C/77 °F)
Vapor Pressure	5.22E-34 mmHg (25 °C/77 °F)
Henry's Law Constant	1.23E-35 atm-m^3/mole (25 °C/77 °F)
Atmospheric OH Rate Constant	2.30E-10 cm^3/molecule-second (25 °C/77 °F)

Mechanism of Toxicity

The chronic ingestion of large doses of licorice produces hypertension, hypokalemia, and pseudohyperaldosteronism in some patients. Cortisol is the active mineralocorticoid that binds to mineralocorticoid receptors in the renal cortex and salivary glands. The two 11-β-hydroxysteroid dehydrogenase isozymes catalyze the interconversion of cortisol and cortisone. Type I 11-β-hydroxysteroid dehydrogenase converts inactive cortisone to the active cortisol in the liver and adipose tissues. The other isoenzyme, type II 11-β-hydroxysteroid dehydrogenase, rapidly transforms the active mineralocorticoid, cortisol, to the inactive metabolite, cortisone. This biotransformation allows aldosterone, which is not metabolized by this enzyme, to bind to the mineralocor-

ticoid receptors. The absorption of glycyrrhetinic acid after the ingestion of licorice inhibits the activity of type II 11-β-hydroxysteroid dehydrogenase. The aglycone, glycyrrhetinic acid, is approximately 200–1000 times a more potent inhibitor of 11-β-hydroxy-steroid dehydrogenase than the parent compound, glycyrrhizic acid.[18,19] This inhibition allows excess amounts of cortisol to bind to the renal mineralocorticoid receptors in the collecting ducts, resulting in excessive stimulation and a state of apparent mineralocorticoid excess. Although the secretion of aldosterone is suppressed, the excess mineralocorticoid activity causes a state of pseudohyperaldosteronism similar to primary hyperaldosteronism. Licorice ingestion increases the plasma atrial natriuretic peptide activity in healthy subjects, probably as a response to sodium retention and volume expansion. Following the ingestion of 100 g licorice daily for 8 weeks by 12 healthy volunteers, the mean plasma atrial natriuretic peptide concentration increased about 80% compared with baseline.[20]

Glycyrrhetinic acid also inhibits the activity of 17-hydroxysteroid dehydrogenase and of 17–20 lyase. The former catalyzes the conversion of androstenedione to testosterone, whereas the latter converts 17-hydroxyprogesterone into androstenedione. After one week of receiving 7 g licorice daily, the serum testosterone concentration in 17 healthy volunteers decreased about 25%.[21] However, the effect of licorice on 17-hydroxysteroid dehydrogenase and 17–20 lyase is relatively weak and transient, and the clinical significance of this reduction remains unclear because, even with the decrease, the serum testosterone concentrations generally remain within the normal range.[22] Glycyrrhetinic and glycyrrhizic acid do not bind to estrogen receptors,[23] but licorice ingestion can reduce plasma prolactin, and potentially cause gynecomastia.[24]

DOSE RESPONSE

Typical daily doses of licorice range from about 1–5 g (2–10 mg glycyrrhizinic acid based on 2% content). The acute ingestion of licorice containing an estimated 50 mg glycyrrhizinic acid/kg body weight by a 35-year-old man was associated with hypertension (260/130 mmHg) and vertigo that resolved within 24 hours.[25] Excessive intake of licorice can cause sodium retention and potassium loss, edema, increased blood pressure and depression of the renin–angiotensin–aldosterone system. There is substantial individual variation in the response to the ingestion of glycyrrhizic acid. The chronic daily dose of licorice in patients with signs of mineralocorticoid excess ranges from 1.5–250 g licorice.[26] The typical daily dose of licorice ingestion in patients with severe hypokalemia is 100–200 g over many months.[27] Predisposing factors associated with the development of licorice-induced hypokalemia at lower doses of chronic licorice ingestion include familial periodic paralysis, chronic diarrhea or laxative abuse, and chronic diuretic use without potassium replacement.[28]

The effect of licorice ingestion on blood pressure is dose-related. In a study of healthy volunteers, the ingestion of 50 g licorice (75 mg glycyrrhetinic acid) daily for 2 weeks increased the systolic blood pressure about 3 mmHg compared with baseline measurements.[29] For subjects receiving 200 g licorice (540 mg glycyrrhetinic acid) daily for 2 weeks, the systolic blood pressure increased about 14 mmHg at the end of 2 weeks of licorice use, when compared with baseline measurements. The maximum increase in systolic blood pressure occurred within about 2 weeks, and the systolic blood pressure in the low dose group (50 g licorice) was not statistically different from baseline when licorice use was continued for 2 additional weeks. These studies suggest that the effect of licorice is greater on hypertensive subjects than normotensive subjects. Daily doses of 100 g licorice (150 mg glycyrrhetinic acid) produced a mean increase of 15 mmHg in the systolic blood pressure of hypertensive subjects compared with a mean increase of approximately 3–4 mmHg in normotensive subjects.[30] This difference in mean systolic blood pressure occurred despite similar cortisol/cortisone ratios between the two groups.

TOXICOKINETICS

Absorption

Following ingestion of licorice, the glycyrrhizic acid in the licorice undergoes presystemic hydrolysis primarily in the large intestine to glycyrrhetinic acid as a result of specialized glycyrrhizin β-glucuronidase activity by anaerobic intestinal bacteria (*Eubacterium* spp., *Ruminococcus* spp., *Clostridium innocuum*).[31] Common β-glucuronidases (e.g., *Escherichia coli*) are unable to hydrolyze glycyrrhizic acid.[32] After oral therapeutic doses of glycyrrhizic acid ranging from 100–800 mg, this compound is not usually detectable in plasma.[33,34] Capacity-limited carriers transport glycyrrhetinic acid to the liver, where glycyrrhetinic acid undergoes conjugation to glucuronides and sulfates. The excretion of these conjugates in the bile and the subsequent hydrolysis of these conjugates by commensal bacteria results in the reabsorption and enterohepatic recirculation of glycyrrhetinic acid. Peak plasma concentrations of this compound occurs about 8–12 hours after the ingestion of glycyrrhizic acid.[35,36] In a study of six healthy adult volunteers ingesting approximately 200 mg glycyrrhizic acid in licorice candy, the mean peak plasma glycyr-

rhetic acid concentration of 570 ng/mL occurred about 10 hours after ingestion.[37] For healthy volunteers receiving single doses of 500 mg glycyrrhetinic acid orally, the mean peak plasma glycyrrhetinic acid concentration of 4.5 ± 0.6 µg/mL occurred at 3.1 ± 0.3 hours.[38] In comparison, the mean peak plasma concentration of glycyrrhetinic acid was 9.0 ± 2.6 µg/mL at 4.3 ± 0.5 hours following the ingestion of 1500 mg glycyrrhetinic acid.

Biotransformation

The liver metabolizes glycyrrhetinic acid primarily to glucuronide and sulfate conjugates before excretion of these compounds into the bile.

Elimination

The enterohepatic recirculation of glycyrrhetinic acid causes a substantial delay in the terminal plasma elimination half-life of this compound. The plasma elimination rate of glycyrrhetinic acid is dose-dependent, and the accumulation of glycyrrhetinic acid may occur following multiple doses as a result of enterohepatic recirculation of this compound.[39] In a study of human volunteers receiving single doses of 1,000 mg and 1,500 mg glycyrrhetinic acid, the mean terminal plasma elimination half-life of glycyrrhetinic acid was 11.5 ± 1.2 hr and 38.7 ± 10.5 hours, respectively.[38]

Drug Interactions

In vitro studies indicate that flavonoids (e.g., glabridin) in licorice extract inhibit CYP3A4, CYP2C9, and CYP2B6 activities.[40] In an *in vitro* study of inhibitory activity of an extract of *Glycyrrhiza uralensis* on human CYP3A4, licopyranocoumarin, liquiritin apioside, and liquiritin demonstrated the highest inhibitory activity.[41] Glycyrrhetinic acid inhibits 5α-, 5β-reductase and 11-β-dehydrogenase, and these actions potentially decrease the inactivation of steroids. However, there are few clinical data to determine the clinical significance of these potential interactions. The use of licorice reduces the effectiveness of spironolactone, and patients with congestive heart failure (e.g., digoxin) or hypertension (e.g., diuretics) should be monitored closely for hypokalemia during the use of licorice.

CLINICAL RESPONSE

There are few data on the acute ingestion of licorice. A 35-year-old man developed hypertension and vertigo after the ingestion of licorice drops that resolved within 24 hours without sequelae.[25] Chronic, high-dose licorice consumption can cause a syndrome similar to primary hyperaldosteronism, characterized by hypertension, hypokalemia, metabolic alkalosis, low plasma renin activity, reduced plasma aldosterone concentrations, and normal urinary cortisol excretion.[42,43] Clinical features of this apparent mineralocorticoid excess include headache, fatigue, generalized muscle weakness, myalgias, edema, and myoclonus.[44] In cases associated with severe hypokalemia, rhabdomyolysis, renal dysfunction, and muscle paralysis can develop.[45,46] Rare case reports suggest that a substantial elevation of blood pressure can occur in sensitive individuals after the chronic ingestion of licorice.[47] A 38-yearold woman developed blood pressure up to 250/110 mmHg after the chronic ingestion of large doses of licorice candies.[48] After cessation of the ingestion of licorice, she became normotensive without the use of antihypertensive agents. Several case reports associated the chronic use of relatively low doses of licorice with the development of hypertension, headache, vomiting, focal weakness, and alteration of consciousness.[49,50] However, the changes in mentation did not immediately resolve after the normalization of the blood pressure, and complete resolution of some neurological abnormalities (slight hemiparesis, paresthesias) required 3–5 months.

Neither licorice nor glycyrrhizic acid are listed by the International Agency for Research on Cancer (IARC) or the US National Toxicology Program as suspected carcinogens. A cross-sectional study of Finnish women suggests the possibility of an association between heavy licorice consumption (>500 mg/week) and preterm delivery (OR = 3.07, 95% CI: 1.17–8.05), when compared with mothers reporting low licorice consumption (<250 mg/week).[51] There was no statistically significant association between licorice consumption and maternal blood pressure or birth weight.[52] The possible role of licorice, if any, in preterm deliveries requires further clarification.

DIAGNOSTIC TESTING

Analytical Methods

Methods for the detection of glycyrrhetinic and glycyrrhizinic acids include high performance liquid chromatography (HPLC) with UV detection,[53] capillary zone electrophoresis with diode array detection,[54] micellar electrokinetic chromatography,[55] and liquid chromatography/tandem mass spectrometry (LC/MS/MS).[56] The lower limit for quantitation of glycyrrhizinic and glycyrrhetinic acids by LC/MS/MS with solid phase extraction was 10 ng/mL in 0.2 mL plasma samples compared with 10 ng/mL and 20 ng/mL, respectively, for HPLC with isocratic elution.[13] The limits of quantitation are higher for capillary zone electrophoresis (5 µg/mL and 2.5 µg/mL,

respectively),[54] whereas the limit of quantitation for glycyrrhetinic acid using solid-phase extraction with HPLC was 50 ng/ml.[57] The analytes in these samples were stable at room temperature for at least 24 hours.

Biomarkers

Measurements of plasma glycyrrhetinic acid concentrations confirm licorice ingestion. Case reports suggest that glycyrrhetinic acid persists in the urine at least one week after the cessation of chronic, high-dose licorice use.[58] Alternately, elevation of the ratio of cortisol to cortisone in saliva or urine also suggests the use of licorice and the subsequent inhibition of type II 11-β-hydroxysteroid dehydrogenase. In a placebo-controlled study of 20 normotensive subjects, the mean cortisol/cortisone ratios in arterial plasma at baseline levels 90–150 minutes after placebo was 4.9 ± 1.2 compared with 12.3 ± 3.4 during the same time period after the administration of 500 mg glycyrrhetinic acid.[59] This ratio is related to the dose of glycyrrhetinic acid ingested. In a study of healthy volunteers, the daily ingestion of 1,500 mg glycyrrhetinic acid produced consistent inhibition of type II 11-β-hydroxysteroid dehydrogenase, whereas the daily ingestion of 500 mg glycyrrhetinic acid caused transient inhibition.[38] Urine cortisol excretion and the cortisol/cortisone ratio gradually normalize over 3–4 weeks after cessation of licorice use. The chronic ingestion of high doses of licorice produces profound suppression of the renin–angiotensin–aldosterone system with low plasma renin activity and markedly reduced urinary excretion of aldosterone.[60] Plasma cortisol concentrations are usually normal or low normal. Suppression of renin and aldosterone concentrations in plasma begins with about one week after initiating licorice use, and complete resolution of the reduced renin and aldosterone concentrations may require 1–4 months.[61,62]

Abnormalities

Case reports indicate that profound hypokalemia and metabolic alkalosis can develop following the chronic ingestion of large doses of licorice. A 35-year-old man developed an acute myopathy with complete paralysis of the proximal muscles of his arms and shoulder girdles following the ingestion of 20–40 g licorice daily for 2 years.[63] His serum potassium concentration was 2.1 mEq/L, and the paralysis resolved within 3 day of the initiation of potassium replacement. In contrast to patients with licorice-induced excessive mineralocorticoid effect, patients with hypokalemic familial periodic paralysis do not usually have metabolic alkalosis. Elevation of serum creatine kinase can result from licorice-induced hypokalemia.[64]

TREATMENT

The most common serious complication of chronic licorice intoxication is hypokalemia. Rarer serious complications of chronic licorice ingestion include rhabdomyolysis, renal dysfunction, and hypertensive encephalopathy. Patients with chronic licorice intoxication should be evaluated with a complete blood count, serum electrolytes including serum magnesium and calcium, serum creatinine, and serum creatine kinase. Licorice-induced hypokalemia usually responds to spironolactone (25–100 mg PO daily) and cessation of licorice use. Potassium supplementation is necessary when the potassium concentration is critically low (<2.5–2.8 mEq/L). In cases of profound life-threatening hypokalemia (<2.0 mEq/L) associated with chronic licorice ingestion, patients have received 10–20 mEq KCL/h during initial potassium replacement.[65] Because of the long biological half-life of glycyrrhetinic acid, complete resolution of the electrolyte and acid–base disturbances associated with chronic licorice ingestion may require 2 weeks. Therefore, the serum potassium should be monitored during this period of time. Potential adjunctive therapy includes the use of dexamethasone to reduce the cortisol-induced stimulation of the mineralocorticoid receptors by suppressing endogenous cortisol production. However, there are few human data on the use of dexamethasone during treatment of chronic licorice intoxication.

Chapter 79

MA HUANG
(*Ephedra* Alkaloids)

HISTORY

Ma huang has a long history of medicinal use in China dating back over 5,000 years. The use of ephedra juice as a drink of longevity was an ancient Indian custom mentioned in the sacred Sanskrit Vedas, Rigveda.[1] The Japanese chemist, Nagai, isolated ephedrine in 1887. A series of articles in the early 1930s popularized the use of ephedra alkaloids (ephedrine) for the treatment of asthma.[2] In 2004, the US Food and Drug Administration (FDA) issued a ban on the use of ma huang in herbal preparations.

BOTANICAL DESCRIPTION

The genus *Ephedra* contains over 50 species, but most of these species are not used for medicinal purposes because of the low concentration of ephedra alkaloids in their stems and leaves. The most commonly used *Ephedra* species is the Chinese species, *E. sinica* Stapf. Other less common medicinal herbal species include *E. equisetina* Bunge, *E. gerardiana* Wallich ex Stapf, and *E. intermedia* Schrenk. ex C.A. Mey. (zhong ma huang). Ephedra alkaloids are not usually detectable in *Ephedra* species (e.g., *E. nevadensis* S. Wats., Nevada Mormon tea) native to the New World.[3]

Common Name: Ma Huang, Chinese Ephedra, Herbal Ecstasy

Scientific Name: *Ephedra sinica* Stapf

Botanical Family: Ephedraceae

Physical Description: This small, almost leafless shrub has a thick woody base with many slender, jointed, yellow-green branches covered with tiny leaves. The average height of this plant is about 1 ft (~0.3 m), but some specimens may reach 4 ft (~1.2 m) in height. Flowers appear in the summer and produce fleshy, red, succulent, 2-seeded bracts.

Distribution and Ecology: This evergreen shrub is a native plant in central Asia, but this plant is cultivated throughout China, Japan, Southern Siberia, and India. These perennial shrubs grow primarily in arid regions.

EXPOSURE

Sources

The usual source of ma huang is the dried, green branches of Chinese ephedra (*Ephedra sinica*) because of the high ephedra alkaloid content of green branches compared with other plant parts. Most preparations containing ma huang also contain other herbal stimulants, such as caffeine in guarana (*Paullinia cupana* Kunth), kola nut [*Cola nitida* (Vent.) A. Chev.], or yerba mate (*Ilex paraguariensis* A. St. Hil.) and salicylates in white willow bark (*Salix alba* L.). Herba Ephedrae consists of the dried stem or aerial part of *Ephedra sinica* Stapf or other ephedrine-containing *Ephedra* species.

Medicinal Uses

TRADITIONAL

In traditional Chinese medicine, the main indication for *E. sinica* is the treatment of wheezing, cough, and

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

congestions associated with bronchitis and asthma. Typically, ma huang is used in a decoction of several herbs (e.g., licorice, ginger, cinnamon, apricot seed, honey) for these purposes.[4] Other traditional uses include the treatment of urticaria, enuresis, narcolepsy, myasthenia gravis, and chronic postural hypotension.

Current

Ma huang and ephedrine-containing products have recently been promoted as an appetite suppressant, as a stimulant, and as an aphrodisiac. Most herbal products contain ephedra alkaloids combined with other stimulants (e.g., caffeine). Other herbal uses of ma huang include the treatment of low blood pressure, arthralgia, edema, enuresis, narcolepsy, cold and flu symptoms, asthma, and upper respiratory infections. Ephedrine-containing herbal preparations promote modest, short-term weight loss (<1 kg/month), but there are few data to support the use of these preparations for long-term weight loss or for the enhancement of athletic performance.[5] Additionally, the use of these products with caffeine is associated with a moderate (2- to 4-fold) increased risk of adverse effects (psychiatric, gastrointestinal, autonomic, palpitations, transient elevated heart rate/blood pressure).[6]

Regulatory Status

The German Commission E approved the use of ephedra only for the treatment for respiratory tract illness and mild bronchospasm for adults and children over 6 years of age. Health Canada banned the use of all combination products containing ephedra alkaloids and caffeine in 2002, including herbal supplements. In 2004, the FDA prohibited the sale of dietary supplements contain *Ephedra* species or ephedra alkaloids. However, the implementation of this ban was overturned by one of the lower courts in the United States.[7] The use of ma huang and ephedra alkaloids is banned as a performance enhancement supplement by the International Olympic Committee, The National Collegiate Athletic Association, and the National Football League.[8]

PRINCIPAL INGREDIENTS

Chemical Composition

The yield of ephedra alkaloids form commercially cultivated *Ephedra* species varies with species and ranges from about 0.5% to 3.5% with ephedrine accounting for approximately 30–90% of these alkaloids.[9] Concentrated extracts of *E. sinica* can contain up to 4–8% ephedra alkaloids.[10] The roots, fruits, and basal woody stems of *Ephedra* species generally contain none to minimal amounts of ephedra alkaloids. Figure 79.1 displays the chemical structures of ephedra alkaloids. Ephedra alkaloids include primarily (–)-ephedrine and (+)-pseudoephedrine with minor amounts of (–)-*N*-methyl ephedrine, (–)-*N*-pseudomethylephedrine, (+)-norpseudoephedrine (cathine), and (–)-norephedrine.[11] The latter compound is structurally identical to phenylpropanolamine, which typically is sold as the racemic mixture (*d,l*) in pharmaceutical preparations. The *l*-(levorotatory, –) isomer is the natural form of ephedrine in *Ephedra* species, whereas synthetic ephedrine is usually a racemic mixture of both the *l*- (–) and *d*- (+) isomers.

The ephedra alkaloid content of commercial preparations of *Ephedra* herbs depends on a variety of factors including species, lot, plant part, harvesting techniques, and extraction methods. (–)-Ephedrine and (+)-pseudoephedrine account for the vast majority of the alkaloid content of ephedra-containing commercial products.[12] In a study of 20 *Ephedra*-containing dietary supplements, the total ephedra alkaloid content ranged from 0–18.5 mg/dose with (–)-ephedrine and (+)-pseudoephedrine accounting for 1.1–15.3 mg/dose and 0.2–9.5 mg/dose, respectively.[13] A study of 25 lots of three ephedra-containing dietary supplements demonstrated an average amount of ephedrine was approximately 12–13 mg ± 1 mg per dose.[14] In general, the content of methyl ephedrine, norephedrine, and norpseudoephedrine is below 0.25–0.3 mg/dose in most dietary

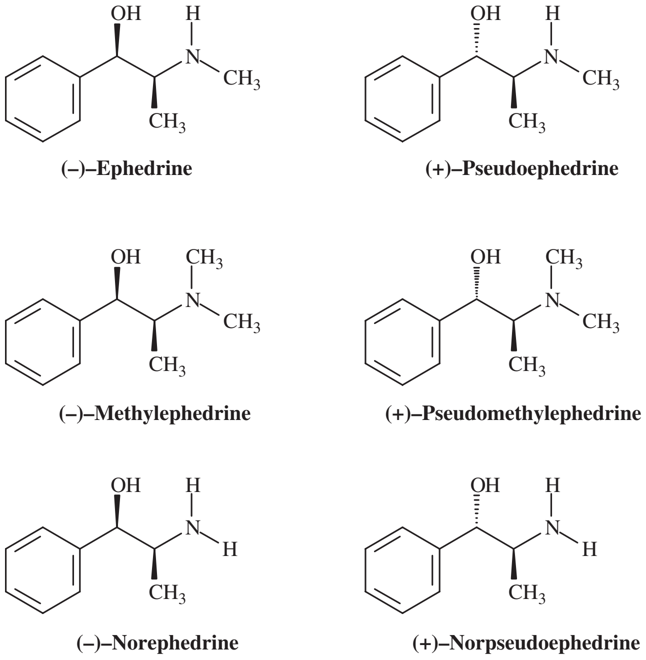

FIGURE 79.1. Chemical structures of ephedra alkaloids.

supplements containing ma huang as measured by high performance liquid chromatography (HPLC).[15] Occasionally, the amount of methyl ephedrine is higher (e.g., 3 mg).

Physiochemical Properties

The cut branches of ma huang (*E. sinica*) are yellow with a pine-like odor and a sharp bitter taste. Ephedrine is highly lipophilic, and this compound easily crosses the blood–brain barrier.

Mechanism of Toxicity

Ephedra alkaloids, which are phenethylamine derivatives, are the active ingredients in ma huang. Standard pharmacology texts typically emphasize that ephedrine is both a direct acting adrenergic agonist by the activation of adrenergic receptors and an indirect agonist by the release of norepinephrine via carrier-mediated exchange mechanism.[16] However, human *in vivo* data indicate that urinary catecholamine concentrations are not increased following the administration of typical doses of ephedrine in dietary supplements,[17] and this observation suggests that the physiologic effects of ephedrine are mediated by a direct adrenergic response. The central nervous system and cardiopulmonary stimulation are probably mediated predominantly by direct β-adrenergic agonist action with a much smaller degree of concomitant α-adrenergic involvement. There is little evidence of ephedra alkaloids having a significant indirect agonist action through the augmentation of norepinephrine release from the presynaptic neurons.

In vitro studies on cloned human receptors indicate that ephedrine acts as a substrate of the norepinephrine transporter with lesser substrate activity at the dopamine transporter.[18] These studies also indicate that ephedrine has weak affinity for α_2-adrenergic and 5-hydroxytryptamine receptors with little β-adrenergic or α_1-adrenergic receptor agonist activity. The reasons for this apparent mechanistic conflict with the human *in vivo* data are not clear. The stimulant and euphoric effects of ephedrine are less intense than amphetamines, but ephedra alkaloids have some abuse potential.[19,20] Pseudoephedrine has less potent cardiovascular effects than ephedrine. The relatively low rate of serious adverse effects compared with the high rate of use of these herbs suggests these adverse events may have a pharmacogenetic or idiosyncratic etiology.

DOSE RESPONSE

The FDA recommends limiting ephedrine doses to 8 mg as a single dose, 24 mg as a daily dose, and 7 days as the limit for the duration of treatment. Daily ephedrine doses in clinical trials on weight loss and physical endurance ranged from 90–150 mg without major cardiovascular side effects,[21,22] while a daily dose of pseudoephedrine ranged up to 240 mg.[23] Most of the case reports of serious cardiovascular or cerebrovascular complication involve the use of ma huang or ephedrine-containing herbal preparations in excessive doses for prolonged periods,[24,25] or the manufacturer's recommended doses for more than 1 month.[26]

TOXICOKINETICS

The pharmacokinetics of ephedra alkaloids in ma huang is similar to pharmaceutical preparations of these alkaloids with the possible exception of time to peak serum ephedrine concentrations.[27]

Absorption

The absorption of ephedrine from the gastrointestinal tract is relatively complete. Some studies suggest that the absorption of ephedrine in ma huang is substantially slower than the absorption of pharmaceutical preparations of ephedrine. In a study of 12 healthy, normotensive volunteers, the mean time from ingestion to peak plasma ephedrine concentrations was 3.9 hours for the ma huang preparation compared with 1.69 hours for the pharmaceutical ephedrine tablet.[28] Other studies of ephedrine-containing dietary supplements indicate that the time to peak plasma ephedrine concentrations for ephedrine-containing dietary supplements and pharmaceutical preparations of ephedrine are similar (i.e., about 3 hours).[14]

Distribution

The volume of distribution of ephedrine is large and protein binding in the blood is low. In a study of ephedrine-containing dietary supplements, the steady-state volume of distribution for ephedrine was about 3 ± 1 L/kg.[14]

Biotransformation

Pharmacokinetic studies indicate that substantial variation in the metabolism of major ephedra alkaloids occurs between individuals. In a study of eight healthy volunteers, the coefficient of variation (i.e., standard deviation divided by the mean) was 65% for the plasma AUC ratio of norephedrine to ephedrine and was 55% for the plasma AUC ratio of nor-pseudoephedrine to pseudoephedrine.[27] About 8–20% of the absorbed dose of ephedrine undergoes *N*-demethylation to norephed-

rine, whereas oxidative deamination of ephedrine to 1-phenylpropan-1,3-diol followed by side-chain oxidation to benzoic acid and hippuric acid accounts for approximately 4–13% of the absorbed dose.[29] The amount of aromatic hydroxylation, *N*-demethylation and oxidative deamination of ephedrine is species-specific.[30]

Elimination

The elimination of ephedrine occurs primarily via renal excretion of the unchanged compound. The elimination half-life of ephedra alkaloids increases as the urinary pH increases because of the ionizable amino group on the molecule and a pK_a of 9.6. Alkalinization of the urine increases the renal elimination half-life and prolongs the duration of action of these alkaloids as a result of the enhancement of renal tubular absorption of ephedra alkaloids in alkaline urine.[31] The plasma elimination half-life of ephedrine in ma huang is approximately 5–6 hours under normal conditions and urinary pH (6–7).[14]

Drug Interactions

The drug interactions between ephedrine and other drugs are primarily pharmacodynamic rather than pharmacokinetic. In a randomized, double-blind, placebo-controlled crossover study, 16 healthy adults ingested 25 mg ephedrine, 200 mg caffeine, or both drugs.[17] Pharmacodynamic effects (increased heart rate, increased blood pressure) were observed, but there were no clinically significant pharmacokinetic interactions between these two drugs. Similarly, the administration of 300 mg moclobemide, a reversible MAO-A inhibitor, twice daily and ephedrine (50 mg twice at a 4-hour interval) potentiates the pharmacodynamic effect of ephedrine on systolic blood pressure, but there were no clinically significant pharmacokinetic interactions.[32]

CLINICAL RESPONSE

Ma huang contains ephedra alkaloids and the clinical features associated with the use of ma huang are similar to the effects of ephedrine. The use of ephedra alkaloids produces dose-dependent sympathomimetic effects including headache, nausea, heartburn, anorexia, dry mouth, diaphoresis, mydriasis, tachycardia, palpitations, hypertension, bronchodilation, restlessness, insomnia, anxiety, and agitation.[22] Adverse reactions to the use of ephedrine-containing herbs exceed the rate of most other herbal preparations.[33,34] The sources of most of the data on the clinical effects of ma huang and ephedra alkaloids are case reports rather than clinical trails or epidemiological studies. Case reports associate a number of cardiovascular side effects with the use of herbal preparations containing ma huang including hypertension, ventricular dysrhythmias,[35] myocardial ischemia, myocardial infarction with or without underlying coronary artery disease,[36] cardiomyopathy,[37] hypersensitivity myocarditis,[38] and sudden death.[39] Neurological complication reportedly associated with the use of ma huang and ephedra alkaloids include seizures, cerebral vascular ischemic stroke,[40] intracranial hemorrhage, and vasculitis.[41] In some cases, the abuse of large doses of illicit ephedrine was associated with fatal intracranial hemorrhage.[42] A case-control study of ephedra use within 3 days of developing a hemorrhagic stroke did not detect a statistically significant increase in the risk of hemorrhagic stroke with ephedra use, although the odds ratio was the highest (OR = 3.59; 95% CI: 0.70–18.35) for the high-dose group (>32 mg daily).[43] Rare case reports associate the use of high doses of ephedra containing dietary supplements during risperidone and bupropion therapy with the development of mild delirium, autonomic hyperactivity, diaphoresis, and hyperreflexia.[44]

Reported psychiatric complications of excessive ma huang use include psychosis and affective disturbances, manifest by labile mode, agitation, sleep deprivation, suicidal ideations, and the development of acute paranoid psychosis with delusions and hallucinations.[45–47] These patients usually have clear consciousness, and the clinical presentation is similar to the psychiatric disturbances associated with the abuse of ephedrine.[48,49] In many of these case reports, there were pre-existing psychiatric illnesses or family histories of psychiatric disorders (schizoaffective, bipolar).[50] Many of the case reports associating cardiovascular or neurological complications with ma huang use indicate possible causal effects rather than probable causal effects based the Naranjo Adverse Drug Reaction Probability Scale. Clinical trials on the use of ephedra alkaloids for weight loss and enhancement of athletic performance have not reported serious adverse cardiovascular events (i.e., stroke, myocardial infarction, malignant dysrhythmias).[6] However, these clinical trials are typically relatively short-term (<6 months) with relatively high attrition rates. Rare case reports associate the use of ma huang with the development of acute hepatitis.[51] The presence of antinuclear and antismooth muscle antibodies along with eosinophils on the liver biopsy suggests an immune-mediated reaction. The role of ephedra alkaloids or other constituents of ma huang in these case reports remain unclear.

DIAGNOSTIC TESTING

Analytical Methods

Methods for the determination of ephedra alkaloids include liquid chromatography,[11] gas chromatography,[52]

capillary electrophoresis,[53] HPLC,[54] liquid chromatography tandem mass spectrometry (LC/MS/MS),[55] and gas chromatography/mass spectrometry (GC/MS).[56] The limit of quantitation for ephedra alkaloids as analyzed by liquid chromatography/atmospheric pressure chemical ionization/tandem mass spectrometry is in the low nanogram-per-milliliter range.[57] Ephedra alkaloids in ma huang are a mixture of three diastereoisomeric pairs of ephedrine and pseudoephedrine along with their potential metabolites (norephedrine, norpseudoephedrine, methyl ephedrine, pseudomethylephedrine). Because these alkaloids have two chiral centers, each of the four diastereoisomers has a mirror image enantiomer for a total of eight isomers. Capillary electrophoresis with chiral discrimination allows for the separation and identification of ephedrine enantiomers, but LC/MS/MS does not separate these enantiomers.[58] The natural form of ephedrine in *Ephedra* species is the *l*-(levorotatory) isomer, whereas synthetic ephedrine is usually a racemic mixture of both the *l*- and *d*-isomers. Several analytical methods are available to identify and authenticate ma huang including HPLC chemical fingerprinting,[59] metabolic fingerprinting with ^{1}H-NMR spectroscopy,[60] chiral GC/MS with GC/matrix isolation/Fourier transform infrared spectroscopy,[61] and polymerase chain reaction analysis (PCR).[62] The molecular PCR method uses DNA as the template rather than ephedra alkaloids; therefore, chemical analyses (HPLC, GC/MS) are necessary to identify ephedra alkaloids. Alternatively, botanical identification of Chinese and North American species of *Ephedra* is possibly based on leaf and internode length using light microscopy.[63]

Biomarkers

Therapeutic

Preparations of ma huang contain several ephedra alkaloids, and the presence of only large amounts of ephedrine in an herbal preparation of ma huang without other ephedra alkaloids suggests adulteration with pharmaceutical ephedrine.[15,64] The ephedrine and methyl ephedrine in ma huang can produce positive results for amphetamines on urine drug screens using immunoassays, but these compounds can be separated from amphetamines using GC/MS.[65] The mean maximum serum ephedrine concentration in blood samples from 12 healthy volunteers receiving a single dose of ma huang was 81 ng/mL.[28] The mean dose of ephedrine in this study was 19.4 mg. In a study of volunteers receiving single doses of ephedrine-containing dietary supplements (i.e., about 24–27 mg ephedrine), the mean maximum serum ephedrine concentrations ranged from approximately 75–100 ng/mL.[14] After receiving 50 mg ephedrine orally, the mean maximum plasma concentration of ephedrine in blood samples from 16 volunteers was 138 ± 33 ng/mL (range: 80–207 ng/mL).[66]

Intoxication

A case report of a 22-year-old woman associated the ingestion of an herbal preparation containing 10 mg ephedrine and 100 mg caffeine with the development of vomiting, palpitations, tremulousness, and evidence of myocardial ischemia in her anterior leads.[67] The serum ephedrine concentration 8 hours after her last dose was 150 ng/mL. Methyl ephedrine is present in a variety of over-the-counter cough and cold preparations throughout the world, but this drug is not available in the United States.[68]

Postmortem

Ephedrine is a common constituent of postmortem samples from patients with chronic stimulant abuse, but there are few postmortem data on patients dying from ephedrine as the sole drug. In a case series of 127 decendents testing positive for ephedra alkaloids, the postmortem blood samples contained <0.49 mg/L in a majority of the cases.[69] There was no statistically significant difference in the postmortem ephedrine concentration in patients dying from traumatic (mean = 1.27 mg/L, range: 0.07–11.73 mg/L) or nontraumatic (mean = 1.61 mg/L, range: 0.02–12.35 mg/L) causes. Norephedrine (cathine) was detected in 33% of the samples tested with a mean concentration of 1.81 mg/L (range: 0.04–14.14 mg/L).

Abnormalities

Ephedra alkaloids in ma huang are stimulants with dose-dependent effects on the cardiovascular system (e.g., tachycardia, elevated blood pressure). The presence of electrolyte imbalance suggests a cause other than ma huang.

TREATMENT

The treatment of complications associated with the use of ephedrine-containing herbs is supportive. In general, decontamination measures are not recommended because of the rapid absorption of ephedrine. Rarely, cardiovascular or cerebrovascular complications develop during ephedrine intoxications. Agitation and seizures usually respond to diazepam or lorazepam. The decision to treat hypertension depends on clinical judgement regarding the severity of the hypertension, pre-existing cardiovascular disease, and the clinical effects observed.

There are few clinical data to guide the treatment of hypertension. Potentially useful agents include sodium nitroprusside and phentolamine. There are no definitive data on the use of beta-adrenergic blockers in the setting of an *Ephedra* overdose. Potentially, the use of nonselective beta-blockers can cause unopposed α_1-receptor stimulation on the vasculature and the blood pressure. Patients with potentially serious cardiovascular complication should be monitored for dysrhythmias. Laboratory testing includes complete blood count, serum electrolytes, serum glucose, serum creatinine, serum troponin, serum creatine phosphokinase, and electrocardiogram. There are no specific antidotes for the effects of ma huang. Methods to enhance the elimination of ephedrine are not usually efficacious including the use of dialysis, hemoperfusion, and acidification of the urine. Treatment of anxiety and psychotic manifestations of ephedrine toxicity includes the use of benzodiazepines and, for psychotic features unresponsive to benzodiazepines, antipsychotic drugs.

Chapter 80

MILK THISTLE
[*Silybum marianum* (L.) Gaertner]

HISTORY

For over 2,000 years, milk thistle has been a treatment for hepatobiliary disease. The Roman naturalist, Pliny the Elder (AD 23–79), described this plant as "excellent for carrying off the bile." During the 16th century, milk thistle was a treatment for liver diseases. The English herbalist/physician, Nicolas Culpepper (1616–1654) recommended milk thistle for jaundice, and the Swiss physician, Albrecht von Haller (1708–1777) used milk thistle as a treatment for liver diseases. European colonists introduced milk thistle into the United States and South America. Medical herbalists (eclectics) used milk thistle for liver congestion, menstrual disorders, renal dysfunction, and varicose veins.[1]

BOTANICAL DESCRIPTION

Common Name: Milk Thistle, Blessed Milk-Thistle, Blessed Milkthistle, Spotted Thistle, Variegated Thistle

Scientific Name: *Silybum marianum* (L.) Gaertner

Botanical Family: Asteraceae (sunflowers, tournesols)

Physical Description: This annual or biennial plant reaches 3–10 ft (~1–3 m) in height with large, alternating leaves that contain spines on the edges. The veins on the leaves extrude a white, milky sap when ruptured. Single, large purple flowers with sharp spines appear at the end of each stem from June to August.

Distribution and Ecology: Milk thistle is indigenous to southern Europe, southern Russia, North Africa, and Asia Minor. This plant has naturalized to dry, rocky soils in North and South America, Australia, China, and Central Europe.

EXPOSURE

Sources

The seeds and dried fruits from milk thistle (*Silybum marianum*) are the source of the silymarin complex of flavonolignans, which are used to standardize milk thistle extract to contain 70–80% silymarin flavonolignans. The seeds and dried fruits usually contain about 1.5–3% silymarin. The typical silymarin extraction process involves the defatting of the seeds in a Soxhlet extraction with petroleum ether for 4 hours followed by a second Soxhlet extraction with methanol for 5 hours.[2] The maximum yields (mg/g seed) of flavonolignans in several samples of seeds from milk thistle using ethanol were as follows: silibinin A, 4.0; silibinin B, 7.0; silicristin (silychristin), 4.0; taxifolin, 0.6; and silidianin, 0.4.[3] The active flavonolignans in silymarin are poorly water soluble. Consequently, the extract is administered as a capsule rather than a tea, which typically contains <10% silymarin.

Medicinal Uses

Traditional

Milk thistle has been a traditional treatment of liver disease and dyspepsia since ancient times, including the

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

treatment of gallstones and jaundice. Other traditional uses for milk thistle include amenorrhea, uterine hemorrhage, constipation, diabetes, hay fever, and varicose veins.

Current

Interpretation of the clinical trials measuring the efficacy of milk thistle extract in hepatobiliary disease is difficult because of a number of flaws in these trials including small sample size, variability in the severity and type of hepatic disease, heterogeneous doses, frequent lack of control groups, and poorly defined end points. Based on well-designed clinical trials, the use of milk thistle extracts probably does not alter the clinical course of patients with alcoholic cirrhosis or hepatitis B/C liver disease.[4] Some studies suggest, but do not prove, that milk thistle extract improves liver injury. Pooled data from case reports involving 452 patients with *Amanita phalloides* poisoning suggest a significant difference in mortality favoring the use of silibinin (mortality 9.8% vs. 18.3%, $P < 0.01$).[5] However, there are no randomized clinical trials to document the efficacy of silibinin for amanita poisoning. Silymarin is possibly efficacious as an adjuvant in the therapy of alcoholic liver disease, but the clinical data are inconsistent. A randomized trial of 200 alcoholics with cirrhosis did not demonstrate a statistically significant reduction in mortality between the silymarin and control groups during the 2.5-year observation period.[6] Additionally, a randomized-controlled clinical trial failed to detect a significant difference in serum hepatic aminotransferases between the silymarin and control groups.[7] Despite some positive results in patients with acute viral hepatitis, the value of silymarin in the treatment of these infections is unproven. A systematic review of 148 studies involving the treatment of liver disease with silymarin noted that only seven studies focused on the outcome of patients with hepatitis B, hepatitis C, or unspecified viral hepatitis.[8] These studies suggested the possibility of silymarin treatment reducing serum hepatic aminotransferases in these patients, but there was no evidence of improvement in viral load or liver histology.

Regulatory Status

The German Commission E approves the use of silymarin for the treatment of liver diseases, including hepatitis A, alcoholic cirrhosis, and chemically induced hepatitis.

PRINCIPAL INGREDIENTS

Chemical Composition

Silymarin is a mixture of flavonolignans present in milk thistle (*Silybum marianum*) seed and fruit extracts. The major constituents of the silymarin complex are the following four isomeric flavonolignans: silibinin (silybin, CAS RN: 22888-70-6), isosilibinin (isosilybin, CAS RN: 72581-71-6), silidianin (silydianin, CAS RN: 29782-68-1), and silicristin (silychristin, CAS RN: 33889-69-9) as demonstrated in Figure 80.1. There are at least two pairs of diastereoisomeric flavonolignans compounds (silibinin A and B, isosilibinin A and B).[9] These flavonolignans have phenylchromone skeletons (flavonoid moiety) with different oxidative links to coniferyl alcohols (lignan moiety).[10] Silibinin and isosilibinin occur as a pair of diastereomers, epimeric at C12 and C13. As measured by high performance liquid chromatography (HPLC) and capillary electrophoresis (CE), several samples of dried fruits from milk thistle contained about 2.5–3% weight/weight silymarin complex.[11] Silymarin accounts for about 40–80% of the bulk material for producing pharmaceutic preparations of the milk thistle, depending on the geographical source, season, and growing conditions.[12] Some, but not all, pharmaceutical preparations of milk thistle are standardized to 70% silymarin content. The principal flavonolignane in silymarin is silibinin, which comprises about 50–70% of the silymarin content. Minor flavonolignans in the silymarin complex include isosilicristin, silymonin, silandrin, 2,3-dehyrosilibinin, 2,3-dehydrosilicristin, and taxifolin.[13] The latter compound is a dihydroquercitin precursor to the flavonolignans. Remaining constituents of milk thistle extract are mostly polymeric and oxidized polyphenolic compounds that are not well delineated.[14]

Physiochemical Properties

Taxifolin (CAS RN: 480-18-2, $C_{15}H_{12}O_7$) and silicristin are more polar compounds than silibinin A and silibinin B, resulting in differences in the extraction rates for a given extraction process.[15] Degradation of flavonolignans (e.g., silibinin, silicristin) occurs at temperatures above 100 °C (212 °F).[16] Properties associated with the administration of silymarin include antioxidation, free radical scavenger, inhibition of lipid peroxidation, repletion of glutathione stores, and inhibition of phase I reactions.[17]

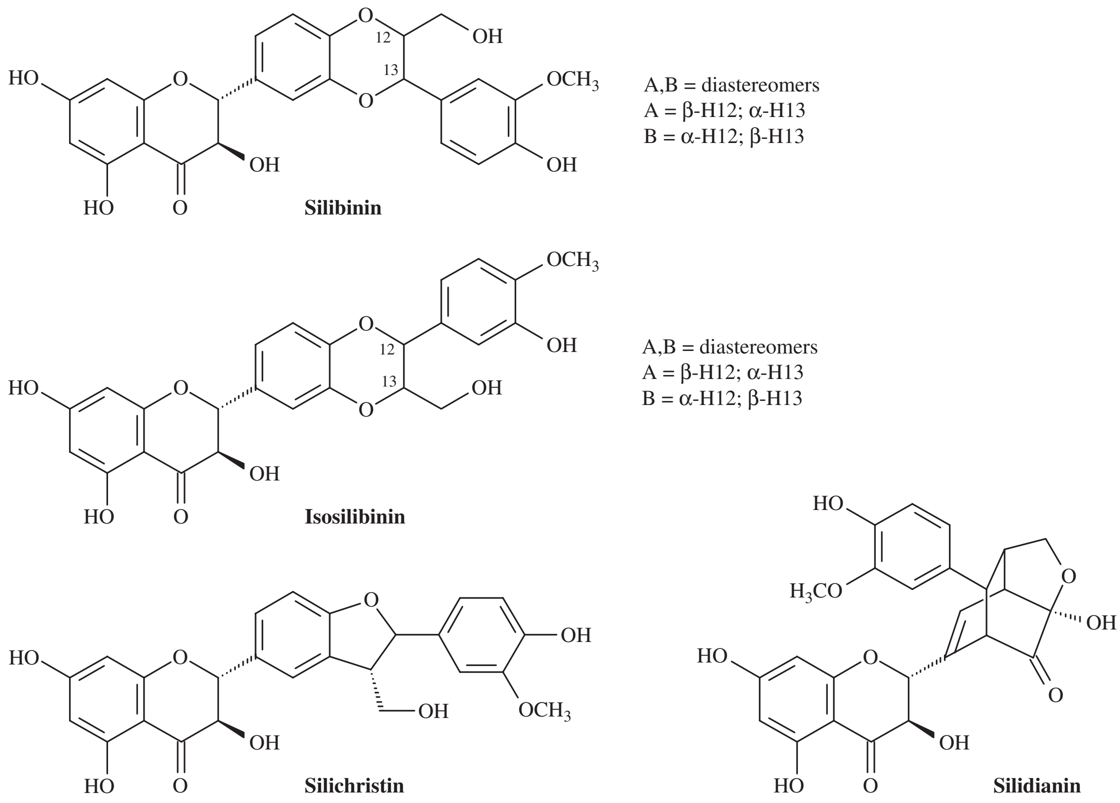

FIGURE 80.1. Chemical structures of major flavonolignans in milk thistle extract.

DOSE RESPONSE

The typical adult dose of the extract of milk thistle is 100–300 mg 3 times daily standardized to 70–80% silymarin.

TOXICOKINETICS

Kinetics

Absorption of silibinin from the gastrointestinal (GI) tract is relatively rapid with peak concentrations of free silibinin occurring about 1.5–2.5 hours after ingestion. The bioavailability of silibinin in milk thistle extract is relatively low (20–50%). The addition of phosphatidylcholine to silymarin improves the bioavailability of the flavonolignans.[18] Most (~90%) of the silibinin in plasma appears as conjugated silibinin as a result of the rapid conjugation of silibinin. The elimination half-life of total silibinin is relatively short. Following the administration of single doses ranging from 102–254 mg to six healthy volunteers, the elimination half-life of silibinin was approximately 6 hours[19] compared with about 4 hours for 12 healthy volunteers receiving a lipophilic silibinin-phosphatidylcholine complex.[20] The latter group received silipide® (IdB 1016, Inverni della Beffa Research and Development Laboratories, Milan, Italy) in a dose of 80 mg expressed as silibinin equivalents. Free silibinin is rapidly cleared from the plasma with a plasma elimination half-life of about 2 hours. The major metabolite of silibinin is a demethylated compound, while mono-hydroxy and di-hydroxy silibinin are minor metabolites.[21] The kidneys excrete <3–5% of the absorbed dose of silibinin as total silibinin (free + conjugated). Biliary excretion is a major route of silibinin elimination.[22]

Drug Interactions

In vitro studies suggest that silibinin inhibits both phase I and II reactions including CYP3A4, CYP2C9, and UGT1A1.[23] However, the clinical relevance of these effects is equivocal. A meta-analysis of three studies on the interaction of milk thistle extract on indinavir pharmacokinetics demonstrated a pooled mean difference of 1% in the $AUC_{0\text{-}8}$ (95% CI: –53–55%) of indinavir before and after the administration of milk thistle extract.[24] This difference was not statistically significant

(P = 0.97). An *in vivo* study of 12 healthy volunteers receiving 700 mg milk thistle extract daily for 28 days did not detect a statistically significant difference between the presupplementation and postsupplementation phenotypic ratios for CYP1A2, CYP2D6, CYP2E1, or CYP3A4 activity.[25] Other *in vivo* studies of volunteers receiving 900 mg standardized milk thistle extract daily for 14 days indicated that supplementation with this extract did not alter digoxin pharmacokinetics (P-glycoprotein transporter)[26] or midazolam (CYP3A4) kinetics.[27] These studies suggest that any potential CYP-mediated herb–drug interaction between milk thistle extract and drugs metabolized by these isoenzymes would be minimal.

CLINICAL RESPONSE

With the exception of anaphylaxis, the adverse reactions associated with the use of milk thistle extract are usually mild. These effects typically involve headache, GI disturbances (nausea, vomiting, diarrhea, epigastric pain), and allergic reaction (pruritus, urticaria, arthralgias).[28] A case report temporally associated the use of milk thistle capsules with intermittent episodes of nausea, vomiting, diarrhea, colicky abdominal pain, sweating, and "collapse."[29] These symptoms resolved after cessation and recurred after re-challenge with the milk thistle extract. There was no analysis of the capsules for contaminants; therefore, a causal link could not be established between silymarin from milk thistle extract and the observed clinical effects.

DIAGNOSTIC TESTING

Methods for the quantitation of flavonolignans in the silymarin complex include capillary zone electrophoresis[30] and high performance liquid chromatography with UV,[31] and liquid chromatography with electrochemical or mass spectrometric detection.[32] Stereoselective assays can quantitate free plasma (unconjugated) silibinin using column-switching HPLC with electrochemical detection and total plasma (free and conjugated) silibinin using reverse-phase HPLC with UV detection.[33] The limit of quantitation for these methods is approximately 0.25 ng/mL per diastereomer. The limits of detection and quantitation for flavonolignans by HPLC with photodiode array detector and electron spray ionization-mass spectrometry ranged from 0.5–2 ng/mL and 2.5–10 ng/mL, respectively.[34] The thermal stability of the silymarin complex is relatively low, and long-term studies indicate that the shelf-life of milk thistle tinctures (hydro-alcohol extracts) is about 3 months at 25 °C (77 °F).[35]

TREATMENT

Adverse reactions to the use of milk thistle extracts are usually mild and treatment is supportive. Gut decontamination is unnecessary. Rarely, allergic reactions including anaphylaxis may occur that requires standard care (epinephrine, antihistamines, intravenous fluids, vasopressors).

Chapter 81

PASSIONFLOWER
(*Passiflora incarnata* L.)

HISTORY

Archeological excavations in North America suggest that the passionflower was used by prehistoric cultures in Virginia.[1] The Spanish explorer, Monardus, discovered *Passiflora incarnata* during an expedition to Peru in 1569. He associated the beautiful flower with the passion of Christ.[2] This plant became a popular traditional remedy and homeopathic medicine for insomnia and anxiety. During the late 18th century, the *Materia Medica Americana* mentioned the use of *Passiflora incarnata* for the treatment of sleeping problems in infants and adult epilepsy.

BOTANICAL DESCRIPTION

The genus, *Passiflora*, contains approximately 500 species. *Passiflora incarnata* L. and *Passiflora edulis* Sims are nearly identical *Passiflora* species that require sophisticated analysis for separation including microscopy (vein-inlet number, vein-termination number, stomatal number, stomatal index), physicochemical properties (ash values, extractive values), and thin layer chromatography profile.[3] The latter species is primarily an edible tropical fruit that does not possess significant central nervous system (CNS) depressant activity.[4] Some immature *Passiflora* fruits (e.g., *Passiflora adenopoda* DC, *P. edulis*) are toxic as a result of the presence of the cyanogen, prunasin.[5–6] However, most of the hydrogen cyanide is lost during maturation and the crushing of the fruit during processing. Although *Passiflora alata* Dryander has a lower total flavonoid concentration compared with *P. incarnata, P. alata* is an official herb and a substitute for *P. incarnata* in the *Pharmacopoeia* of Brazil.[7] *P. incarnata* does not grow well in the Brazilian climate.

Common Name: Purple Passionflower, Maypops, Maracuja, Apricot Vine, Passion Vine, Fleur de la Passion, Passiflore, Corona de Cristo

Scientific Name: *Passiflora incarnata* L.

Botanical Family: Passifloraceae (passionflower)

Physical Description: This woody, climbing vine has broadly cordate-ovate, serrated, palmately three-lobed leaves and glabrous stems with thin, green to purple bark. The flowers are solitary with a calyx containing five white petals and a purplish fringe called a corona. The fruit is ovoid and yellow.

Distribution and Ecology: This plant is indigenous to warm temperate and tropical regions in the southeastern United States.

EXPOSURE

Sources

This herbal remedy is administered as an infusion or an extract, often in combination with other herbs (valerian root, hops, *Melissa officinalis* L.).

Medicinal Uses

Traditional

The dried aerial parts (leaves, flowers, fruit) from several *Passiflora* species are widely used in folk medicine as sedatives, anxiolytic agents, and antispasmodics.[8] Other traditional uses include the treatment of hysteria, neurasthenia, neuralgias, insomnia, epilepsy, dysmenorrhea, burns, hemorrhoids, diarrhea, cough, and asthma.[9]

Current

Preliminary clinical trials suggest that extract of passionflower is a possibly effective adjunctive agent for the treatment of opiate withdrawal and as a treatment for anxiety. However, there are too few randomized controlled clinical trials to determine the efficacy and safety of the use of passionflower for the treatment of anxiety.[10] A double-blind randomized controlled trial of 65 opiate addicts assigned to clonidine only and clonidine plus 60 drops passiflora extract daily detected no statistically significant difference between the two groups on the Short Opiate Withdrawal Scale.[11] There was a reduction in opiate withdrawal-associated psychological symptoms (nonstandardized observations by blinded physician) on the second day of treatment compared with baseline, and a higher psychological symptoms score than baseline (statistical significance not reported) for the clonidine only group on days 2,3,4,7, and 14 after withdrawal began. A pilot double-blind randomized controlled trial of 36 outpatients with generalized anxiety disorder assigned 18 patients to the oxazepam group (30 mg daily) and passiflora group (45 drops extract daily).[12] There was no statistically significant difference in the Hamilton Anxiety Rating Scale during the 28-day study. However, the reduction in these scores began earlier with the oxazepam group (day 4) compared with the passiflora group (day 7).

Regulatory Status

Passionflower extract is an approved dietary supplement and flavoring agent in the United States and Europe. The German Commission E approves the use of passionflower for nervous restlessness.

PRINCIPAL INGREDIENTS

Chemical Composition

Extracts of *Passiflora incarnata* contain flavonoids, β-carboline alkaloids, and terpene derivatives. The specific active ingredients are unknown. In rodent studies, both a lipophilic and hydrophilic fraction prolongs sleeping time and raises the nociceptive threshold in tail-flick and hot-plate tests.[13] Suspected bioactive compounds in passiflora extract include C-glycosyl flavonoid derivatives of apigenin and luteolin (vitexin, isovitexin, orientin, isoorientin, schaftoside). The most abundant flavonoids in passiflora extract include isovitexin, isovitexin-2″-*O*-β-D-glucopyarnoside, schaftoside, isoschaftoside, isoorientin-2″-*O*-β-D-glucopyranoside, and swertisin.[14] As measured by liquid chromatography with UV detection, the mean concentration of isovitexin in three samples of passiflora extract was 11.98 ± 0.09 mg/mL compared with vitexin (1.64 ± 0.0 mg/mL), hyperoside (0.32 ± 0.009 mg/mL), and apigenin (0.23 ± 0.03 mg/mL).[15] The concentrations of passiflora flavonoids vary substantially between various extracts, depending on the plant part, season, and *Passiflora* species. The flavonoid content in *Passiflora incarnata* is highest in the leaves, with peak isovitexin concentrations occurring just before the flowering stage.[16] In a study of 10 commercial *Passiflora incarnata* extracts analyzed by capillary electrophoresis, isovitexin-2″-*O*-β-D-glucopyarnoside was the major flavonoid in seven samples compared with isovitexin in two samples and swertisin in one sample.[17] The total mean flavonoid content in these extracts ranged from 0.37–3.75% with most flavonoid concentrations in the range of 1.18–2.48%. Figure 81.1 displays the chemical structures of some major and minor flavanoid compounds in passionflower extract.

FIGURE 81.2. Chemical structures of β-carbolines in passionflower.

Indole harmala alkaloids in *Passiflora* species include β-carbolines (harman, norharman, harmol, harmine), and dihydro-β-carbolines (harmalol, harmaline).[18] Figure 81.2 displays the chemical structures of these β-carboline compounds. The concentration of these alkaloids in *P. incarnata* is relatively small as measured by reversed-phase high performance liquid chromatography (RP/HPLC), depending on growing conditions.[19] In a study of dry pulverized plant material using RP/HPLC with selective fluorometric detection, the range of harmala alkaloid concentrations (ng/g dried material) in specimens of passionflower were approximately as follows: harman, 48–224; norharman, 51–81; harmine, nondetectable to 79; harmol, 24–977; and harmalol, 745–776.[20] Harmaline was not detectable in these specimens. The leaves typically contain the highest concentration of harmala alkaloids.[21] *P. incarnata* contains several aromatic monoterpenes including limonene, cumene, and α-pinene.[2] The unripe fruits and stems of some species of *Passiflora* (*P. adenopoda*) contain cyanogenic glycosides, but there are inadequate data to determine if clinically significant amounts of cyanogenic glycosides are present in the fruits of *P. incarnata*. Ripe fruits of *Passiflora* species do not usually contain cyanogenic glycosides.

Physiochemical Properties

Infusions of *P. incarnata* have higher total flavonoid content per gram of dry plant material than hydroethanol extracts probably because of extraction requirements and the higher solubility of glycosylated flavonoids in water than in ethanol/water extracts.[7]

DOSE RESPONSE

Typically, daily oral doses of *Passiflora incarnata* include the following: dried herb, 0.5 to 2 g 3–4 times daily; tincture (1:8), 1–4 mL 3–4 times; tea, steeping 4–8 g dried herb; and infusion, 2.5 g 3–4 times. *Passiflora* extracts typically are not standardized, in part, because of the lack of clearly defined bioactive substances.

TOXICOKINETICS

Kinetics

There are few, if any, formal pharmacokinetic studies on the flavonoids or harmala alkaloids in *Passiflora incarnata*.

Drug Interactions

There are several potential drug interactions as a result of the ingredients in passiflora extracts including additive sedative effects (sedative-hypnotics, ethanol), enhancement of bleeding (aspirin, warfarin), and elevation of blood pressure (ephedra). However, there are few clinical data to suggest that these potential interactions are clinically relevant.

CLINICAL RESPONSE

Adverse effects associated with the use of passiflora extracts include sedation, dizziness, ataxia, and impaired cognitive function. A case report of a 34-year-old woman associated the development of severe nausea, vomiting,

drowsiness, prolonged QTc interval (539 ms with nonspecific ST-T wave changes), and episodes of nonsustained ventricular tachycardia following the ingestion of 7 tablets of a commercial passiflora extract over 2 days.[22] The electrocardiogram normalized after several days of hospitalization. The tablets reportedly contained 500 mg of active ingredients, and the chromatographic profile of remaining tablets was similar to other tablets obtained from the manufacturer. Because of the lack of similar case reports, the authors suggested that this episode resulted from unique pharmacogenetics (e.g., CYP2D6) in this patient. However, no pharmacogenetic testing was done. Five patients required hospitalization for altered consciousness after ingesting an herbal product containing primarily passionflower fruit extract.[23] Several case reports associate the development of hypersensitivity skin and pulmonary reactions with exposure to *Passiflora* species. A case report documented the onset of cutaneous vasculitis and urticaria following the ingestion of passiflora extract.[24] A Brazilian pharmacy worker developed IgE-mediated occupational asthma and rhinitis following exposure to another species of *Passiflora* (*P. alata* Dryander).[25] Skin testing and Western blot confirmed the sensitization of the patient to this plant species and *Frangula purshiana* (cascara).

DIAGNOSTIC TESTING

Methods to determine flavonoid content in passiflora extracts include thin-layer chromatography, isocratic liquid chromatography,[26] RP/HPLC and capillary electrophoresis. The latter method has a limit of detection for passiflora flavonoids in the range of 4 µg/mL.[17] The limit of quantitation for flavonoids in passiflora extracts using liquid chromatography with UV detection was 1.29 µg/mL.[15] High performance thin layer chromatography is an alternative to HPLC for fingerprinting passiflora flavonoids.[7] The thermal stability of the passionflower tincture (60% volume/volume hydroalcoholic extract) is relatively low, and long-term studies indicate that the shelf-life of these tinctures is about 3 months at 25 °C (77 °F).[27]

TREATMENT

The treatment of adverse effects associated with passionflower is supportive, and there are few clinical data to guide management.

Chapter 82

PENNYROYAL and PULEGONE
(*Mentha pulegium* L.)

HISTORY

Dating back to Roman times, pennyroyal has a long history in folk medicine as an abortifacient and as a method to induce menses.[1] Toxic effects usually result from the misuse of the herb in folk medicine. Reports of pennyroyal toxicity date back to the late 1800s when the ingestion of pennyroyal oil was associated with syncope, seizures, diaphoresis, vomiting, and coma.[2,3] In 1897, a 23-year-old woman developed gastrointestinal (GI) distress 4 days after ingesting pennyroyal oil, and died 4 days later.[4] Pennyroyal exposure in these cases was not confirmed by any laboratory analysis.

BOTANICAL DESCRIPTION

Common Name: Pennyroyal, European Pennyroyal, Squaw Mint, Mosquito Plant

Scientific Name: *Mentha pulegium* L.

Botanical Family: Lamiaceae (mint)

Physical Description: This perennial mint has a variable habit, ranging from low-growing, spreading plants to lanky, upright shrubs. The stems are square in cross-section, ascending from rhizomes. Branches and simple leaves are opposite on the stems. The flowers are pale or deeper pink, blue, or violet, and these flowers cluster in dense whorls at the upper nodes. Unlike many mints, the flowers are not strongly bilateral, but only slightly two-lipped. The plant has a pungent minty odor.

Distribution and Ecology: Pennyroyal is a perennial weed that is native to Europe, and this plant has naturalized in the western and northeastern regions of the United States.

Common Name: American False Pennyroyal

Scientific Name: *Hedeoma pulegioides* (L.) Pers.

Botanical Family: Lamiaceae (mint)

Physical Description: This strongly aromatic herb is a low-growing plant from 1/2–1 ft (~0.2–0.3 m) in height with slender erect, branched, somewhat hairy stems. The leaves are small, thin, and rather narrow. Clusters of pale-bluish flowers appear from July to September.

Distribution and Ecology: The American false pennyroyal is a native annual present in the midwestern, northeastern, and southern parts of the United States with the exception of Louisiana and Florida.[5] Table 82.1 lists the pennyroyal species present in the United States.

EXPOSURE

Sources

Pennyroyal oil is a volatile oil derived by steam distillation from European (*M. pulegium*) and American (*H. pulegioides*) varieties of pennyroyal, primarily from the leaves and flowering tops. Although pennyroyal contains high concentrations of pulegone, the main commercial source of pulegone is peppermint (*Mentha* X *piperita*) and cornmint (*Mentha arvensis* L.).[6]

Medicinal Uses

TRADITIONAL

Herbalists use pennyroyal oil as an abortifacient, an emmenagogue (i.e., induction of menses), a pesticide for pets, and a treatment for chronic inflammation (e.g., chronic bronchitis, influenza, upper respiratory tract infections).[7] Some cultures (e.g., Hispanic) use boiled leaves from mint plants to treat infant colic and other minor ailments in children, as well as a traditional medicine for abortions and the induction of menses.[8] These teas are called *yerba buena*, and these preparations are not usually toxic unless confused with pennyroyal oil.[9]

CURRENT

Because of the mint-like odor, pennyroyal oil is a constituent of alcoholic beverages, foods (candy, baked goods, ice cream) and a fragrant for soaps and detergents. In an Italian study, the concentration of pulegone in mint syrup, mint-flavored candy, mint-flavored lozenges, and toothpaste ranged up to about 30 mg/kg, while the range for 5 samples of chewing gum was 1.63–138.15 mg/kg.[6] Pulegone was present almost exclusively as the (+)-isomer. There are inadequate data to support the use of pennyroyal oil for traditional treatments (i.e., abortifacient, induction of menses), and the toxicity associated with the administration of pennyroyal oil contraindicates these uses.

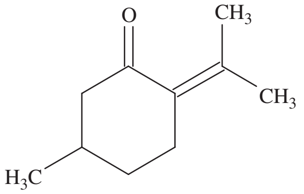

FIGURE 82.1. Chemical structure of pulegone.

REGULATORY STATUS

There are no approved medicinal uses for pennyroyal oil. Pulegone is a component of peppermint oil, which is a fragrance component of cosmetic formulations. Recommended limits of pulegone in these formulations are ≤1%.[10] The European Commission (Directive 88/388/EEC) set maximum pulegone concentrations in the following foods and beverages: foodstuffs, 25 mg/kg; beverages, 100 mg/kg; peppermint or mint-flavored beverages, 250 mg/kg; and mint confectionary, 350 mg/kg.[11]

PRINCIPAL INGREDIENTS

Chemical Composition

The major constituent of pennyroyal oil is the cyclohexanone, (R)-(+)-pulegone (CAS RN: 89-82-7, $C_{10}H_{16}O$). This ketone constitutes about 80–90% and 16–30% of European and American pennyroyal oil, respectively. In addition, these oils contain several other monoterpenes including 3-methylcyclohexanone, α-pinene, β-pinene, p-cymene, limonene, menthone, isomenthone, isopulegone. Figure 82.1 displays the chemical structure of pulegone. Peppermint (*Mentha piperita* L.) also contains relatively high concentrations of pulegone, particular in young leaves. However, as the leaves mature, pulegone in peppermint undergoes metabolism to menthol and methone (dimedone).

Physiochemical Properties

Pennyroyal oil has a strong aromatic, mint-like odor and a pungent taste. Pulegone is a colorless, oily liquid that is almost insoluble in water. Table 82.2 demonstrates some physiochemical properties of pulegone. In animal studies, the pulegone metabolite, menthofuran, is more hepatotoxic than (R)-(+)-pulegone, whereas the (S)-(−) enantiomer of pulegone is about 30% as hepatotoxic as the (R)-(+) enantiomer of pulegone.[12]

TABLE 82.2. Physiochemical Properties of Pulegone

Physical Property	Value
Molecular Weight	152
Melting Point	<25 °C/77 °F
Boiling Point	224 °C/~435 °F
Specific Gravity	0.94
log P (Octanol-Water)	3.08
Atmospheric OH Rate Constant	1.12E-10 cm^3/molecule-second (25 °C/77 °F)

Mechanism of Toxicity

Experimental studies suggest that oxidative metabolites of pulegone cause hepatotoxicity because inhibitors of cytochrome P450 oxidases mitigate the hepatic damage caused by the administration of pennyroyal oil.[13] Reactive oxidative metabolites of pulegone and its oxidative metabolite, menthofuran bind to target cell proteins producing hepatocellular necrosis.[14] Pulegone forms reactive metabolites that deplete hepatic stores of glutathione to a substantially greater extent than menthofuran. Although menthofuran is a more potent hepatotoxin in animal studies, pulegone comprises 80–90% of pennyroyal oil compared with about 0.2% for menthofuran.

DOSE RESPONSE

There is no established safe dose of pennyroyal oil, and pennyroyal is not recommended for children as a result of potential toxicity and the lack of scientific data to support efficacy. In animal models, the intraperitoneal administration of pennyroyal oil produces a dose-dependent, centrilobular hepatic necrosis at doses exceeding 400 mg/kg body weight.[12] Depletion of glutathione exacerbates this hepatotoxicity. Case reports suggest that the ingestion of <10 mL of pennyroyal oil causes gastritis and mild central nervous system toxicity without hepatorenal damage, whereas fatalities result from the ingestion of 15–30 mL pennyroyal oil. The ingestion of ≤10 mL of pennyroyal oil by an adult was associated with GI distress, but no abnormalities of hepatorenal function or coagulation.[15] The ingestion of an estimated 30 mL of pennyroyal oil produced massive centrilobular hepatic necrosis, renal dysfunction, hepatic coma, and death in an 18-year-old woman.[16]

TOXICOKINETICS

Pulegone, the major monoterpene constituent of pennyroyal oil, undergoes extensive hepatic metabolism with the primary metabolite being menthofuran. Analysis of urine from rats administered pulegone demonstrated 11 metabolites including menthofuran, piperitone, piperitenone, p-cresol, 5-hydroxypulegone, 4-methylcyclohexenone, 3-methylcyclohexanone, isopulegone, pulegol, 7-hydroxypiperitone, and benzoic acid.[17] There are at least three distinct pathways involved in the metabolism of pulegone.[18] These three pathways include the following: 1) hydroxylation to monohydroxylated pulegone compounds followed by glucuronidation, 2) reduction of the carbon-carbon double bond to form diastereomeric menthone and isomenthone followed by hydroxylation and glucuronidation, and 3) Michael addition of glutathione to pulegone followed by further metabolism to produce diastereomeric 8-(*N*-acetylcystein-S-yl) menthone/isomenthone.[19]

Oxidation of the allylic methyl groups of pulegone produces the proximate hepatotoxic metabolite, menthofuran.[20] Subsequently, menthofuran undergoes oxidation by cytochrome P450 enzymes to form mintlactone and isomintlactone via several intermediaries (e.g., 2-hydroxymenthofuran). This metabolic pathway apparently does not involve the depletion of glutathione based on animal studies.[21] *In vitro* studies indicate that the oxidation of pulegone involves CYP1A2, CYP2E1, and CYP2C19, whereas the oxidation of menthofuran involves CYP2A6 in addition to these three isoenzymes.[22] A study using specific inhibitors of cytochrome P450 pathways suggested that CYP1A2 is more important than CYP2E1 in the development of a hepatotoxic metabolite responsible for pulegone-induced liver damage in the mouse model.[23] In mice administered 150 mg/kg, the plasma half-lives of pulegone and menthofuran were approximately 1 hour and 2 hours, respectively. There are few data on the toxicokinetics of pulegone during pennyroyal intoxication in humans other than documentation of the presence of pulegone and menthofuran.

CLINICAL RESPONSE

Toxicity results from the ingestion of pennyroyal oil as an abortifacient and as an infusion for the treatment of colic in children. The ingestion of pennyroyal oil produces direct toxic effects on the GI tract and the liver. Depending on the dose, the clinical presentation includes nausea, vomiting, abdominal pain, burning of the throat, and dizziness within 2 hours of ingestion followed by the delayed development of liver dysfunction in serious cases. In severe cases, lethargy, shock, consumptive coagulopathy (disseminated intravascular coagulation [DIC]), massive hepatic necrosis, and hepatorenal failure occur.[16,24] Multiple grand mal seizures and hypoglycemia occur rarely during pennyroyal intoxication.[25] Minor ingestions of pennyroyal oil are associated with GI dis-

tress and nonspecific symptoms (lightheadedness, generalized weakness). A rare case reports associated topical application of pennyroyal leaves with the development of contact dermatitis (erythema, vesiculation, edema, desquamation).[26] The patient had a positive direct patch test with pennyroyal leaves along with a history of atopic dermatitis (e.g., nickel allergy).

DIAGNOSTIC TESTING

Serum pulegone and menthofuran concentrations help confirm exposure to pennyroyal, but there are inadequate data to correlate these levels to clinical outcome. Pulegone is present in other members of the mint family, including peppermint oil. Therefore, the presence of pulegone and menthofuran alone does not necessarily confirm the ingestion of pennyroyal. Approximately $3^1/_2$ days after the ingestion of approximately 120 mL of a tea brewed from a pennyroyal plant, the menthofuran concentration of a serum sample from an 8-week-old infant was 10 ng/mL.[9] At that time, the infant had severe hepatic failure with cerebral edema. The following day the child died, and analysis of antemortem serum demonstrated a menthofuran concentration of 2 ng/mL. Neither sample contained detectable concentrations of pulegone. The chronic ingestion of pennyroyal tea by a 6-month-old child produced serum pulegone and menthofuran concentrations of 25 ng/mL and 41 ng/mL, respectively, at the time of admission. On presentation to the emergency department the child was lethargic, post-ictal, hypoglycemic (serum glucose 7 mg/dL), and hypoxic.[9] The child survived with residual muscle spastic rigidity and elevated serum hepatic aminotransferases 2 months after admission. Postmortem concentrations of pulegone and menthofuran in a sample of heart blood from a 24-year-old woman, who died after ingesting an unknown amount of pennyroyal herbal extract over 2 weeks, were 18 ng/mL and 1 ng/mL, respectively.[15] The last estimated ingestion of the pennyroyal herbal extract was approximately 2 days before death.

TREATMENT

Stabilization

The development of hepatorenal failure is delayed at least 24–48 hours after ingestion of pennyroyal. Seizures are usually self-limited and respond to diazepam or lorazepam. Severe hypoglycemia may occur due to hepatic dysfunction, particularly in children receiving toxic doses of teas brewed from pennyroyal.[9] All patients with altered mental status following pennyroyal ingestion should be promptly evaluated for blood glucose concentrations as well as respiratory function.

Decontamination

The administration of activated charcoal is a therapeutic option for alert patients who have ingested significant amounts of pennyroyal oil (i.e., more than a taste) within 1 hour of presentation; however, there are inadequate clinical data to determine if these decontamination measures improve outcome. Syrup of ipecac is not recommended because of the early onset of seizures and central nervous system (CNS) abnormalities.

Elimination Enhancement

No methods are available.

Antidotes

There are inadequate data to evaluate the efficacy of any antidotes for pennyroyal toxicity. The use of *N*-acetylcysteine is a potential antidote based on experimental studies suggesting that glutathione depletion enhances the hepatotoxicity of pennyroyal oil.[21] Case reports associate a benign clinical course with the administration of *N*-acetylcysteine (NAC) after the ingestion of pennyroyal oil.[15,27] However, efficacy of NAC is difficult to evaluate because of lack of knowledge about the clinical course of pennyroyal intoxication not treated with NAC. There are no clinical studies to guide treatment with NAC during pennyroyal intoxication. The case reports described the use of the same NAC doses as administered for acetaminophen toxicity.

Supplemental Care

Asymptomatic patients or those whose symptoms subside within 4 hours postingestion may be discharged. Symptomatic patients should be admitted. Patients admitted for observation should be monitored for mental status changes, respiratory depression, and hepatorenal failure. Laboratory tests include a complete blood count, electrolytes, creatinine, liver function tests, urinalysis, and coagulation profiles. Bedside glucose monitoring is necessary several times daily in patients with fulminant hepatic failure. The efficacy of vitamin K_1 for elevation of the prothrombin time during fulminant hepatic failure is unclear. Fresh frozen plasma (rarely, recombinant human factor VIIa) should be used for evidence of current bleeding or prophylactically for invasive procedures. Prophylactic correction of coagulopathy in a nonbleeding patient is not usually recommended. Serial hemoglobin and stool guaiac tests should be followed for evidence of GI bleeding. The administration of proton pump inhibitors (e.g., omeprazole) should be administered to reduce the risk of GI hemor-

rhage. Cerebral edema is the major cause of death following the development of hepatic encephalopathy, and treatment includes mannitol, elevation of the head to 10–20 degrees, adjustment of ventilator settings, and fluid restriction. Epidural intracranial pressure monitoring is usually necessary to guide treatment of patients with grade 3–4 hepatic encephalopathy. Patients with severe pennyroyal toxicity are candidates for liver transplantation, and these patients should be considered for liver transplantation early (i.e., before cerebral edema causes permanent sequelae).

Chapter 83

PURPLE CONEFLOWER and OTHER *ECHINACEA* SPECIES

HISTORY

Echinacea is one of the most popular herbs in the United States. Prior to the immigration of Europeans to North America, Native Americans (e.g., Blackfoot, Cheyenne, Choctaw, Comanche, Dakota, Sioux) used *E. angustifolia* to treat a variety of illnesses ranging from snakebite and toothaches to colds and arthritis.[1] The uses of *E. purpurea* by Native Americans varied by tribe with the herb being used as an antitussive (Choctaw), antisyphilitic agent (Delaware), and analgesic for sore throats and toothaches (Comanche). The Sioux used *E. pallida* for the treatment of pain and snake bites, whereas the Cheyenne used this herb for the treatment of colds, rheumatoid arthritis, and rashes. The use of these herbs spread to colonial pharmacopoeias (*Flora Virginica*, *Materia Medica Americana*) by the late 18th century.[1] Echinacea was a popular herb with eclectics, homeopaths, and naturopaths. During the 19th century, echinacea preparations were used as "blood purifiers." In the 1880s, the Lloyd Brothers from Cincinnati, Ohio manufactured an echinacea tincture and later developed an aqueous alcohol extract, called Specific Echinacea. The use of this herb for upper respiratory infections and other types of infection began in the early 20th century in the United States. During this period, the efficacy of echinacea was questioned,[2] and use of echinacea preparations in the United States waned until the late 20th century.

In the 1920s, the German pharmaceutical manufacturer, Gerhard Madaus, brought seeds of *E. purpurea* to Germany, believing them to be the more common *Echinacea* species, *E. angustifolia*.[1] *Echinacea purpurea* became a popular herb in Germany during the 20th century as a result of the ease and lower cost of cultivation compared with *E. angustifolia* and *E. pallida*.

BOTANICAL DESCRIPTION

Echinacea species are hardy, perennial herbs with either simple or branched stems. Linnaeus originally listed *Echinacea* as the genus, *Rudbeckia*. Of the nine American species of *Echinacea*, the main three medicinal species of *Echinacea* are *E. purpurea*, *E. angustifolia* (narrow-leaved echinacea), and *E. pallida* (pale-flowered echinacea) with the cultivated species, *E. purpurea*, being the most common constituent in herbal preparations containing *Echinacea*. Milled materials from different *Echinacea* species do not have distinctive morphological characteristics that separate these species.

Common Name: Purple Coneflower, Eastern Purple Coneflower

Scientific Name: *Echinacea purpurea* (L.) Moench

Botanical Family: Asteraceae (Compositae, daisy)

Physical Description: An erect herb reaching 3 ft (~1 m) in height with long, hairy stalks and alternate, oval leaves. The solitary reddish-orange flowers surrounded by purple bracts appear from June to September. The root is thick, black, and pungent. Figure 83.1 displays a specimen of the purple coneflower.

FIGURE 83.1. Purple coneflower [*Echinacea purpurea* (L.) Moench]. Photography Courtesy of Saralyn Williams, MD. See color insert.

Distribution and Ecology: Species from the genus *Echinacea* are native plants of midwestern North America. *Echinacea purpurea* is widely cultivated throughout the United States, Canada, and Europe, particularly in Germany. Common locations for this plant are open meadows or damp areas in woods, swamps, river banks, low-lying thickets, and ditches.

Common Name: Blacksamson, Blacksamson Echinacea, Kansas Snakeroot

Scientific Name: *Echinacea angustifolia* (DC.) Hell.

Botanical Family: Asteraceae (Compositae, daisy)

Physical Description: The smallest herb reaches about 1.5 ft (~0.5 m) in height.

Distribution and Ecology: This species is more predominant in the dry prairies and barren regions of Saskatchewan to Minnesota and south to Oklahoma and Texas.

Common Name: Pale Echinacea, Pale Purple Coneflower, Purple Coneflower

Scientific Name: *Echinacea pallida* (Nutt.) Nutt.

Botanical Family: Asteraceae (Compositae, daisy)

Physical Description: This perennial plant grows to 3 ft (~1 m) with a stout central gray to reddish green stem covered with coarse, white hairs. Most leaves originate at the base of the plant with a few along the lower one-third of the stem. These leaves are narrowly lanceolate, oblanceolate, or ovate with a length of up to 9 in. (~23 cm) and a diameter of 2 in. (5 cm). The margins are smooth, often curling upward. Fine white hairs cover the upper and lower surfaces of the leaves.

Distribution and Ecology: These plants inhabit sunny locations from Michigan to Nebraska and south to Texas.

EXPOSURE

Sources

Echinacea is available in a variety of commercial preparations including direct pressed juices, ethanolic or hydrophilic extracts, and freeze-dried whole or powdered leaves, flowers and roots that comprise a variety of tablets, capsules, tinctures, and teas. Herba Echinaceae Purpureae consists of the fresh or dried aerial parts of *Echinacea purpurea* (L.) Moench harvested in full bloom, whereas Radix Echinaceae consists of the fresh or dried roots of *Echinacea angustifolia* or *E. pallida* (Nutt.) Nutt. In Germany, intravenous preparations of echinacea extract are available. However, there is wide variation in the content, quality, and composition of echinacea preparations.[3] The fresh aerial parts of *Echinacea purpurea* are the most common source of herbal preparations.

Medicinal Uses

Traditional

Native Americans used echinacea for a variety of infections as well as snake bite, bee stings, wound infections, mumps, rabies, mouth sores, blood poisoning, and tumors. This herb was considered an immunostimulant, which promoted wound healing and increased resistance to colds. Additionally, this herb was a treatment for hemorrhoids, wound infections, syphilis, gangrene, malaria, typhoid, flu, and skin infections. Herbal preparations include ethanol extracts as well as fresh or dried *Echinacea* root or flowers. Frequently, echinacea is combined with other herbs (e.g., garlic, ginseng, goldenseal).

Current

Echinacea is a common herbal treatment for upper respiratory tract infections (URI) based on potential immunomodulatory properties, such as macrophage activation and enhanced neutrophil phagocytosis. Evaluation of studies of *Echinacea* herbs is complicated by the lack of standardized doses, the variety of preparations used in these studies, small study sizes, and other methodological flaws.[4] There is limited evidence for the efficacy of echinacea for the *treatment* of URI with most positive studies containing methodological flaws and nonstandardized dosage forms.[5] More recent studies have not confirmed the efficacy of echinacea herbs in treating URIs. A placebo-controlled, randomized, double-blind clinical trial of 80 employees of a German pharmaceutical firm detected a statistically significant reduction (i.e., 6 days vs. 9 days, $P = 0.01$) in the median duration of URI in the group treated with 5 mL EC31JO (pressed juice from fresh flowering purple coneflower) twice daily for 10 days, when compared with the placebo group.[6] However, a randomized, controlled clinical trial of 524 children aged 2–11 years did not detect a reduction in the duration or severity of URI in the children receiving 7.5–10 mL pressed *E. purpurea* juice daily, when compared with the placebo group.[7] A randomized, double-blind, placebo-controlled study examined the severity and duration of cold symptoms as recorded by 128 patients with the onset of URIs within the preceding 24 hours.[8] There was no statistically significant difference between treatment (100 mg freeze-dried pressed juice from the aerial portion of *E. purpurea* 3 times daily) and placebo groups for total symptoms scores, mean individual symptom scores, or time to resolution of symptoms. In a study of three *E. angustifolia* root extracts (supercritical carbon dioxide, 60% ethanol, 20% ethanol) involving subjects receiving both prophylactic and treatment for experimental infection with rhinovirus type 39, there was no statistically significant effects of any these extracts on the rates of infection, the severity of symptoms, or volume of nasal secretions when compared with placebo.[9] Analyses of the extracts demonstrated the following: supercritical carbon dioxide (73.8% alkamides, no polysaccharides), 60% ethanol extract (48.9% polysaccharides, 2.3% alkamides), and 20% ethanol extract (42.1% polysaccharides, 0.1% alkamides). There is little evidence that the *prophylactic* use of echinacea herbs reduces the frequency, duration, or severity of upper respiratory tract infections.[10]

Regulatory Status

Echinacea is approved as a dietary supplement in the United States, and the German Commission E list contains both *E. purpurea* herb (i.e., excluding the root) and *E. pallida* root. Uses in Germany include the treatment of colds, respiratory tract infections, poor-healing external wounds, urinary tract infections, and vaginal fungal infections. The fresh or dried root of *E. pallida* is approved by the German Commission E for the treatment of influenza-like illnesses.

PRINCIPAL INGREDIENTS

Chemical Composition

The chemical composition of extracts from medicinal *Echinacea* species is complex, consisting of alkamides (straight-chain fatty acids with olefinic and/or acetylenic bonds), polyacetylenes, phenolic caffeic acid conjugates (phenylpropanoids), polysaccharides, and glycoproteins. All plant tissues from these species contain acetaldehyde, camphene, dimethyl sulfide, hexanal, limonene, and β-pinene.[11] The chemical profile of these compounds in medicinal *Echinacea* species varies with the specific species, plant part, geographic location, season, processing, and type of extract. Terpenoids (camphene, limonene, β-myrcene, ocimene, α- and β-pinene, terpene) predominated (i.e., 82–91%) in the headspace analysis of volatile components from flowers and stems, whereas headspace analysis of volatile components from roots contain 41–57% aldehydes (2- and 3-methylbutanal, 2-methylpropanal, 2-propanal, acetaldehyde), alcohols, and 6–21% terpenoids.[11]

The active ingredients in Echinacea herbal preparations have not been defined. The major categories of chemicals in *Echinacea* species are alkamides and caffeic acid conjugates (caftaric acid, chlorogenic acid, cynarin, echinacoside, cichoric acid). In a study of roots from 3-year-old plants, the total phenolic compounds (i.e., caffeic acid derivatives) ranged from 13.92 ± 0.31 mg/g dry weight (*E. pallida*) to 22.79 ± 0.37 mg/g dry weight (*E. purpurea*). Caffeic acid was not detected in samples of roots from the three medicinal *Echinacea* species as measured by high performance liquid chromatography (HPLC). The composition of phenolic compounds in medical *Echinacea* species depends on growing season as well as plant part and species. The cichoric acid (chichoric acid) content in dried *E. purpurea* roots varied from 2.27% weight/weight in summer to 1.68% in autumn, whereas the cichoric acid content in dried tops from this species varied from 2.02% in summer to 0.52% in autumn.[12] Enzymatic browning during extraction substantially reduces the phenolic content of medicinal *Echinacea* species. Echinacea extracts also contain at least 20 alkamides, which are primarily undecenoic and dodecanoic acid derivatives differing in the degree of unsaturation and the configuration of the

double bonds.[13] Fresh, dried *Echinacea purpurea* roots contain higher concentrations of alkamides (2.65–3.28 mg/g) than leaves (0.10–0.18 mg/g).[14] Alkamides occur in alcoholic extracts of the aerial parts and roots from *E. purpurea* and *E. angustifolia*. In a study of 11 healthy subjects administered a 60% ethanolic extract from the roots of *E. angustifolia*, the plasma contained at least six alkamides with dodeca-2E,4E,8Z,10Z/E-tetraenoic acid isobutylamides being the most prominent.[15] The major constituents of alcoholic extracts of the roots of *E. purpurea* were cichoric acid (2,3-dicaffeoyltartaric acid) and verbascoside, whereas echinacoside and 6-*O*-caffeolyechinacoside predominated in extracts of *E. pallida* roots.[16] Cynarine (1,3-dicaffeoylquinic acid) and dodeca-2E,4E,8Z,10Z/E-tetraenoic acid isobutylamides were the major chemicals in *E. angustifolia* root extracts. Volatile oils of *Echinacea* species contain a variety of alkenes, alkynes, and alkyl ketones with some of the former compounds subject to oxidation to 8-hydroxy derivatives. The volatile oils from the aerial parts of these species also contain borneol, bornyl acetate, caryophyllene, and germacrene D.[13] Saturated pyrrolizidine alkaloids (e.g., tussilagine, isotussilagine) occur in *Echinacea* species, but the toxicity of these compounds is low compared with the unsaturated pyrrolizidine compounds associated with venoocclusive disease and hepatotoxicity.[13]

Physiochemical Properties

A pilot study suggested that the alkamide, alkaloid, and polyacetylene fractions in echinacea preparations stimulate leukocytes and increase the release of cytokines (tumor necrosis factor-alpha, interleukin-1,-6, and -10).[17,18] Caffeic acid conjugates (echinacoside, chlorogenic acid, cichoric acid, cynarine) are free radical scavengers and antioxidants, particularly cichoric acid.[19] However, the bioavailability of these phenolic compounds is low.

Mechanism of Toxicity

Most serious reactions to echinacea preparations result from allergic reactions to echinacea preparations in atopic individuals. There are few data on dose-related toxicity to these preparations.

DOSE RESPONSE

Typical doses of liquid extract of *E. purpurea* root for the treatment of upper respiratory illness is 3 mL every 3–4 hours for the first 1–2 days, then 3 times daily for the following week.[20] The dose of echinacea tea from the roots of *E. angustifolia* or *E. purpurea* is 6–8 oz 4 times daily for the first 2 days, then once or twice daily for the rest of the week.

TOXICOKINETICS

Kinetics

Human studies indicate that the gastrointestinal tract rapidly absorbs alkamide compounds (e.g., dodeca-2E,4E,8Z,10E/Z-tetraenoic acid isobutylamides).[21] In volunteer studies, the time to maximum alkamide concentrations (T_{max}) ranged from about 30 minutes to $2\frac{1}{2}$ hours.[15,22] The mean plasma elimination half-life for total alkamides was about 3.5 ± 0.4 hour. In general, the bioavailability of caffeic acid conjugates is poor.

Drug Interactions

There is little clinical evidence of significant drug–herb interactions during the use of *Echinacea* herbs.[23] Short term *in vivo* studies in volunteers indicate that the administration of echinacea (400 mg *E. purpurea* root 4 times daily for 8 days) reduces the mean oral clearance of caffeine (CYP1A2) by approximately 27%.[24] The effect of *E. purpurea* root on CYP3A4 is complex because this study indicated that echinacea inhibited intestinal CYP3A activity, while inducing hepatic CYP3A activity. There was no alteration of CYP2C9 or CYP2D6 activity. However, the administration of botanical supplements (800 mg twice daily for 28 days, 2.7% cichoric acid) of *E. purpurea* to 12 healthy volunteers had no significant effect on CYP1A2, CYP2D6, CYP2E1, or CYP3A4 activity as measured by phenotypic ratios before and after supplementation.[25] Echinacea is not recommended for patients with autoimmune or collagen vascular disorders (e.g. rheumatoid arthritis, systemic lupus erythematosus), multiple sclerosis, tuberculosis, or HIV because of the potential alteration of immune response. However, there are few clinical data to evaluate the clinical relevance of this potential effect.

CLINICAL RESPONSE

Adverse Reactions

In general, echinacea herbal preparations are well tolerated with few adverse effects as evidenced by the similarity of adverse effects between treatment and placebo groups reported in most clinical studies.[26] Animal studies support the low toxicity of herbal preparations from *Echinacea* species at doses up to 60 times higher than typical doses administered to humans.[27] The most common serious adverse effects of treatment with these

products are allergic reactions, particularly in individuals hypersensitive to plants from the Asteraceae family (chamomile, feverfew, ragweed, mugwort). In a randomized trial using pressed *E. purpurea* juice, the incidence of skin rash was significantly higher (7.1% vs. 2.7%, $P = 0.008$) in the group receiving echinacea than in the placebo group.[7] Case reports associate a variety of allergic reactions with ingestion of *Echinacea* herbal preparations including urticaria, acute bronchospasm, diffuse maculopapular rash, and angioedema.[28] These reactions occurred primarily in atopic individuals, some of whom had no prior exposure to *Echinacea* species. Other adverse effects associated with the use of echinacea preparations include unpleasant taste, headache, dizziness, nausea, vomiting, diarrhea, and difficulty swallowing.[29] Rare case reports temporally associate the use of echinacea herbal preparations with recurrent erythema nodosum.[30] There is little clinical information on dose-related toxicity of echinacea.

Chronic Effects

In a study of 206 women self-referred for evaluation of the use of echinacea preparations (i.e., up to 1 g daily capsule/tablets or 60 drops tincture daily) during pregnancy, there were no statistical differences in the spontaneous abortion rate or major congenital malformations between the echinacea group and a control group matched for diseases, alcohol, and cigarette use.[31] The limitations of the study included small sample size (i.e., low statistical power) and potential misclassification (reporting bias as a result of self-reporting of exposure).

DIAGNOSTIC TESTING

Methods to distinguish the three main *Echinacea* species based on differences in the chemical profiles of alkamides and caffeoyl conjugates in extracts from these herbs include capillary electrophoresis with photodiode array UV detection and gradient elution reversed phase high performance liquid chromatography (HPLC) coupled to photodiode array UV or electrospray ionization mass spectrometric detection.[32,33] Cichoric acid is the predominant caffeoyl conjugate in extracts of *E. purpurea* root, whereas echinacoside and 6-caffeoylechinacoside are the main caffeoyl conjugates in extracts of *E. pallida* root.[16] The presence of cynarine and echinacoside and the absence of cichoric acid distinguish *E. angustifolia* roots from *E. purpurea* and *E. pallida* roots. The leaf extracts of these three *Echinacea* species also have distinctive chemical profiles. Cichoric acid is detectable in *E. purpurea* and *E. pallida*, but not in *E. angustifolia*, whereas echinacoside is detectable in *E. pallida*, but not in *E. angustifolia* or *E. purpurea* leaves.[34] Infrared reflectance spectroscopy is an alternative to HPLC techniques for the detection of adulteration of *Echinacea purpurea* roots with *Parthenium integrifolium* L. or other *Echinacea* species. This method can detect samples of *E. purpurea* root with >10% adulteration, and there are relative few false-positives with this method.[35] Although the impact of milling and drying on total alkamide content in *E. purpurea* roots is slight, storage at room temperature for prolonged periods can substantially reduce alkamide content. Over a 64-week period, the total alkamide content decreased about 80% in *E. purpurea* roots stored at 24 °C (~75 °F).[36] Freezing reduced, but did not eliminate, this loss. The content of the main phenolic compound, cichoric acid, is relatively stable at room temperature over at least 6 months in dry alcoholic extracts of *E. purpurea*.[37]

TREATMENT

Treatment is supportive. The most serious potential adverse effects associated with the use of echinacea preparations are allergic reactions that include acute bronchospasm and generalized urticaria.

Chapter 84

ROSEMARY
(*Rosmarinus officinalis* L.)

HISTORY

Rosemary has been used as a medicinal and aromatic herb since ancient Greek and Roman times.[1] Although rosemary is a native species of the Mediterranean, this plant has been cultivated in Northern Europe and England at least since Medieval times where rosemary was a symbol of remembrance of events (birth, marriage, death).[2] Rosemary is mentioned in some classic books, such as *Hamlet* and *Don Quixote*.

BOTANICAL DESCRIPTION

Common Name: Rosemary, Polar Plant, Compass Weed, Compass Plant

Scientific Name: *Rosmarinus officinalis* L.

Botanical Family: Lamiaceae (menthes, mints)

Physical Description: This erect evergreen has pungent, pleasant-smelling, lavender-like, dark green leaves. The rigid branches bear fissured, ash-colored bark and long, linear, needle-like leaves. The small, pale blue flowers appear from April to August.

Distribution and Ecology: Rosemary is a native plant of the arid costal regions of the Mediterranean region. However, this plant is cultivated in warm, dry climates throughout the world.

EXPOSURE

Sources

The essential oil is a distillation product of rosemary leaves and flowers.

Medicinal Uses

TRADITIONAL

In folk medicine, rosemary extract is a treatment for urinary aliments, chronic weakness, nervous disorders, hair loss, and peripheral vascular diseases. In addition, rosemary is a traditional astringent, carminative, tonic, rubefacient, antispasmodic, anti-inflammatory, expectorant, emmenagogue, digestive, diaphoretic, and diuretic.[3,4]

CURRENT

Rosemary extracts are natural sources of antioxidants (rosmarinic acid, carnosic acid, rosmanol, epirosmanol, carnosol), which are alternatives to the common synthetic antioxidants (butylated hydroxyanisole, hydroxytoluene, δ-tocopherol). Additionally, rosemary extract is a constituent of some perfumes, disinfectants, and insecticides. There is no conclusive evidence that rosemary is an effective insecticide.[5] Experimental uses for rosemary include the treatment of alopecia areata.[6] Rose-

mary leaves are a seasoning for meat dishes, sauces, and salami.

Regulatory Status

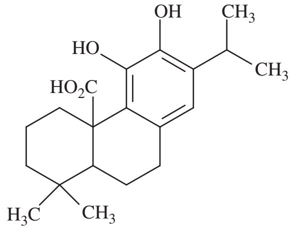
The US Food and Drug Administration approved the use of rosemary in food [GRAS (generally recognized as safe)].

PRINCIPAL INGREDIENTS

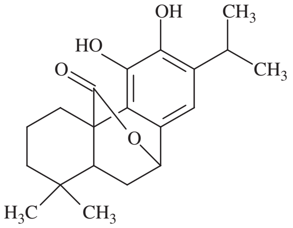
Chemical Composition

The major polyphenolic constituents in rosemary are phenolic diterpenes (carnosic acid, carnosol, 12-*O*-methylcarnosic acid), caffeoyl derivatives (rosmarinic acid), and flavones (genkwanin, isoscutellarein 7-*O*-glucoside, eriocitrin, luteolin 3′-*O*-β-D-glucuronide, hesperidin, diosmin, hispidulin 7-*O*-glucoside).[7,8] Carnosic acid is a synonym for salvin (CAS RN: 3650-09-7). Figure 84.1 displays the chemical structures of the major constituents in rosemary. The flavonoid compounds primarily are derivatives of apigenin and luteolin. The concentration of polyphenolic compounds varies with season, age of the plant, solar radiation, growing conditions, and climate. These compounds are present in young leaves, but the concentrations of these polyphenolic compounds decrease with age.[9] Drought and high solar radiation increases the concentration of highly oxidized abietane diterpenes (e.g., isorosmanol, dimethyl isorosmanol) in rosemary leaves, while the concentration of carnosic acid decreases.[10]

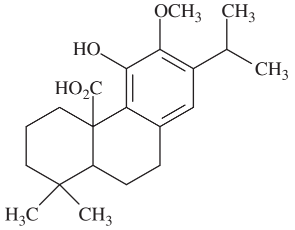
The major constituents of hydro distillates of rosemary include α-pinene, β-pinene, *E*-caryophyllene, borneol, (−)-camphene, 1,8-cineole, camphor, verbenone, and bornyl-acetate.[11,12] The concentrations of these compounds also vary with distillation process, region, climate, environmental conditions (temperature, water stress), and strain.[13] In general, monoterpene compounds account for about 50% of the constituents in aqueous extracts of rosemary, whereas ketones and alcohols each represent <7–10% of the total concentration.[14] The main components in a sample of essential oil obtained from rosemary by supercritical CO_2 extraction were α-pinene, 1,8-cineole, camphor, verbenone, and borneol as measured by gas chromatography/mass spectrometry (GC/MS).[15] These constituents accounted for about 80% of the total oil.



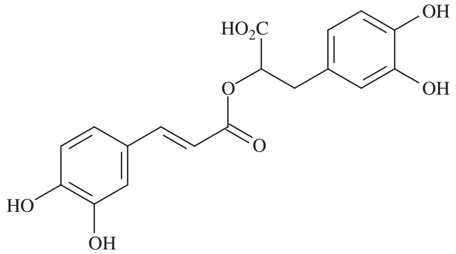
Carnosic Acid



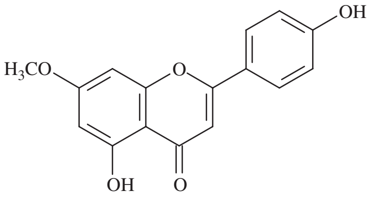
Carnosol



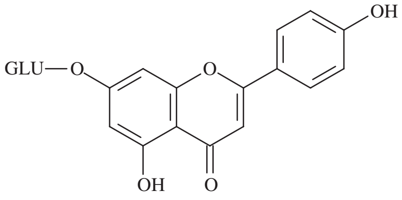
12-O-methylcarnosic Acid



Rosmarinic Acid



Genkwanin



Isoscutellarein-7-O-glucoside

FIGURE 84.1. Chemical structures of major constituents of rosemary extracts.

Physiochemical Properties

Unsaturated fatty acids are sensitive to oxidation, and the resulting lipid oxidation reduces flavor and nutritive value of lipid-containing food products. Antioxidants prolong the shelf life and maintain the nutritional quality of lipid-containing foods.[16] The antioxidant properties of rosemary result primarily from the actions of phenolic diterpenes, such as carnosic acid, carnosol, methyl carnosate, rosmanol, epirosmanol, and 7-methyl-epirosmanol. *In vitro* studies indicate that the main diterpene antioxidant is carnosic acid.[17] Oxidation converts carnosic acid to carnosol, and further degradation produces other phenolic diterpene compounds with γ-lactone structures.[18] Consequently, the concentration of carnosol increases as the plant ages. The other active antioxidant in rosemary extract is the water-soluble phenolic diterpene, rosmarinic acid, which is also present in other members of the mint family (Lamiaceae) including oregano (*Origanum vulgare* L.), kitchen sage (*Salvia officinalis* L.), and common balm (*Melissa officinalis* L.). The concentration of carnosic and rosmarinic acids also depends on drying techniques and distillation processes (aqueous, organic solvent, microwave, supercritical fluid).[19]

Mechanism of Toxicity

Most of the adverse reactions reported from the use of rosemary are allergic reactions.

DOSE RESPONSE

Typical traditional doses of rosemary include 2–4 g dried leaves and twigs or 2–4 mL of 1:1 liquid extract in 45% ethanol.

TOXICOKINETICS

There are few data on the toxicokinetics of constituents in rosemary extracts. Rodent studies suggest the possibility of the induction of CYP1A, CYP2B, CYP2E1, and CYP3A along with some phase II enzymes (e.g., glutathione S-transferase, UDP-glucuronosyltransferase),[20] but the lack of human data limits conclusions regarding the clinical relevance of these potential interactions.

CLINICAL RESPONSE

Adverse reactions to rosemary typically involve hypersensitivity responses. Despite the frequent use of rosemary as an herb, case reports of allergic reactions are relatively rare. These case reports include the development of allergic contact dermatitis (edema, eczema, vesiculation) following direct contact with rosemary leaves,[21] the use of cosmetics and a cleansing gel containing rosemary leaf extract,[22] the application of rosemary alcohol directly to the skin,[23] and the use of rosemary leaf plasters.[24] Patch testing in these patients indicates that carnosol (CAS RN: 5957-80-2) is a major allergen in rosemary. The response of these patients to other members of the mint family (e.g., oregano, sage, mint, thyme, lavender) was variable. The chronic use of rosemary as a culinary spice in food was associated with the development of chronic contact cheilitis.[25] Exposure to rosemary extracts also has been associated with occupational contact dermatitis[26] and occupational asthma.[27] Although rosemary extracts contain variable quantities of camphor,[28] there are no human data to support the development of seizures as a complication of the ingestion of rosemary extract.

DIAGNOSTIC TESTING

Techniques for the separation of the major phenolic diterpene compounds responsible for the antioxidant properties of rosemary extract include capillary zone electrophoresis,[29] pressurized liquid extraction/capillary electrophoresis/electrospray-mass spectrometry,[30] high performance liquid chromatography with UV detection,[31] solid-phase extraction and capillary zone electrophoresis coupled to electrospray ionization/ion trap mass spectrometry,[32] and LC/MS.[33] Capillary electrophoresis with electrochemical detections allows the simultaneous determination of the active components (e.g., rosmarinic acid, caffeic acid, apigenin, luteolin) with detection limits in the range of 0.1–1 µg/mL.[34]

TREATMENT

Treatment is supportive.

Chapter 85

RUE
(*Ruta graveolens* L.)

HISTORY

In addition to the medicinal use of rue for analgesia and inflammation, the use of this herb for defense against witches and evil spells dates back to ancient Greece and the Middle Ages.

BOTANICAL DESCRIPTION

Although the two most common *Ruta* species used for herbal medicine are *R. graveolens* L. (common rue) and *R. chalepensis* L. (fringed rue), other *Ruta* species (*R. corsica* DC., *R. montana* L.) are also traditional herbal treatments.

Common Name: Common Rue, Rue

Scientific Name: *Ruta graveolens L.*

Botanical Family: Rutaceae (rues, rutacées)

Physical Description: This evergreen shrub has bi- or tripinnate, bluish-green leaves, which emit a strong, disagreeable odor. The yellow flowers are about 1 cm (~0.4 in.) in diameter with toothed petals that appear from June to September.

Distribution and Ecology: Common rue is a native species of southern Europe and northern Africa that was introduced into North America after the Spanish Conquests. Common locations for this plant include moist fields, pastures, and roadsides.

EXPOSURE

Sources

The essential oil obtained by steam distillation of the dry aerial parts of *R. graveolens* typically yields <1% essential oil. Steam distillation of Italian rue (*R. graveolens*) produced 0.74% yellowish essential oil with an intense, penetrating odor.[1] This yield compares with about 4.5% following supercritical-fluid extraction of common rue.[2] Rue is also a seasoning for cooking and a source of methyl nonyl ketone, which is used in soaps, creams, and perfumes.

Medicinal Uses

Traditional

There are many traditional herbal uses for *Ruta* species throughout the world. Fresh aerial parts of rue are a traditional treatment for palpitations and circulatory disorders in Taiwan.[3] In Saudi Arabia, decoctions of the aerial parts of rue are a traditional treatment for fever, pain, rheumatism, and mental disorders.[4] This plant is a treatment for syncope, menstrual disorders, rheumatism, and neuralgias in Ayurvedic medicine. Decoctions of the roots of rue are traditional Chinese treatments for snake and scorpion envenomations. The aqueous extract of rue is an herbal treatment for fever in Africa. *Ruta* species are common herbs used as emmenagogues to initiate delayed menses, as abortifacients to terminate

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

pregnancies,[5] and as a birth control method.[6] In a retrospective study on the use of herbal infusions to induce abortions, 86 cases were reported to the Montevideo Poison Center between 1986 and 1999.[7] *Ruta* species (*R. chalepensis* L., *R. graveolens* L.) were an ingredient in 26 of the cases with *Ruta* species being the single plant used in 12 cases. Rue also is used as an insect repellant and antihelminthic.[8]

Current

Extracts of *Ruta graveolens* are experimental chemotherapeutic agents, but the efficacy of these agents has not been established.[9] Other experimental uses include the treatment of parasitic infections.[10]

Regulatory Status

Most countries do not regulate the use of rue.

PRINCIPAL INGREDIENTS

Chemical Composition

Ruta species contain a variety of chemicals including quinoline alkaloids (graveoline), acridone alkaloids,[11] flavonoids, furanocoumarins (5-methoxypsoralen, 8-methoxypsoralen),[12] tannins, sterols, and terpene compounds. Volatile components of aqueous extracts of *Ruta graveolens* leaves, flowers, stems, foots, and fruits include primarily oxygenated compounds, such as ketones (2-undecanone), alcohols (2-undecanol), and aliphatic acids (pentanoic, hexanoic, octanoic, nonanoic).[13] The composition of the essential oil varies with plant part. Following subcritical (CO_2) extraction, the main constituents of the essential oil as measured by capillary chromatography with nitrogen-phosphorus, flame ionization, and mass selective detection were as follows: leaves, 2-nonanone (8.9%); flowers, 2-undecanone (13.4%); stems, chalepensin [3-(α-,α-dimethylallyl) psoralen,13%]; and roots, geijerene (19.3%).[2] Gas chromatography/mass spectrometry (GC/MS) detected 38 compounds in a steam distillate of dry aerial parts of *R. graveolens* with the primary constituents being 2-keto compounds.[1] Methyl nonyl ketone (undecan-2-one, RN: 112-12-9) and 2-nonanone (nonan-2-one, CAS RN: 821-55-6) represented 46.8% and 18.8% of the hydrodistillate, respectively. Triterpenoid compounds accounted for about 11% of the constituents with limonene, 1,8-cineole, and α-pinene being the most common monoterpene compounds. Minor constituents included octanoic acid, methyl salicylate, 2-decanone, and methyl undecyl ketone (2-tridecanone). The ethyl acetate extract of leaves from *Ruta graveolens* contains furanocoumarin compounds (5-methoxypsoralen, 8-methoxypsoralen) and quinolone alkaloids (graveoline) with 8-methoxypsoralen being the strongest photoirritant.[14] The biogenic precursor of these linear furanocoumarin compounds is umbelliferone.[15]

Physiochemical Properties

Animal studies suggest that extracts of rue have bacteriostatic, antihelminthic, anti-inflammatory, antipyretic, and analgesic properties.[4,16] However, there are few clinical data to support the use of this herb for any of these purposes.

Mechanism of Toxicity

Most adverse reactions to the use of rue result from photosensitization to the psoralen compounds, such as bergapten (5-methoxypsoralen) and xanthotoxin (8-methoxypsoralen) in the plant.

DOSE RESPONSE

Recommended doses for herbal preparations of *Ruta graveolens* include one cup of boiling water poured over 1–2 teaspoons of dried herb or the ingestion of 0.5–1 g dried herb 3 times daily. The development of allergic contact dermatitis is a hypersensitivity reaction that is not specifically dose-related. However, phytophototoxicity is an irritant type of photodermatitis that requires UV light and no prior sensitization. These dermal reactions increase with increasing doses of irritants.

TOXICOKINETICS

There are few data on the toxicokinetics of the components of rue extract.

CLINICAL RESPONSE

Rare case reports associate the use of rue with the development of phytophotodermatitis on sun-exposed portions of the face and extremities.[17] Skin lesions include the appearance of pruritic, erythematous, linear macules,[18] and acute vesiculobullous dermatitis[19] within 6–48 hours of exposure to rue.[20] These lesions are characterized by linear erythema with sharp demarcation between the lesion and unaffected skin. Potential complications include changes in pigmentation and infected bullae. Phytophotodermatitis occurs following exposure to several *Ruta* species in addition to *R. graveolens* including *R. montana* L. (mountain rue),[21] *R. corsica* (Corsican rue),[22] and *R. chalepensis* (fringed rue).[23,24] Postabortion sepsis with multiorgan failure is a potential complication of the use of *Ruta* infusions for the induc-

tion of abortions.[24] A case report associated the recent consumption of a decoction of *Ruta graveolens* with the development of dyspnea, bradycardia, renal dysfunction, and hyperkalemia in a 78-year-old woman. She began the decoction 1 day before development of dyspnea and 3 days before admission to an emergency department. A causal connection between rue and her symptoms was not established because of the presence of pre-existing disease and the lack of serum drug concentrations of her prescribed medications (i.e., bisoprolol, diltiazem).

DIAGNOSTIC TESTING

Methods for analyzing the constituents of extracts from *Ruta* species include GC with nitrogen-phosphorus or flame ionization detection,[1,2] gas/liquid chromatography,[25] and GC/MS.[13]

TREATMENT

Treatment is supportive. Therapy for skin lesions includes antihistamines, soothing baths to reduce pruritus, and topical corticosteroid creams. Oral steroids may be necessary for more severe cases of rue-induced phytophotodermatitis. The use of soap and water, sun screens, and avoidance of sun exposure for 48 hours reduces the severity of phytophotodermatitis if initiated before the appearance of skin lesions.

Chapter 86

SASSAFRAS
[*Sassafras albidum* (Nutt.) Nees]

HISTORY

Sassafras was a common tonic and herb of many native North American Indian tribes for the treatment of upper respiratory tract infections, kidney dysfunction, rheumatism, and skin lesions.

BOTANICAL DESCRIPTION

The sassafras tree is native to the eastern United States, but other species also contain safrole. *Ocotea odorifera* (Vell.) Rohwer (Brazilian sassafras) is a medium-sized tree indigenous to southeastern Brazil, Columbia and Paraguay, whereas *Cinnamomum camphora* (L.) J. Presl (Chinese sassafras) occurs throughout Southeast Asia. The forest shrubs of the Piperaceae family (*Piper auritum* Kunth, *P. hispidinervum* C.DC., *P. callosum* Ruiz & Pav.) are indigenous to the humid forests of Central America and the Brazilian Amazon.

Common Name: Sassafras Tree, Ague Tree, Cinnamonwood, Saloop, Saxifrax, Smelling-Stick

Scientific Name: *Sassafras albidum* (Nutt.) Nees

Botanical Family: Lauraceae (laurel)

Physical Description: A large tree with alternate, deep green leaves up to 8–15 cm (~3–6 in.) long. This tree reaches 15 m (~49 ft) in height and 35 cm (~14 in.) in diameter. Older stems are deeply furrowed with reddish brown bark. The leaves, stems, and bark that contain pleasant-smelling oils. Small yellowish-green flowers appear in early spring in axillary racemes. The dark blue or black, oblong, fleshy fruit develops in August to September, and this drupe contains brown, oblong seeds.

Distribution and Ecology: This native eastern US species ranges from Florida to southern Maine and from western Iowa to Texas.

EXPOSURE

Sources

The roots of North American species, *Sassafras albidum*, are the source of true sassafras oil. This oil once was the main flavoring in root beer, but commercial production of this oil ceased as a result of concern about the health effects of safrole in this oil. The two important sources of commercial sassafras oil now are Brazilian sassafras oil and Chinese sassafras oil. The source of Brazilian sassafras oil is the woody trunk of *Ocotea odorifera* (*Ocotea cymbarum*) from southeastern Brazil, whereas the source of Chinese sassafras oil is the Southeast Asian species, *Cinnamomum camphora* (L.) J. Presl. Some forest shrubs of the Piperaceae family (*Piper auritum, P. hispidinervum, P. callosum)* contain high concentrations of safrole in their leaves, but there is limited commercial production of safrole from these sources.

Medicinal Uses

TRADITIONAL

Traditional uses of sassafras oil include topical anesthesia, muscle relaxation, blood purification, dental disin-

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

fectant, and the treatment of skin disorders, hypertension, renal disorders, cancer, syphilis, and menstrual irregularity. Sassafras oil was a common flavoring agent for soft drinks and baked goods until the US Food and Drug Administration (FDA) banned the oral use of sassafras oil as a food additive because of the presence of an animal carcinogen in the oil. Some dietary supplements may contain detectable quantities of safrole.[6]

Current

Sassafras oil is a fragrance added to soap and toiletries. Brazilian and Chinese sassafras oils are raw materials for the isolation of safrole. Commercial safrole from these sources is a raw material for the production of the flavoring agent and fragrance, heliotropin, and the synergistic agent, piperonyl butoxide. The latter compound is an important ingredient of pyrethroid insecticides that enhances the effectiveness of pyrethroid insecticides. Safrole and isosafrole can be used as precursors in some synthetic processes that produce 3,4-methylenedioxymethylamphetamine (MDMA).[1]

Regulatory Status

Until 1960, safrole-containing sassafras extracts were flavoring agents in beverages, such as root beer in concentrations up to 20 ppm safrole. Because of the hepatotoxic effects of safrole in animal models and the classification of safrole as a weak hepatic carcinogen, the FDA prohibited the use of safrole, dihydrosafrole, oil of sassafras, and isosafrole as food additives in foods and beverages in the early 1960s.[2] This ban was extended to sassafras tea in 1977. Consequently safrole, isosafrole, and safrole-containing products are not recognized as safe for human consumption. However, the 1994 Dietary Supplement Health and Eduction Act allows the use of certain dietary supplements containing sassafras. Further, the FDA permits the use of nutmeg and mace, which contain small amounts of safrole. Uses of safrole as a pesticide also have been canceled by the EPA. In 1988, the Council of the European Communities also banned safrole as a flavoring agent in foodstuffs. Isosafrole is a minor constituent of some soaps, detergents, cream, and perfumes as a result of the addition of ilang-ilang (ylang-ylang) oil from the ilang-ilang tree [*Cananga odorata* (Lam.) Hook. F. & T. Thomson].[3] Brazilian and Chinese safrole oils contain about 80% safrole.

PRINCIPAL INGREDIENTS

Chemical Composition

The major constituent of sassafras oil is the alkenyl benzene compound called safrole (4-allyl-1,2-methylenedioxybenzene). The root bark from the sassafras tree contains about 5–9% volatile oil composed primarily of safrole (80–85%) along with camphor (3%), methyleugenol (1%), and minor amounts of monoterpenes (α-camphene, β-pinene, 1,8-cineole, *p*-cymene) and sesquiterpene compounds other than methyl eugenol.[4] Figure 86.1 displays the chemical structure of safrole. A commercial sample of essential oils from *Sassafras albidum* contained approximately 82% safrole, 3% methyleugenol, 1% α-cubebene, 1% α-calacorene, and <1% of a variety of terpenoid compounds (limonene, 1,8-cineole, carvone, eugenol) as measured by gas chromatography/mass spectrometry (GC/MS).[5] The safrole content in teas brewed from the root bark of the sassafras tree is highly variable with analysis of the safrole content in six samples of brewed tea ranging from 0.09–4.66 mg/cup.[6]

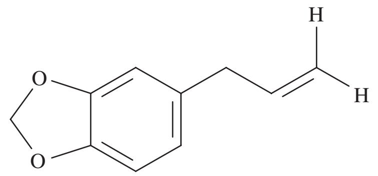

FIGURE 86.1. Chemical structure of safrole.

Concentrations of safrole in most leaf samples are not detectable (i.e., <1.5 ng/mL).[6] Safrole is also present in other spices (e.g., star anise, cumin, nutmeg, mace, black pepper, ginger) as well as betel quid (*Piper betle* inflorescence).[7,8] Methylsafrole (myristicin) is the major aromatic ingredient of nutmeg and mace. Isosafrole (4-propenyl-1,2-methylenedioxybenzene) is an isomer of safrole that occurs in the essential oil of ilang-ilang from the Philippines and in the fruit of Japanese star anise. However, isosafrole is not a constituent of sassafras oil.

Physiochemical Properties

A variety of food processing methods reduce >90% of the safrole content in food including washing and heating the seed at 70 °C (158 °F) for 30 minutes, boiling 5 minutes in distilled water, and sun drying for 48 hours.[8] Safrole is a clear, colorless to slightly yellow liquid with an aromatic odor of sassafras. This compound is water insoluble. Table 86.1 lists some physical and chemical properties of safrole.

Mechanism of Toxicity

Both safrole and its proximate metabolite, 1′-hydroxysafrole, are carcinogenic in animal models with the latter being more potent than the parent compound.[9] The

TABLE 86.1. Physical and Chemical Properties of Safrole

Property	Value

Atmospheric OH Rate Constant	7.56E-11 cm^3/molecule-second (25 °C/77 °F)

carcinogenicity of safrole requires metabolic activation, probably to reactive quinone compounds via *O*-dealkylation to hydroxychavicol followed by oxidation to form the reactive quinone compounds.[10]

DOSE RESPONSE

Although the contents of a single sassafras tea bag may exceed the estimated toxic dose for humans as extrapolated from animal models, there are few clinical data to assess human toxicity. The inadvertent ingestion of 5 mL of sassafras oil was associated with tremulousness and vomiting, but the patient developed no evidence of hepatorenal dysfunction.[11] She recovered without sequelae. A 72-year-old woman developed diaphoresis and hot flashes after the daily ingestion of 10 cups of sassafras tea.[12] All symptoms resolved after she stopped drinking the tea.

TOXICOKINETICS

The absorption and elimination of low doses of safrole in humans is rapid. In a volunteer study, most of a 1.66-mg dose of safrole was eliminated in the urine within 24 hours with conjugated 1,2-dihyrodxy-4-allylbenzene being the main urinary metabolite.[13] This study suggested some differences in metabolism between species. The proximate carcinogen of safrole, 1′-hydroxysafrole, was present in the urine of rats, but not humans, following the oral administration of safrole. The major metabolic pathways for the formation of reactive metabolites are 1) allylic hydroxylation to 1′-hydroxysafrole followed by oxidation and *O*-dealkylation leading to the formation of 4-allyl-*O*-quinone, and 2) epoxidation of the allylic side chain or aromatic ring of safrole.[14] Several CYP450 isoenzymes are involved in the biotransformation of safrole to reactive intermediates. *In vitro* studies of human liver cells indicate that CYP2C9, CYP2A6, CYP2D6, and CYP2E1 are the main cytochrome P450 isoenzymes involved in the biotransformation of safrole to the carcinogen, 1′-hydroxysafrole.[15,16] The conversion of 1′-hydroxysafrole to 1′-sulfoxysafrole by sulfotransferase enzymes followed by the cleavage of the sulfate moiety results in the formation of a carbocation, which can produce DNA damage by covalently binding to nucleophilic sites on macromolecules.

CLINICAL RESPONSE

Acute Effects

There are limited data on the clinical effects of sassafras oil. The ingestion of 5 mL sassafras oil was associated with mild transient symptoms (tremulousness, vomiting),[11] whereas the daily ingestion of 10 cups of sassafras tea produced diaphoresis and hot flashes.[12]

Carcinogenicity

Sassafras oil contains 80% safrole, which is a weak liver carcinogen when fed to rodents in high doses.[17] The International Agency for Research on Cancer (IARC) lists safrole and dihydrosafrole as possible human carcinogens (Group 2B) based on the production of liver and lung tumors in rodents.[18] The US Toxicology Program lists safrole as reasonably anticipated to be a human carcinogen based on the increased incidences of liver hepatocellular carcinomas and cholangiocarcinomas in both sexes of rats and hepatocellular carcinomas in male mice following administration of safrole in the diet.[19] There are no case reports or epidemiological data on the carcinogenicity of safrole in humans.

DIAGNOSTIC TESTING

The use of reversed-phase liquid chromatography with UV detection at 235 nm allows the detection of safrole, isosafrole, and dihydrosafrole at concentrations of 1.5 ng/mL, 1.8 ng/mL, and 3.8 ng/mL, respectively.[6] Other methods to determine the content of safrole and isosafrole include GC and GC/MS.[4,20]

TREATMENT

Treatment is supportive. Gut decontamination measures are not usually necessary.

Chapter 87

SAW PALMETTO
[*Serenoa repens* (Bartram) J.K. Small]

HISTORY

Native Americans used extracts of saw palmetto for the treatment of abdominal disorders and dysentery, whereas the fruit of the plant was a food and nutrient. The crude extracts have been used for centuries to improve breast size, sperm production, and sexual vigor. The American Indians used saw palmetto berries for genitourinary symptoms. In the late 19th century, saw palmetto was investigated for medicinal effects including stimulation of appetite and breast milk, amelioration of ovarian dysfunction, relief of dysmenorrhea and prostatitis, and the treatment of gonorrhea. Saw palmetto was listed as an official drug in the *US Pharmacopoeia* from 1906–1917 and as part of the *US National Formulary* from 1926–1950. Currently, saw palmetto is one of the top five most popular herbal products, primarily as a result of the use of saw palmetto to treat the symptoms related to benign prostatic hypertrophy.[1]

BOTANICAL DESCRIPTION

Common Name: Saw Palmetto, American Dwarf Palm Tree, Sabal

Scientific Name: *Serenoa repens* (Bartram) J.K. Small

Botanical Family: Arecaceae (Palmae, palm)

Physical Description: This palm plant grows up to 10 ft (3 m) tall with fan-shaped leaves being cleft at the apex. In spring, a seed stalk (spadix) sprouts and flowers. Subsequently, a hard green fruit, which is the size of an olive, develops during the summer and turns to varying shades of red and then to black. Harvesting of the mature fruit occurs in late summer and fall.

Distribution and Ecology: *Serenoa repens* grows in the southeastern United States, particularly in the swamps of eastern Florida and southern Georgia. This shrubby palm inhabits areas of the southern Atlantic coast (Carolina's region) and southern United States as far west as Texas. *Serenoa repens* is also indigenous to the West Indies. The berries are typically harvested in late fall and early winter.

EXPOSURE

Sources

Commercially, saw palmetto is available alone (160 mg–585 mg capsules, soft gelcaps, tablet) or in combination with other substances (zinc, pygeum, pumpkin seed oil extract, ginseng, bee pollen, pyridoxine, amino acids).

Medicinal Uses

TRADITIONAL

Traditional uses of *Serenoa repens* extract include breast enhancement, improvement of sexual desire, diuresis, and the treatment of cystitis. Alternative treatments of symptoms associated with prostatic hypertrophy include *Pygeum africanum* Hook.f. (African plum tree), *Hypoxis rooperi* T. Moore (African star grass), and rye grass pollens.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Current

The primary use of saw palmetto is the short-term treatment of urinary symptoms associated with benign prostatic hypertrophy. Saw palmetto is a safe treatment that provides mild to moderate improvement in urinary symptoms and urinary flow measurements in some,[2,3] but not all randomized clinical studies.[4] A meta-analysis of 18 randomized, double-blind clinical trials (10 of them placebo controlled), which involved a 2,939 men with benign prostatic hypertrophy demonstrated superiority of saw palmetto over placebo in the treatment of nocturia. A 6-month double-blind randomized equivalence study compared the effects of saw palmetto extract (320 mg Permixon®; Pierre Fabre Medicament, Boulogne, France) with 5 mg finasteride in 1,098 men with moderate benign prostatic hypertrophy.[5] Both treatments were equally effective in increasing peak urinary flow rates and improving urinary tract symptoms as measured by the International Prostate Symptom Score. However, in contrast to finasteride, prostate size and prostatic specific antigen (PSA) concentrations in the saw palmetto group remained similar to baseline with fewer complaints of decreased libido and impotence in the saw palmetto group. The use of saw palmetto was less effective in clinical trials of more advanced cases of chronic prostatitis. In a prospective, 1-year study of 64 men with category III prostatitis and chronic pelvic pain syndrome, the daily administration of 325 mg saw palmetto did not produce long-term improvement as measured by the National Institutes of Health Chronic Prostatitis Symptom Index and the American Urological Association Symptom Score.[6] In contrast, the use of 5 mg finasteride improved the quality of life and pain scores, but did not produce a statistically significant improvement in symptoms related to urination. Similarly, a double-blind controlled clinical trial of the use of saw palmetto extract (160 mg twice daily) for moderate-to-severe symptoms of benign prostatic hypertrophy did not detect a statistically significant difference between placebo and treatment groups in measures of the quality of life, prostate size, or residual volume.[4] There was no significant difference between the saw palmetto and placebo groups in the change in American Urological Association Symptom Index scores (mean difference = 0.04 point; 95% CI: —0.93–1.01), or in maximal urinary flow rate (mean difference = 0.43 mL/min; 95% CI: –0.52–1.38).

Regulatory Status

Saw palmetto extracts are classified as dietary supplements by the US Food and Drug Administration (FDA). The German Commission E approved the use of saw palmetto for urinary problems associated with benign prostatic hyperplasia stages 1 (abnormal frequent urination, nocturia, delayed urination onset, weak urinary stream) and stage 2 (urge to urinate, residual urine). Although there are few data, saw palmetto is not recommended for use in children and pregnant women.[7] Permixon® is available in Europe, but not in the United States.

PRINCIPAL INGREDIENTS

Chemical Composition

Saw palmetto (Permixon®) is an *n*-hexane lipidosterolic extract of the berries from *Serenoa repens* (American dwarf palm tree). This drug is a complex mixture primarily of free fatty acids (90%) and related esters (7%) along with small amount of phytosterols (campesterol, β-sitosterol, stigmasterol),[8] aliphatic alcohols (C_{26}, C_{28}, C_{30}), and various other compounds (arabinose, flavonoids, galactose, glucose, uronic acid). The unsaturated and unsaturated fatty acids include capric, caproic, caprylic, lauric, linolenic, myristic, isomyristic, oleic, palmitic, and stearic acids, whereas the phytosterols include β-sitosterol, campesterol, stigmasterol, cycloartenol, lupeol, and lupenone. The major free fatty acids are oleic acid, lauric acid, myristic acid, and palmitic acid. The remaining components include carotene, lipase, and tannin. In contrast to most other herbs, there is no specific chemical constituent of saw palmetto that is a marker for product standardization. The composition of saw palmetto preparations in the United States is generally similar to marker compounds on the label. Analysis of eight US saw palmetto products indicated that the total free fatty acids content as measured by gas chromatography with flame ionization detection (GC/FID) ranged from 77–106% of the stated amounts.[9]

Physiochemical Properties

The lipidosterolic extract of saw palmetto berries has multiple effects including inhibition of 5α-reductase, which is the isoenzyme that converts testosterone to the biologically more potent dihydrotestosterone. The human prostate contains type I and type II isoenzymes of 5α-reductase with the latter being the most important isoform. Saw palmetto is a noncompetitive inhibitor of both type I and type II isoenzymes, whereas the synthetic 5α-reductase inhibitor, finasteride (Proscar®; Merck & Co., Whitehouse Station, NJ), is a selective competitive inhibitor of type II 5 α-reductase.[10] Saw palmetto extract also possesses anti-androgen effects by inhibiting the binding of dihydrotestosterone to cytosolic androgen receptors in prostatic cells as well as

anti-inflammatory effects by reducing arachidonic acid metabolites by inhibiting aromatase cyclooxygenase and lipoxygenase.[11] Unlike other 5α-reductase inhibitors, lipophilic extracts of saw palmetto block the 5α-reductase activity of prostatic epithelial cells without interfering with the secretion of the prostate tumor marker, PSA.[12]

Mechanism of Action

Saw palmetto has several effects, but the exact mechanism responsible for improvement of urinary tract symptoms associated with benign prostatic hypertrophy is unclear.[13,14] Androgens have a significant effect on prostate growth, and dihydrotestosterone comprises about 95% of the total androgenic steroid content within the prostate cell nuclei.[15] Possible mechanisms of action of saw palmetto on the prostate include inhibition of 5α-reductase, which is the enzyme that converts testosterone to dihydrotestosterone and inhibition of the binding of dihydrotestosterone to androgen receptors in prostate cells. However, clinical trials comparing the 5α-reductase inhibitor, finasteride, with saw palmetto indicate that the saw palmetto extract, Permixon®, has little effect on androgen-dependent parameters compared with finasteride.[5] In a 1-week open, randomized, placebo-controlled study of 32 healthy male volunteers, 5 mg finasteride daily reduced the serum dihydrotesterone concentration an average of 65%, whereas there was no significant difference in serum dihydrotesterone concentrations between placebo and Permixon® 80 mg twice daily.[16] Other potential mechanisms based on animal studies involve inhibition of growth factors associated with proliferation of prostate cells, reduced prolactin binding, and decreased arachidonic acid metabolites from inhibition of 5-lipoxygenase.[17]

DOSE RESPONSE

Typical medicinal doses of saw palmetto are 160–320 mg daily of the lipophilic extract containing 80–90% volatile oils or 1–2 g of the dried saw palmetto fruit. Tea products are considered ineffective because of the lack of volatile oils.[18] Symptomatic relief may take up to 6 weeks to occur. The toxic dose of saw palmetto is not well defined.

TOXICOKINETICS

Kinetics

Because saw palmetto is a complex mixture of free fatty acids and other compounds, there are few data on the pharmacokinetics of this lipidosterolic extract. The dosage of saw palmetto refers to milligrams of the plant extract administered, and the portion of the extract studied is determined by the migration of the extract on the chromatograph. A study of 12 healthy volunteers ingesting 320 mg saw palmetto determined the pharmacokinetic parameters of the second component of saw palmetto based on high performance liquid chromatography (HPLC) with a retention time of 26.4 minutes.[19] Oral absorption was relatively low. The peak time to oral absorption is 1.5 hours with a mean peak plasma concentration of 2.58 μg/mL (range: 2.3–2.9 μg/mL). The elimination half-life was approximately 1.9 hours.

Drug Interactions

In vivo studies with single-time-point phenotypic ratios indicate that there is minimal risk of saw palmetto–drug interactions based on lack of effect on CYP1A2, CYP2D6, CYP2E1, and CYP3A4 isoenzymes.[20] The interaction of saw palmetto with other drugs during the treatment of urinary tract symptoms is rare.[21] In a study of 12 healthy volunteers receiving 320 mg saw palmetto daily for 14 days, the drug probe substrates dextromethorphan (CYP2D6 activity) and alprazolam (CYP3A4 activity) were administered to compare the baseline and posttreatment activity of these cytochrome P450 isoenzymes.[22] The lack of significant change in activity suggests that short-term saw palmetto therapy does not alter the metabolism of drugs dependent on CYP2D6 and CYP3A4 isoenzymes. Serious intraoperative bleeding developed during resection of a meningioma in a 53-year-old man, who used saw palmetto for benign prostatic hypertrophy.[23] The prothrombin (PT) and activated partial thromboplastin time (aPTT) were normal, but the bleeding time was prolonged to 21 minutes (normal: 2–10 minutes). After cessation of saw palmetto, the bleeding time returned to normal values within 5 days.

CLINICAL RESPONSE

Adverse effects associated with the use of saw palmetto are uncommon and typically involve mild gastrointestinal distress.[24] Reported adverse effects include gastrointestinal upset, abdominal pain, nausea (about 2%), vomiting, diarrhea, muscle pain, rhinitis (8.6%) headache (8%), dizziness (3%), and xerostomia (1%). Orthostatic hypertension was noted in 1.1 % of individuals treated with 320 mg for 12 months. Other cardiovascular effects include tachycardia and exacerbation of angina pectoris. Genitourinary effects include reduced libido, ejaculation disorders, and urinary retention. Case reports have associated the use of saw palmetto with

cholestatic hepatitis, cholecystitis, and intraoperative hemorrhage.[23] None of the above adverse effects appear to result from a dose-effect relationship. Adverse effects occur in less than 5% of patients in clinical trials. Case reports indicate that rarely an allergic contact dermatitis can develop following the chronic topical application of saw palmetto extract.[25]

DIAGNOSTIC TESTING

There are no specific analytical methods for evaluating saw palmetto because there are no biomarkers or well-defined chemical constituents of saw palmetto. The use of saw palmetto does not affect determination of serum PSA concentrations.

TREATMENT

Gut decontamination is unnecessary. The treatment of adverse effects is symptomatic and supportive; there is no specific therapy for exposure to saw palmetto.

Chapter 88

SENNA
(*Senna alexandrina* P. Mill.)

HISTORY

The history of senna dates back at least to the 9th century AD, when Arabian physicians used both the pod and leaves for the treatment of constipation.

BOTANICAL DESCRIPTION

Common Name: Alexandrian Senna, Indian or Tinnevelly Senna, True Senna

Scientific Name: *Senna alexandrina* P. Mill. (*Cassia acutifolia* Delile, *Cassia angustifolia* Vahl, *Cassia lanceolata* Forssk., *Cassia senna* L.)

Cassia acutifolia Delile and *Cassia angustifolia* Vahl are no longer considered separate species in the genus *Senna*.

Botanical Family: Fabaceae

Physical Description: This annual herb reaches up to 1 m (~3 ft) in height. The leaves are alternate with 3–7 pairs of leaflets. Yellow flowers appear in erect terminal racemes that produce a broadly elliptical, flattened, parchment-like, dehiscent pod containing 6–10 seeds. The oblong pods are yellow-green to yellow-brown with a dark brown central area.

Distribution and Ecology: Senna is indigenous to tropical Africa, and this plant has naturalized near the Nile River from Aswan to Kordofan as well as the Arabian Peninsula, India, and Somalia. These small shrubs are cultivated in areas near Somalia, Sudan, the Arabian Peninsula, and the upper Nile River, as well as South India and Pakistan.

EXPOSURE

Sources

Senna consists of dried leaves or fruits of *Senna alexandrina* P. Mill. (formerly *Cassia senna* or *Cassia acutifolia*). Folium sennae consists of the dried leaflets of *Senna alexandrina*, whereas fructus sennae is derived from the dried ripe fruit. Branches with leaves and pods are dried in the sun before separating the leaves and pods for sale. Whole leaves are sold as herbs, while broken leaves are used as galenicals. Senna products include senna leaf powder (Herb-Lax®; Shaklee Corp., Pleasanton, CA), senna tea, senna pod concentrate, senna syrup, senna fluid extract, and senna fruit extract along with tablets containing sennosides A and B. A variety of commercial senna-containing products are available, such as Senokot® (Purdue Pharma, Stamford, CT), Dr. Caldwell's Senna Laxative® (Sterling Drug, New York, NY), and Fletcher's Castoria® (Rohto Pharmaceutical Co. Ltd, Osaka, Japan).

Medicinal Uses

Traditional

Senna is a well-known herbal drug in both Ayurvedic and Allopathic systems of medicine for the treatment of constipation. Other traditional uses of senna include the treatment of gonorrhea, bronchial congestion, wounds, diarrhea, intestinal gas, skin diseases, dyspepsia, fever, and hemorrhoids.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Current

Although senna has been used for centuries as a peristaltic stimulant laxative, there are few data on the efficacy of this herb for the treatment of chronic constipation.[1] In a study of 50 geriatric patients, senna (Senokot®) and sodium picosulfate (unavailable in the United States) were equally effective laxatives with few adverse effects.[2] A study of elderly psychiatric and mentally handicapped patients did not detect a significant difference in the efficacy of a bulk laxative (bran) and senna (Senokot® syrup).[3] Senna is also a constituent in some hair dyes.

Regulatory Status

Most pharmacopoeias recommend evaluation of the total senna leaf glycoside content based on sennoside B (e.g., 2.5% in the German *Pharmacopoeia* for senna leaves). The German Commission E approves the use of senna pod and senna leaf as laxatives. In the United States, senna is available in a variety of over-the-counter products for the treatment of constipation.

PRINCIPAL INGREDIENTS

Chemical Composition

The main active ingredients in senna are dianthrone compounds from the anthraquinone family, called sennosides. These compounds are prodrugs for the peristalsis-stimulating dianthrone and anthraquinone compounds. The most common sennosides are sennoside A and B (i.e., about 1–2.5%), which hydrolyze to the corresponding aglycone (sennidin) and two molecules of glucose.[4,5] Smaller concentrations of sennoside C and D occur in the leaves and fruits along with naphthalene glycosides (6-hydroxymusicin glucoside, tinnevellin glucoside), monomeric glycosides, and free anthraquinone compounds (aloe-emodin, emodin, rhein).[6] Figure 88.1 displays the chemical structures of sennosides A–D. Minor constituents of senna include kaempferol (yellow flavonol) and related glucoside, isorhamnetin, calcium oxalate, and sterol glucosides. The concentration of sennosides depends on a variety of factors including the plant part, the growing season, and the extraction process.

Physiochemical Properties

Sennoside A and B are highly hydrophilic with a large molecular mass (863 Da). Neither sennosides nor rhein increase the permeability of the mucosa in the colon or enhance intestinal protein loss. Some degradation of sennosides occurs during the storage of crude senna plant materials as a result of the formation of sennidin glycosides from sennosides and the hydrolysis of rhein-8-*O*-glucoside to rhein by enzymatic processes.[7]

Mechanism of Toxicity

Sennosides and their degradation products affect both motility and secretory activity in the colon independent of any nonspecific irritation or increase in gut permeability. As a result of the decreased intestinal transit time, fluid absorption decreases. At lower doses, motility effects of senna predominate, whereas at higher doses the secretory actions of senna dominate. The effects of senna result from direct stimulation of neuronal

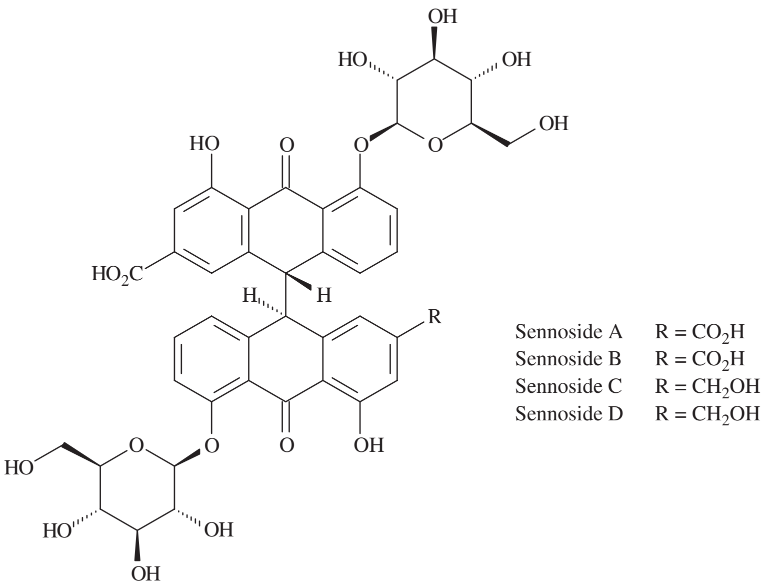

FIGURE 88.1. Chemical structures of sennosides A–D.

receptors, neurohumoral mechanisms, and alteration of prostaglandin E_2 concentrations.[8] In clinical studies, high doses of sennosides induce acute massive cell loss in colonic mucosa, probably by apoptosis.[9] This action reduces the length of crypts. To restore cellularity, a reduction in apoptosis and an increase in cell proliferation occur. Damaged epithelial cells appear as apoptotic bodies in the pigmented colonic mucosa that characterizes *pseudomelanosis coli*.[10]

DOSE RESPONSE

The typical dose for adults and children over 10 years of age is 1–2 g of the leaf powder at bedtime. The standardized daily dose is equivalent to 10–30 mg sennosides (calculated as sennoside B). The toxicity of senna is relatively low. The most serious adverse effects are fluid and electrolyte abnormalities from chronic abuse of senna products. In rats, gavage with purified sennosides (25, 40, 64 mg/kg) reversed the net absorption of fluid and produced diarrhea in a dose-dependent relationship.[11]

TOXICOKINETICS

Sennosides are natural prodrugs, which undergo degradation by intestinal bacteria to the active compound, rhein anthrone, in the lower gastrointestinal tract. The large molecular mass and poor lipid solubility of sennoside A and B limit the absorption of these dianthrone compounds. Human digestive enzymes do not split the β-glycoside bond in sennosides. Consequently, these compounds pass through the upper intestinal tract to lower gastrointestinal tract where intestinal bacteria hydrolyze sennosides A and B (dianthrone-*O*-glycosides) to the corresponding anthraquinone aglycone followed by the reduction of these compounds to the corresponding pharmacologically active anthrone (i.e., rhein anthrone). Figure 88.2 demonstrates the metabolism of sennosides by bacteria to rhein. *In vitro* experiments indicate that several bacteria in the human intestine can hydrolyze sennosides including *Streptococcus faecalis, Streptococcus faecium*, and *Bacteroides fragilis*.[12] Bacteria capable of reducing the anthraquinone aglycone to rhein include *Clostridium perfringens*, *Peptostreptococcus intermedius*, and *Eubacterium limosum*.[13]

Physiochemical factors and increased peristalsis limit the absorption of rhein anthrone by the large intestine; therefore, most of the rhein anthrone is excreted in the feces.[14] Rhein anthrone does not undergo first-pass metabolism. Peak concentrations of rhein (i.e., the oxidized product of rhein anthrone) occur about 3–5 hours and 10–11 hours after administration, probably as a result of the absorption of free rhein in the senna and the absorption of rhein after the degradation of sennosides.[15] The mean elimination half-life of rhein is about 7 hours.[15] Animal studies indicate that excretion of absorbed anthraquinone aglycone compounds occurs in the bile and urine after conjugation to the glucuronide or sulfate.[16] The excretion of rhein in breast milk after ingestion of senna is small. After the ingestion of a senna laxative containing 15 mg sennosides daily for 3 days, the concentration of rhein in breast milk was <10 ng/mL in 94 of 100 breast milk samples from 20 lactating women.[17] Aloe-emodin probably does not accumulate in the body after the administration of therapeutic doses of senna.

CLINICAL RESPONSE

Acute Effects

The onset of action of senna is about 8–10 hours after ingestion.[18] Potential adverse effects of chronic laxative abuse include fluid, electrolyte (hypokalemia), and acid-base imbalances (metabolic alkalosis). Several case reports associated the development of mild to moderate

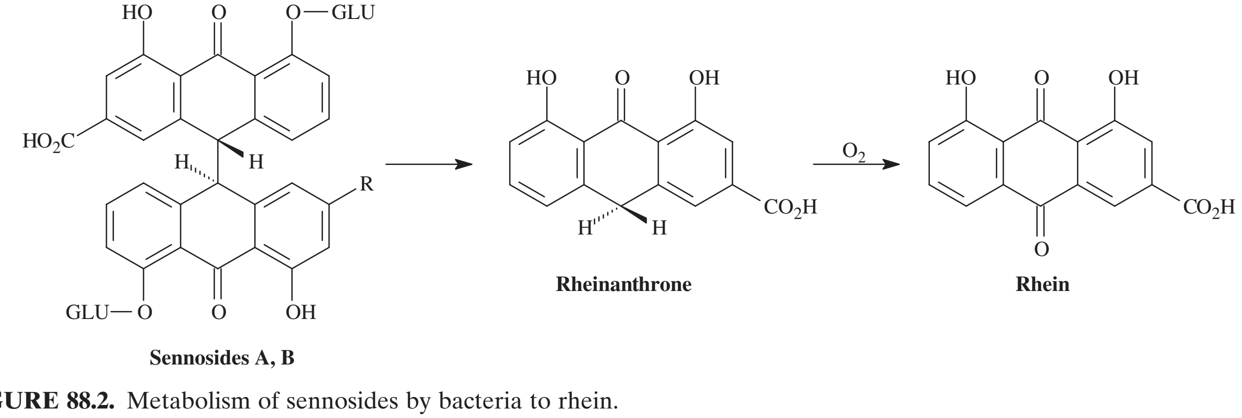

FIGURE 88.2. Metabolism of sennosides by bacteria to rhein.

hepatitis including cholestatic jaundice with chronic, large doses of senna.[19] In these case reports, reintroduction of senna laxatives was associated with mild elevation of serum hepatic aminotransferase concentrations.[20] Pharmacogenetic studies in one of these case reports suggested that inhibition of CYP2D6 activity (i.e., CYP2D6*4 variant) increased the risk of developing hepatitis following the use of senna laxatives.[21] Occasionally, sensitization occurs in workers exposed to dusts from senna during the manufacturing of senna laxatives. A cross-sectional study of 125 pharmaceutical workers involved in the manufacturing of bulk laxatives based on psyllium and senna pods demonstrated senna sensitization in about 15% of these workers.[22] The incidence of sensitization was particularly high in atopic workers and smokers. However, the risk of developing asthma was not increased in sensitized workers when compared with nonsensitized workers. Rare case reports associated occupational exposure to senna with asthma and allergic rhinitis, usually in atopic workers.[23]

Chronic Effects

Crude senna extracts and several minor anthranoid constituents (aloe-emodin, emodin) cause mutagenic effects in some, but not most *in vitro* studies.[24–25] Fluid and electrolyte imbalance are potential complications of chronic laxative abuse with senna extracts. A case report associated the chronic use of senna tea (daily ingestion of 1 L senna tea for over 3 years) with the development of hepatorenal failure and encephalopathy.[26] Analysis of concurrent tea samples failed to detect any adulterants including heavy metals. However, there was no rechallenge or analysis of serum samples for sennosides; therefore, the causal link remains weak and speculative.

Although some studies suggest that the chronic use of anthranoid laxatives increases the risk of colorectal cancer,[27] there is no direct evidence that the use of senna increases the risk of cancer. A 2-year carcinogenic study of Sprague-Dawley rats receiving 0, 5, 15, and 25 mg/kg purified senna extract via drinking water did not detect an increased incidence of neoplastic lesions in the exposed group.[28] Sennoside A and B account for about 25% of the purified extract. Although the high dose was near the maximum tolerated dose (i.e., 7% weight loss compared with controls), there were no ultrastructural changes in the myenteric nerve plexus of the colon or jejunum. No treatment-related neoplastic changes were detected in Sprague-Dawley rats gavaged with up to 300 mg/kg crude senna extract daily for 2 years.[29] All treatment groups had some minimal to slight hyperplasia of the mucosa in the colon and cecum, but these changes were reversible. The International Agency for Research on Cancer (IARC) does not list senna as a suspected carcinogen. There is no evidence that the ingestion of senna laxatives in therapeutic doses during pregnancy increases the risk of fetal abnormalities.

DIAGNOSTIC TESTING

High performance liquid chromatographic techniques with reverse-phase chromatography[30] or ion-pair liquid chromatography[31] can separate various sennosides with limits of detection of the former method in the range of 0.5 ng/mL.[4] Gas chromatography/mass spectrometry techniques can separate and quantitate various laxatives including senna with limits of detection in the range of 10–25 ng/mL in full-scan mode.[32] Using this procedure, rhein was detectable in the urine for 24 hours after the ingestion of a therapeutic dose of senna extract. Other procedures for the detection of sennosides include reversed-phase column liquid chromatography.[33] Metabolites of anthranoid compounds in senna produce discoloration of the urine that can cause false-positive tests for urinary urobilinogen.

TREATMENT

Treatment is supportive. Patients with chronic laxative abuse should be evaluated for evidence of fluid and electrolyte imbalance. Severe hypokalemia may develop following chronic abuse of senna.

Chapter 89

SKULLCAP
(*Scutellaria lateriflora* L.)

HISTORY

American skullcap (*Scutellaria laterifolia*) has a long tradition of use by Native Americans in North America as a tonic and tranquilizer. The term mad-dog weed derives from the use of skullcap to treat rabies in the 18th century.

BOTANICAL DESCRIPTION

Scutellaria lateriflora L. is one American species of approximately 300 species of *Scutellaria* worldwide. Other *Scutellaria* species used as herbal medicines include *S. baicalensis* Georgi (eastern Asia, huang-qin), *S. barbata* D.Don (southern China, ban-zhi-lian), *S. pinnatifida* A. Hamilt. subsp. *alpina* (Iran), *S. planipes* Nakai & Kitagawa (Argentina, China), and *S. amabilis* Hara (Japan, yamaji-tatsunamisou). Contamination of skullcap with hepatotoxic species of germander (*Teucrium* spp.) can be recognized by digital photomicroscopy of the cell structures of these herbs.[1]

Common Name: Blue Skullcap, Mad Dog Skullcap, American Skullcap, Skullcap, Madweed

Scientific Name: *Scutellaria lateriflora* L.

Botanical Family: Lamiaceae (menthes, mints)

Physical Description: Skullcap is a slender, heavily branched plant that reaches 2–4 ft (~0.6–1.2 m) in height. In July, small, blue flowers appear that contain an outer whorl shaped like a cap. The name skullcap derives from the helmet-shaped upper lid of the seed pods from this perennial plant.

Distribution and Ecology: *Scutellaria lateriflora* is a perennial herb indigenous to North America that is cultivated in Europe. This plant grows in meadows and swampy woods from Canada to Florida and westward in North America to New Mexico, Oregon, and British Columbia.

EXPOSURE

Sources

Skullcap is available as a tea, liquid extract, tincture, capsule, and crude root extract. In health food stores, *S. lateriflora* typically is available as a tonic or as an herbal combination of valerian, passionflower, and skullcap for sleeping. Hydro-distillation of the dried aerial parts of *S. barbata* yields about 0.2–0.3% yellow essential oil.[2]

Medicinal Uses

TRADITIONAL

Extracts of *S. lateriflora* are traditionally used as a nerve tonic, antispasmodic, diuretic, anticonvulsant, sedative, and tranquilizer. In traditional Chinese medicine, huang-qin (*S. baicalensis* Georgi) is an herbal treatment for fever, inflammation, bacterial and viral infections, elevated cholesterol, hypertension, ulcers, neonatal jaundice, and cancer.

CURRENT

Although skullcap is promoted as a sedative and antispasmodic for the treatment of anxiety, menstrual

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

tension, depression, and muscle spasms, there are few clinical data to support the use of this herb for these purposes.

Regulatory Status

The US Food and Drug Administration (FDA) regulates this herb as a dietary supplement, but the safety of skullcap has not been determined. Huang-qin (i.e., root of *Scutellaria baicalensis*) is officially listed in the Chinese *Pharmacopoeia*. Skullcap is approved as a nonprescription medication in Canada and is available in the United Kingdom. Skullcap in not listed in the German Commission E monographs.

PRINCIPAL INGREDIENTS

Chemical Composition

The dried roots from *Scutellaria* species contain over 30 flavone compounds with phenylethanoids, amino acids, sterols, and essential oils. Major flavonoids in *Scutellaria* species include baicalein, wogonin, baicalein glucuronide (baicalin), wogonin-6-*O*-glucuronide (wogonoside), chrysin, scutellarin, scutellarein (isocarthamidin), and oroxylin A.[3,4] Minor flavonoid compounds include dihydrobaicalin, ikonnikoside I, lateriflorin, oroxylin A-7-*O*-glucuronide, apigenin, wogonin-7-*O*-glucuronide, chrysin-7-*O*-glucuronide, and numerous other flavonoid compounds.[5] Figure 89.1 displays the chemical structures of several major flavonoid compounds in skullcap. The concentration of flavonoid compounds in roots from *Scutellaria* species depends on several variables including the extraction process, plant species, plant part, and growing conditions.[6] In a study of the methanol extract of roots from *Scutellaria baicalensis*, the most common flavanoid compounds were baicalin (8.12% of dry root mass) and wogonoside (2.52% of dry root mass). The concentration of baicalein was low (<0.01%). Typically, the concentration of baicalin is much greater in the root of *Scutellaria* species than baicalein, oroxylin A, or wogonin.[7] In a study of an aqueous ethanol extract of *S. baicalensis* root, the concentration of the major flavonoid compounds by dry weight were as follows: baicalin 144 μg/mg; baicalein, 29.6 μg/mg; and wogonin, 9.7 μg/mg.[8] The crude solvent extract of dried roots from *S. baicalensis* contained about 30% baicalein, 11% wogonin, and 2.5% oroxylin A, as measured by high-speed counter-current chromatography.[9]

Hydro-distillation of aerial parts from *Scutellaria* species produces essential oils consisting primarily of oxygenated monoterpene (menthol, linalool, α-terpineol, thymol) and sesquiterpene (α-*trans*-bergamotol, globulol) compounds.[2] Other compounds include methyl eugenol, hexahydrofarnesylacetone, 1-octen-3-ol, and 3,7,11,15-tetramethyl-2-hexadecen-1-ol. The predominate compounds in an Iranian sample of a hydro-distilled essential oil from dried aerial parts of Iranian skullcap (*S. pinnatifida* A. Hamilt. subsp. *alpina*) were germacrene-D (39.7%) and β-caryophyllene (15%).[10] All other compounds were present in concentrations ≤5%.

Physiochemical Properties

Baicalin and wogonoside are polar glycoside compounds with poor lipid solubility in contrast to their relatively nonpolar, lipophilic aglycones, baicalein and wogonin. Based on receptor binding studies, the affinity of flavonoid compounds in *Scutellaria* roots for the benzodiazepine site of the $GABA_A$ receptor is as follows: wogonin, K_i = 2.03 ± 0.24 μM; baicalein, K_i = 5.69 ± 0.95 μM; scutellarein, K_i = 12 ± 1.27 μM; and baicalin, K_i = 77.10 ± 4.79 μM.[11]

Mechanism of Toxicity

The toxicity of this herb has not been established.

DOSE RESPONSE

There is no standard dose of skullcap.

TOXICOKINETICS

Absorption

Bioactive flavonoid compounds in skullcap include baicalin and the aglycone, baicalein along with wogonoside and the associated aglycone, wogonin. Typically, absorption of the aglycone occurs after the hydrolysis

	R_1	R_2	R_3
Baicalein	H	OH	OH
Baicalin	H	O-glucuronyl	OH
Wogonin	OCH_3	OH	H
Wogonoside	OCH_3	O-glucuronyl	H
Oroxylin	H	OH	OCH_3

FIGURE 89.1. Chemical structures of baicalein, baicalin, wogonin, wogonoside, and oroxylin.

of the flavonoid glycoside by intestinal bacteria, but conjugation of the aglycone by hepatic microsomes during first-pass metabolism restores the original glycoside following absorption of the aglycone.[12] In human volunteers receiving baicalin, detectable (i.e., >5 ng/mL) and peak plasma baicalin concentrations occurred about 1 hour and 5 hours, respectively, after oral administration.[13]

Distribution

The low lipid solubility of baicalin probably limits the diffusion of this compound across the blood–brain barrier.

Biotransformation

The major metabolites of baicalin following oral administration are baicalein-6-*O*-sulfate and baicalein-7-*O*-glucuronide (baicalin).[13] Following the ingestion of herbs containing baicalin and wogonoside by 10 healthy male volunteers, conjugated metabolites of these two compounds accounted for 11.6% and 7.2%, respectively, of the total administered dose.[14]

Elimination

Based on animal studies, baicalin probably undergoes hepatobiliary excretion.[15] The plasma elimination half-lives of baicalein and wogonin conjugates were approximately 8 hours and 10 hours, respectively.[14] The kidneys excrete little free baicalin or wogonin in the urine.

Drug Interactions

In vitro studies suggest that extracts of *Scutellaria* species inhibit CYP1A2 and CYP3A4, but the clinical significance of these potential interactions remain undetermined.[16,17]

CLINICAL RESPONSE

Rare case reports associate the ingestion of skullcap with hepatic toxicity.[18] However, the role of skullcap in producing hepatotoxicity is unclear because of the potential contamination of this herb with germander (*Teucrium* spp.) and the lack of hepatotoxic diterpene compounds in skullcap. There are few experimental data to support the hepatotoxicity of skullcap.

DIAGNOSTIC TESTING

Methods for the detection of flavonoid compounds in *Scutellaria* species include thin-layer chromatography,[11] capillary electrophoresis, gas chromatography, high-speed counter-current chromatography,[19] solid-phase or reverse-phase high performance liquid chromatography (HPLC), HPLC with diode array and mass spectrometric detection,[20] and micellar electrokinetic capillary chromatography.[21] Extracts of skullcap contaminated with germander (*T. canadense, T. chamaedrys*) can be identified by the presence of phenylpropanoid compounds (verbascoside, teucrioside).[1] The major compounds in extracts from *Teucrium canadense* and *Teucrium chamaedrys* are verbascoside and teucrioside, respectively, whereas these compounds are not present in extracts of skullcap (*Scutellaria* spp.). The latter extracts contain predominantly flavonoid compounds (baicalin, wogonin, baicalein, wogonoside).

TREATMENT

Treatment is supportive.

Chapter 90

ST. JOHN'S WORT
(*Hypericum perforatum* L.)

HISTORY

Carolus Linnaeus first described *Hypericum perforatum* L. in 1753. This plant has been used for centuries as a medicinal plant to treat neuralgias and minor skin lesions.[1] In antiquity, Dioscorides cited St. John's wort as a remedy for sciatica and skin wounds during the Middle Ages.[2] In Europe, this herb was available commercially in the mid-20th century. In 1984, the German Commission E monograph recommended the use of *Hypericum* for "psychogenic disturbances, depressive states, anxiety, and/or nervous excitement." [2]

BOTANICAL DESCRIPTION

Common Name: St. John's Wort

This common name relates to the fact that the plant blooms around St. John the Baptist Day (June 24th).

Scientific Name: *Hypericum perforatum* L.

Botanical Family: Clusiaceae

Physical Description: St. John's wort is a perennial herbaceous plant with mature stems and branches that are smooth without hairs (glabrous). Young stems have two ridges on opposite faces. Leaves are simple, without stalks (apetiolate) and elliptic, oblong or ovate in shape; 10–25 mm (~0.4–1 in.) long and 2.5–11 mm (~0.1–0.4 in.) wide; usually with five lateral veins; apex obtuse and base clasping. Flowers are bisexual and radially symmetrical, borne in flat or round topped inflorescences; sepals 5, 2.5–4 mm (~0.1–0.2 in.) long; petals 5, yellow and usually with black-spots, 7–10 mm (~0.3–0.4 in.) long; the pollen receptive part (stigma) of the female organ of the flower is a head-shaped cluster (capitate) that connects to the ovary with three narrow, about 3–5 mm (~0.1–0.2 in.) long, separate tubes (styles), trisegmented ovary. Fruits are ovoid capsules, 3.5–5.5 mm (~0.1–0.2 in.) long, 2.5–4 mm (~0.1–0.2 in.) wide; the brown seeds are numerous, averaging about 1 mm (~0.04 in.) in length.

Distribution and Ecology: This plant is native to Europe, North Africa, and western Asia. In Africa, Asia, Australia, and the Americas, St. John's wort has become a naturalized plant. A common habitat for this plant includes neglected fields, dry pastures, rangelands, and the sides of country roads.

EXPOSURE

Sources

Hypericum extract (CAS RN 84082-80-4) is an extract of capsules, leaves, flowers, and stems of *Hypericum perforatum* (St. John's Wort) prepared by crushing these parts in stabilized olive oil over several weeks followed by dehydration and filtration.

Medicinal Uses

TRADITIONAL

St. John's wort consists of the leaves and flowering tops of *Hypericum perforatum* L. Traditional uses of *Hypericum* extract include the treatment of anxiety, depres-

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

sion, insomnia, wounds, neuralgia, fibrositis, sciatica, gout, gastritis, rheumatism, bronchitis, hypothyroidism, and excitability.[3] Topically, this herb has been used as an astringent for burns, abrasions, hemorrhoids, vesicles, and bites.[4] Extracts and oils from *Hypericum perforatum* are biological additives in some cosmetic formulations at concentrations of 0.01–0.5%.[5]

Current

Botanical formulations are commercially available as herbal preparations in the forms of tea, tincture, tablet, and capsule usually containing about 300 mg hypericin. Hypericum extract is a popular alternative treatment for mild to moderate depression. Interpretation of clinical studies on the effectiveness of hypericum extract for the treatment of depression is complicated by numerous methodological flaws including lack of objective diagnostic criteria for depression, the use of subclinical doses of comparison antidepressants, high placebo responder rates of mild depression, limited analysis of adverse drug reactions, and lack of extended follow-up.[6] Several meta-analyses of the clinical effectiveness of hypericum extracts suggest that this herb is more efficacious for *mild* to *moderate* depression than placebo and as effective as low doses of some tricyclic antidepressants.[7,8] However, in a large-scale, multicenter, randomized, placebo-controlled trials of participants with *major* depressive illness, the use of St John's wort did not produce significant difference on any outcome measure when compared with placebo.[9,10]

Regulatory Status

Hypericum extracts are classified as dietary supplements by the US Food and Drug Administration (FDA). Some US manufacturers of herbal products obtain *US Pharmacopoeia* (*USP*) recognition for consistent product purity and potency. The German Commission E approved the use of hypericum as an herbal medicine for depression, insomnia, anxiety, and other psychogenic disturbances. Current hypericum preparations are standardized to a fixed hypericin content of 0.3%. Total hypericin content usually includes both hypericin and pseudohypericin.[3]

PRINCIPAL INGREDIENTS

Chemical Composition

Hypericum perforatum contains at least 10 classes of biologically active substances that vary in concentration among individual plants depending on a variety of factors including the extraction process, plant location, and environmental conditions (growing conditions, season, stage of plant development).[1] Biologically active constituents account for about 15–20% of the plant extract.[11,12] These compounds include phenylpropanes (chlorogenic acid, *p*-coumaric acid), flavonol glycosides (quercetin, hyperin, rutin, isoquercitrin, quercitrin, luteolin, campferol, myricetin), biflavones (biapigenin, amentoflavone), tannins-proanthrocyanidins (procyanidin B2, catechin, epicatechin), xanthones (kielcorin, 1,3,6,7-tetrahydroxyxanthone, mangiferin), phloroglucinols (hyperforin, adhyperforin, hydroperoxycadiforin), essential oils (α-pinene, β-pinene, myrcene, limonene), amino acids, γ-aminobutyric acid, and naphthodianthrones (hypericin, pseudohypericin, cyclopseudohypericin). Figure 90.1 displays the chemical structure of most important constituents, hypericin (CAS RN: 548-04-9) and hyperforin (CAS RN: 11079-53-1).

St. John's wort is an air-dried methanol or ethanol extract of the buds and flowers of *Hypericum perforatum*. These aerial parts are typically collected just before or during blossom. The composition of St. John's wort preparations in the United States is similar to marker compounds on the label. Analysis of 10 St. John's wort products from the US market indicated that the total hypericin content ranged from 88–110% of the stated amounts with one outlier at 139%.[13] There is substantial

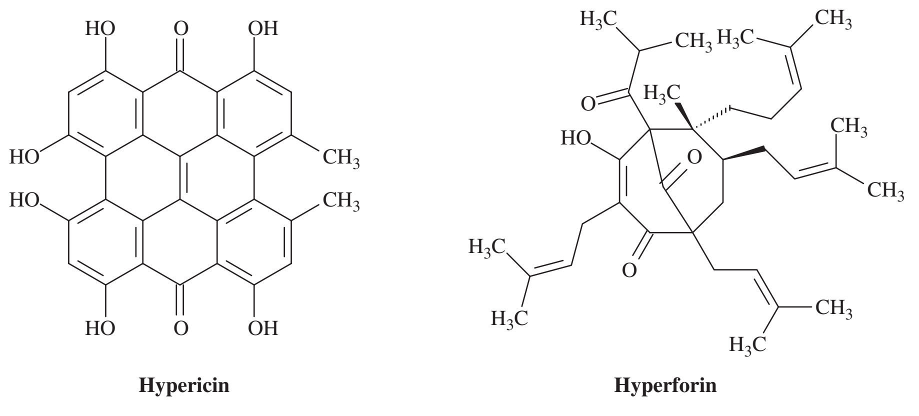

FIGURE 90.1. Chemical structures of hypericin and hyperforin.

variation in the standardization of active ingredients (hypericin, pseudohypericin) in batches of St. John's Wort.[14] In a study of the major components of eight commercially available dry extracts of *Hypericum perforatum*, the approximate content of the active ingredients from the dry extract was as follows: hypericin, 0.19–0.3%; hyperforin, 1.3–3.9%; and flavonoids (calculated as rutin), 4.8–11.4%.[15] Other components included water-soluble sugars, citric acid, malic acid, tannins, and ash. The flowering portion of the plant contains naphthodianthrones (hypericin, pseudohypericin). Numerous flavonoid compounds (hyperoside, campferol, luteolin, isoquercitrin, quercitrin, myricetin, quercetin) are present in aboveground portions of the plant.[1] Hypericin and pseudohypericin account for almost all of naphthodianthrone compounds in the extract, whereas the raw plant contains very small amounts of these compounds. During the extraction process, a photodynamic reaction converts most of the protohypericin and protopseudohypericin to hypericin and pseudohypericin, respectively.[16] The flowers and buds also contain biologically active phloroglucinol compounds (hyperforin, adhyperforin).[17] Other compounds present in hypericum preparations that do not possess any antidepressant activity include amino acids, phenylpropanes, coumarin, tannins, and procyanidins.[1]

Physicochemical Properties

Some of the aromatic compounds in the leaves and flower buds of hypericum turn red when exposed to light. Hyperforin decomposes during storage at room temperature.[15] Because of the presence of hypericin, *H. perforatum* is a primary photosensitizer. A mixture of hypericum extract (10–25%) and propylene glycol (>75%) is a clear, slightly reddish, water soluble liquid with a faint herbal odor.

Mechanism of Action

The mechanism of action and active ingredients of *Hypericum perforatum* are not well defined. There is some experimental evidence that the administration of preparations of *Hypericum perforatum* affect the transmission of catecholamines (norepinephrine, dopamine) and serotonin. *In vitro* data suggest that the potential antidepressant action of hypericum extract results from alterations in central monoamine concentrations, similar to other antidepressants (e.g., selective serotonin reuptake inhibitors).[1] However, the mechanism of action probably is different from standard antidepressants because of the noncompetitive enhancement of intracellular sodium ion concentrations at neuronal synapses by hypericum extracts.[18] At the receptor level, chronic treatment with hypericum extracts may down-regulate β_1-adrenoceptors, and up-regulate post-synaptic 5-HT_{1A} and 5-HT_2 receptors. High concentrations of hypericin and flavonoid compounds inhibit MAO-A and MAO-B activity, but the concentrations of these compounds required to produce MAO inhibition are not obtainable in biological systems. Although hypericum extracts are frequently standardized to hypericin content, there is some clinical evidence that correlates antidepressant activity in a dose-dependent relationship with hyperforin content.[3,19,20] Hypericin is probably responsible for the photosensitivity reaction associated with the use of hypericum extract.[3]

DOSE RESPONSE

Medical Use

Most herbal preparations of *Hypericum perforatum* are standardized to hypericin content, but the hypericin content in commercial extracts varies substantially (e.g., 0.05–0.3%).[11] A 300 mg-tablet of hypericum extract corresponds to about 15 mg hyperforin.[21] Most clinical trials use daily doses of 900–1500 mg of the standardized extract (i.e., 0.3% hypericin).

Toxicity

A review of photosensitivity reactions to hypericum extract indicated that the threshold for an increased risk of these adverse reactions was a daily dose of 2–4 grams of the commercial extract (i.e., about 5–10 mg hypericin).[22] In a phase I clinical trial of hypericin for the treatment of HIV-infected adults, hypericin doses up to 0.5 mg/kg twice weekly produced severe cutaneous photosensitivity in 11 of 23 patients.[23] The toxic reaction involved an erythematous rash with painful dysesthesias in the sun-exposed areas of the skin. There were few other adverse reactions.

TOXICOKINETICS

Absorption

The exact constituents responsible for the effects of *Hypericum* remain unclear. The absorption of hyperforin is relatively slow with mean peak plasma concentrations of about 150 ng/mL occurring within $3^1/_2$ hours after ingestion.[21,24] In a study of 12 healthy male volunteers ingesting a single dose of 1,800 mg dried hypericum extract containing 1.5 mg hypericin, the median peak concentration of hypericin was approximately 14 ng/mL and occurred about $2^1/_2$ hours after the ingestion.[25] The equivalent dose of pseudohypericin in the

1,800 mg dose of hypericum extract was about 3.2 mg, and the median peak pseudohypericin concentration of 30.6 ng/mL occurred approximately 1/2 hour after ingestion. The estimated bioavailability of hypericin and pseudohypericin in hypericum extract is approximately 15–20%.[26]

Biotransformation

There are few data on the metabolism of constituents in hypericum extracts. Being large molecules, the potential elimination pathways for hypericin and pseudohypericin include metabolism and hepatic glucuronidation followed by biliary excretion.[27]

Elimination

The elimination of both hypericin and hyperforin is relatively slow. In a study of 13 healthy volunteers administered 0.75 mg hypericin and about 1.6 mg pseudohypericin, the median elimination half-lives were approximately 43 hours and 25 hours, respectively.[27] After a single therapeutic dose of hypericin, pseudohypericin, and hyperforin, the mean elimination half-lives in 18 healthy volunteers were 18.71 hours, 17.19 hours, and 17.47 hours, respectively.[28]

Drug Interactions

Experimental and clinical studies suggest the possibility of drug interactions between constituents of hypericum extract and pharmaceutical drugs based on the induction of the cytochrome P450 isoenzymes, CYP3A4[29,30] and CYP2C19-dependent hydroxylation.[31] In a study of 12 healthy elderly volunteers, a 28-day course of St. John's wort induced the activity of CYP3A4 and CYP2E1 by a mean of 140% and 28%, respectively, when compared with phenotypic ratios prior to supplementation.[32] Additionally, there are potential pharmacodynamic interactions as well as alteration of the energy-dependent membrane-associated drug transporter, P-glycoprotein.[33] However, the clinical relevance of these interactions remains to be determined. Table 90.1 outlines potential drug interactions between St. John's Wort and pharmaceutical drugs. Hyperforin is a ligand for the orphan nuclear receptor SXR (steroid xenobiotic receptor), which is responsible for the induction of CYP3A4 and MDR1 gene expression. A 14-day course of St. John's wort significantly induced the activity of CYP3A4 as measured by changes in alprazolam pharmacokinetics.[34] CYP3A4 substrates include at least 50% of all marketed medications. Drugs metabolized by the CYP3A4 isoenzyme include calcium channel blockers, benzodiazepines, estrogens, macrolide antibiotics, carbamazepine, and nonsedating antihistamines. Potential drug interactions include reductions of the plasma concentrations and clinical effects of cyclosporin, digoxin, HIV protease inhibitors, oral contraceptives, theophylline, and warfarin by the induction of cytochrome P450 isoenzymes CYP3A4, CYP2C9, CYP1A2, and the transport protein, P-glycoprotein.[35,36] Hypericum extract in daily doses of 900 mg significantly induced CYP3A4 isozyme activity in healthy volunteers following treatment for two weeks.[37]

Hyperforin, but not hypericin, is probably the chemical constituent of hypericum extract responsible for the activation of the CYP3A4 isozyme.[38] Theoretically, the use of hypericum extract reduces the efficacy of drugs by enhancing the clearance of drugs metabolized by the CYP3A4 isozyme.[39] Clinically important drugs affected by the CYP3A4 isozyme include indinavir sulfate,

TABLE 90.1. Some Potential Clinically Important Drug Interactions between St. John's Wort and Other Drugs

Drug	Drug Interaction
HIV protease inhibitors: indinavir, nelfinavir, ritonavir, saquinavir	Reduced blood levels; possible loss of HIV suppression
HIV non-nucleoside reverse transcriptase inhibitors: efavirenz, nevirapine	Reduced blood levels; possible loss of HIV suppression
Warfarin	Reduced anticoagulant effect and need for increased warfarin dose
Cyclosporin	Reduced blood levels with risk of transplant rejection
Digoxin	Reduced blood levels and loss of efficacy
Theophylline	Reduced blood levels and loss of control of asthma
Anticonvulsants: carbamazepine, phenobarbitone, phenytoin	Reduced blood levels with increased risk of seizures
Oral contraceptives	Reduced blood levels with risk of unwanted pregnancy and breakthrough bleeding
Triptan compounds: sumatriptan, naratriptan, rizatriptan, zolmitriptan	Increased serotonergic effects with increased incidence of adverse reactions
Selective serotonin reuptake inhibitors: citalopram, fluoxetine, fluvoxamine, paroxetine, sertraline	Increased serotonergic effects with increased incidence of adverse reactions

Source: Adapted from Ref 29.

ethinyl estradiol, coumarin, and cyclosporin.[40] This interaction requires the administration of hypericum extract for more than a few days. The administration of hypericum extract concomitantly with alprazolam (CYP3A4) or dextromethorphan (CYP2D6) for 3 days did not produce clinically significant changes in the pharmacokinetics of these drugs.[41] However, a 14-day course of St. John's wort (900 mg daily) decreased the bioavailability of alprazolam by about 39%.[42] The induction of CYP3A4 by St. John's wort is greater after ingestion than after intravenous administration.[43]

In addition to the induction of CYP3A4, St. John's wort also induces CYP2C19, which catalyzes the metabolism of tricyclic antidepressants. The concomitant use of hypericum extract with digoxin potentially reduces the efficacy of digoxin, possibly by inducing the P-glycoprotein transporter and altering absorption rather than metabolism.[44] The interaction of St. John's wort and digoxin varies depending on the dose and preparation of St. John's wort as a result of differences in hyperforin concentrations.[45]

Pregnancy

A prospective, observational, cohort study of nursing mothers receiving St. John's Wort and their infants did not detect reduced milk production or decreased infant weight over the first year of life when compared with nursing mothers not using St. John's Wort. [46]

CLINICAL RESPONSE

Adverse Reactions

Adverse drug reactions associated with the use of hypericum extract are relatively mild and similar to placebo.[8] The commonly reported side effects of hypericum extract in a European drug-monitoring study of 3250 patients were as follows: gastrointestinal irritation, 0.6%; allergic reactions, 0.5%; fatigue, 0.4%; and restlessness, 0.3%.[47]

Acute Effects

Several case reports associate the use of hypericum extract with development of the serotonin syndrome in both young and elderly patients with (sertraline, nefazodone)[48] and without[49] the concomitant use of serotonin re-uptake inhibitor (SSRIs). Additionally, a case report associated the recent use of hypericum extract with the onset of serotonin syndrome in a patient on stable doses of fluoxetine and eletriptan.[50] However, no rechallenge with these medications confirmed a potential drug interaction. A case series of 17 patients described the onset of mania within 2 days to 6 months after initiating the use of St. John's wort.[51] The doses of St. John's wort were within typical pharmacological range in all but one case. Although the mania resolved in all cases following cessation of St. John's wort, none of the patients were rechallenged to determine a direct causal effect between St. John's wort and the mania. Seizures are a rarely reported adverse effect of the use of St. John's wort, and a case report described the onset of seizures and confusion in a 16-year old girl after the suicidal ingestion of a large dose of St. John's wort (up to 4,000 ug daily for 2 weeks plus 1,500 µg before admission).[52]

Chronic Effects

An increased incidence of photosensitivity occurs during the daily use of high doses (1,800–3,600 mg) of hypericum extract as manifest by a pruritic rash and epidermal erythema.[53] However, the incidence of photosensitization is relatively rare and resolves several days after discontinuation of therapy.[20] One case report associated painful paresthesias in areas of sun exposure (hands, face) during the use of *Hypericum* extract.[54] Another case report associated the chronic nasal insertion of St. John's wort with severe epistaxis requiring endoscopic sphenopalatine artery ligation and anterior ethmoidal artery ligation.[55]

DIAGNOSTIC TESTING

Methods for the determination of hyperforin, hypericin, and pseudohypericin in plasma samples include high performance liquid chromatographic (HPLC) with fluorescence and UV detection[56] and liquid chromatography/tandem mass spectrometry.[57] The limit of quantitation for the latter method was 0.05 ng/mL for hypericin and 0.035 ng/mL for hyperforin with precision ranging from 4.7–15.4% for both analytes. Following liquid-liquid extraction and separation by isocratic reversed-phase HPLC, the limits of quantitation for hypericin/pseudohypericin (fluorometric detection) and hyperforin (UV detection) were 0.25 ng/mL and 10 ng/mL, respectively.[58] Hyperforin decomposes during storage at room temperature. After 18 months, the hyperforin content of samples of St. John's Wort decreases from 17–77% compared with the initial values.[15]

TREATMENT

There are few clinical data on the treatment of toxic effects from the exposure to hypericum extract and treatment is primarily supportive. Decontamination measures are not necessary for casual exposure to hypericum extract.

Chapter 91

STAR ANISE
(*Illicium verum* Hook. F. and *Illicium anisatum* L.)

HISTORY

Chinese star anise is a spice that closely resembles anise, and this herb has a long tradition of use in Chinese medicine for colic and indigestion. In contrast, the toxic herb, Japanese star anise is used as incense and as an ingredient for aromatherapy.

BOTANICAL DESCRIPTION

Separating the fruits of Chinese and Japanese star anise is difficult because these two species share common morphological characteristics including color, broad dehiscence, size, and beaked follicles. Chinese and Japanese star anise should not be confused with the European and North African herb, *Pimpinella anisum* L. (anise seed, aniseed).

Common Name: Chinese Star Anise, Staranise Tree

Scientific Name: *Illicium verum* Hook. f.

Botanical Family: Illiciaceae (illiciums)

Physical Description: This aromatic evergreen tree grows up 8–15 m (~26–49 ft) in height with alternate, simple leaves often clustered on the tip of the branch. The white-pink to red solitary flowers appear in June and in October. The star-shaped fruit matures in the following year.

Distribution and Ecology: Star anise (*I. verum*) inhabits subtropical and tropical areas of Asia. This tree prefers moist soil and sun or light shade.

Common Name: Japanese Star Anise, Shikimi (Japanese)

Scientific Name: *Illicium anisatum* L. (*Illicium religiosum*)

Botanical Family: Illiciaceae (illiciums)

Physical Description: This upright, rounded, bushy shrub grows up 10–15 ft (~3–5 m) in height. The evergreen leaves are 2–4 in. (~5–10 cm) long and medium to dark green in color with undulate margins. Yellowish-white or greenish-white flowers with up to 30 pedals appear in spring. These star-shaped flowers produce a star-shaped fruit that contains dark brown seeds.

Distribution and Ecology: Japanese star anise is an introduced plant species in the United States with a distribution in the western, southwestern, and southeastern United States. The native range of this shrub is eastern Asia, southern China, Japan, and Taiwan.

EXPOSURE

Sources

The fruit of Chinese star anise is a common commodity in Asian marketplaces.

Medicinal Uses

TRADITIONAL

Teas brewed from Chinese star anise (*I. verum*) are a traditional herbal medicine used to treat colic and exces-

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

sive intestinal gas in infants as well as headaches, cough, insomnia, anxiety, rheumatism, back pain, hernia, abdominal pain and indigestion in adults. Hierba anís is a complex consisting of five herbs including star anise (*Illicium verum*) with the odor of anis. This herbal medicine is used to treat menstrual pain and irregularity, upper respiratory tract infections, intestinal colic, and liver-related illness.[1] Dried Chinese star anise (bajiao) is a spice with a licorice-like taste that is found in many Mandarin Chinese dishes. The fruit of star anise is chewed as a breath freshener. The oil is applied topically for the relief of rheumatism, otalgia, and skin infections.[2]

Current

Chinese star anise is a flavoring agent in liqueurs, tobacco, confectionery, and pharmaceutical preparations. Fruits from the Chinese star anise contain substantial amounts of shikimic acid, which is a highly valued compound used as a starting material for the synthesis of the neuramidase inhibitor GS4104 (oseltamivir phosphate). This latter compound was developed under the name Tamiflu® (Roche Pharmaceuticals, Nutley, NJ) for the early treatment of viral infections.

Regulatory Status

Chinese star anise is generally recognized as safe (GRAS) by the US Food and Drug Administration (FDA) when used as a spice or flavoring, whereas as Japanese star anise is considered toxic and unfit for human consumption. Japanese star anise potentially can contaminate Chinese star anise herbal preparations because of the difficulty distinguishing these two types of star anise. After reports of acute neurotoxicity, including seizures, in infants given star anise tea, the FDA issued a warning to avoid the use of these teas in children.[3]

PRINCIPAL INGREDIENTS

Chemical Composition

Illicium species contain prenylated C_6-C_3 compounds, neolignans, and *seco*-prezizaane-type sesquiterpene compounds. The stem bark, root bark and leaves accumulate the former two types of compounds, whereas the fruit contains relatively high concentrations of sesquiterpenes.[4] Star anise species (*I. anisatum, I. verum*) contain several neurotoxic *seco*-prezizaane terpenoids including veranisatin A (CAS RN: 153445-92-2, $C_{16}H_{22}O_8$), veranisatin B (CAS RN: 153445-93-3, $C_{16}H_{20}O_9$), anisatin (CAS RN: 5230-87-5, $C_{15}H_{20}O_8$), and neoanisatin (CAS RN: 15589-82-9, $C_{15}H_{20}O_7$).[5,6] Figure 91.1 and Figure 91.2 displays the chemical structures of veranisatin A and anisatin, respectively. The principal ingredient in Chinese star anise (*I. verum*) is anethole (CAS RN: 104-46-1, $C_{10}H_{12}O$), which accounts for about 72–92% of the herb. Other species of *Illicium* also contain anethole, but the concentration is usually <40%. Safrole and eugenol are not typically present in samples of *I. verum*. Figure 91.3 displays the chemical structure of anethole.

Physiochemical Properties

Anisatin and neoanisatin are picrotoxin-like, noncompetitive GABA-antagonists that produce similar toxicity in rodent studies.[7] In animal preparations (frog spinal cord, crude synaptic membrane from rat brain),[8] anisatin and neoanisatin produce seizure activity.[9] These *seco*-prezizaane terpenoids probably bind to the same

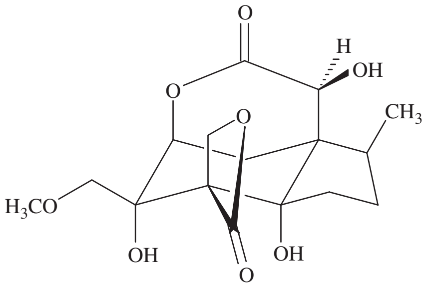

FIGURE 91.1. Chemical structure of veranisatin A.

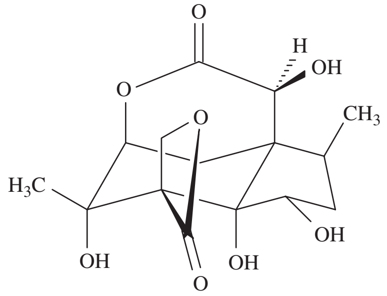

FIGURE 91.2. Chemical structure of anisatin.

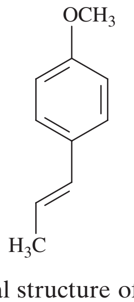

FIGURE 91.3. Chemical structure of anethole.

site as do picrotoxane terpenoids, such as picrotoxinin and picrodendrins. The neurotropic sesquiterpenoid compounds, veranisatins A, B, and C are also proconvulsant compounds in animal studies at high doses (3 mg/kg orally).[9]

Mechanism of Toxicity

Consumption of Japanese star anise is associated with seizures both in animals and in humans. Potential neurotoxins include anisatin and veranisatins. Chinese star anise is relatively safe for consumption, although this herb contains small amounts of potential neurotoxins, veranisatins A, B, and C.

DOSE RESPONSE

There is no recommended dose of Japanese star anise because of the presence of neurotoxins in this herb. In a case series of seven infants aged 2–12 weeks presenting with neurological symptoms ranging from jitteriness to seizures, the dose of Japanese star anise-contaminated herbs ranged from one to six stars boiled in water with the duration of administration varying from a single dose to a dose every 4 hours for 2 weeks.[10] The amount of anisatin present in these teas or in the serum of affected patients was not quantitated by analytical methods.

TOXICOKINETICS

There are few data on the human toxicokinetics of anisatin.

CLINICAL RESPONSE

Star anise oil in concentrations ≥1% is a strong irritant. Sensitization to the components (e.g., anethole, α-pinene, limonene, safrole) in star anise oil occurs in a few individuals, but cross-reactivity to other common essential oils is unusual.[11] A case series of seven infants fed tea made from Chinese star anise (*I. verum*) believed to be adulterated with the more toxic Japanese star anise (*I. anisatin*) resulted in the development of vomiting, jitteriness, myoclonic movements, poor sleep patterns, nystagmus, and seizures.[10] The presence of anisatin in the teas or in biological samples from these patients was not analytically confirmed. Similar symptoms (e.g., tremor, spasms, hypertonia, irritability, excessive crying, nystagmus, vomiting) developed in infants receiving star anise tea in Japan, China, Spain, Scotland, France, and the Netherlands.[12,13] Symptoms usually resolve within 24–48 hours. Contamination or adulteration of Chinese star anise teas with Japanese star anise (*Illicium anisatum*) was analytically confirmed in some of these cases.[14] An epidemic of seizures also occurred in adults consuming Chinese star anise contaminated with Japanese star anise.[15] Over 60 individuals developed nausea, vomiting and general malaise within 2–4 hours of ingesting Chinese star anise tea. Generalized tonic-clonic seizures developed in 16 of these patients. Nuclear magnetic resonance (NMR) analysis of samples of the herbal tea confirmed the presence of the neurotoxin, anisatin, from Japanese star anise.

DIAGNOSTIC TESTING

Analytical Methods

Analytical techniques for detecting the contamination of Chinese star anise by Japanese star anise include macroscopic examination of the herb and analysis of the extracted essential oil for myristicin, methoxyeugenol, eugenol, and safrole.[16] Under fluorescent and scanning electron microscopy there are anatomical differences in the epicarp cells that distinguish the fruits of Chinese star anise (*Illicium verum*) and Japanese star anise (*Illicium anisatum*). The follicle of *I. verum* has bluish-brown polygonal cells of cuticular striation with an indistinct collar, whereas the follicle of *I. anisatum* has thick-walled, frequently branched, beaded cuticular cells forming numerous pits.[17] These latter blue cells appear wavy and beaded with yellow pits. Chromatographically, the presence of methoxyeugenol, eugenol, and 2,6-dimethoxy-4-allyphenol indicate contamination by Japanese star anise as Chinese star anise does not typically contain detectable concentrations of these substances.

Biomarkers

There are few data on the concentrations of anisatin or veranisatins during intoxication with herbs contaminated by Japanese star anise. Anisatin is a biomarker for adulteration of Chinese star anise by the more toxic Japanese star anise. Typically, anisatin concentrations in Chinese star anise do not exceed 0.3 mg/kg. Concentrations of anisatin exceeding 1 mg/kg dry weight, as measured by high performance liquid chromatography/tandem mass spectrometry with thin layer chromatography, indicate contamination with Japanese star anise.[18] The limits of detection and quantitation for this method are approximately 1.2 μg/kg and 4 μg/kg, respectively.

Abnormalities

Laboratory tests and electroencephalograms are usually normal during star anise intoxication, when seizures are brief.

TREATMENT

Treatment is supportive. The main concern is the development of seizures following the ingestion of tea contaminated with Japanese star anise. Intravenous access for the administration of any necessary anticonvulsants (e.g., lorazepam, diazepam) should be obtained, and these patients should be closely observed for 24 hours to prevent trauma associated with seizures. There are few data to guide management after ingestion of Japanese star anise. Currently, there are no antidotes or methods to enhance elimination. Decontamination measures are not recommended because of the possibility of seizures and subsequent aspiration.

Chapter 92

STAR FRUIT
(*Averrhoa carambola* L.)

HISTORY

Star fruit originated in Southeast Asia, and this fruit has been cultivated in tropical areas of Southeast Asia and Malaysia for many centuries.

BOTANICAL DESCRIPTION

Common Name: Star fruit, carambola

Scientific Name: *Averrhoa carambola* L.

Botanical Family: Oxalidaceae (oxalis)

Physical Description: This slow-growing, short-trunked, subtropical evergreen tree has a branched, round, bushy canopy reaching up to 25–30 ft (~8–9 m) in height. The spirally arranged, alternate leaves are 6–10 in. (~15–25 cm) long with smaller, nearly opposite, ovate-oblong leaflets. The medium-green leaves are soft with a smooth upper surface and slightly hairy white underside. The yellow-green star fruit is ovate to ellipsoid in length with five to six prominent longitudinal ribs and star-shaped cross-section.

Distribution and Ecology: The star fruit probably originated in Sri Lanka and the Moluccas. This fruit tree is a commonly grown plant in southern China, Taiwan, India, and Brazil. In the United States, star fruit is cultivated in California, Hawaii, and Florida.

EXPOSURE

Star fruit is a popular tropical fruit available throughout the world as a fresh fruit, gourmet jam, fruit juice (sweet or sour), and constituent of fruit salad. Traditional uses for star fruit by Chinese herbalists and bomohs (Malay medicine men) include the treatment of headache, cough, sore throat, upper respiratory tract infections, vomiting, and restlessness. In India, star fruit is a traditional treatment for hemorrhage and hemorrhoids, while in Brazil this fruit is a diuretic. Star fruit has no approved medical uses in the United States or Europe.

PRINCIPAL INGREDIENTS

The neurotoxic principal in star fruit has not been identified.[1] Star fruit contains high concentrations of potassium and oxalates, but these substances have not been directly linked to the illness associated with the ingestion of star fruit by patients with renal dysfunction. The two types of star fruit are sour and (slightly) sweet. The potassium content in samples of homogenized sweet star fruit and star fruit juice were approximately 34 mEq/L and 3 mEq/L, respectively.[2] Sour star fruit juice contains substantially higher oxalate concentrations than sweet star fruit juice. The oxalate concentrations of sour star fruit juice consumed in two cases of acute renal failure were 308 mg/dL and 820 mg/dL.[3] Animal studies indicate that the neurotoxin in star fruit intoxication is a dialyzable, nonprotein with a molecular weight below

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

500 Da. *In vitro* studies indicate that the neurotoxic fraction from star fruit inhibits GABA binding in a concentration-dependent manner (IC_{50} = 0.89 μM), but not glutamate binding. This fraction does not affect the uptake or release of either GABA or glutamate.[4]

DOSE RESPONSE

Star fruit intoxication occurs primarily in patients with chronic renal failure with the exception of individuals ingesting large amounts of sour star fruit juice.[3] There is no specific dose-response effect as patients with this syndrome have eaten a few pieces to several fruits without a direct correlation to the severity of illness. Case series of uremic patients developing star fruit intoxication report the ingestion of two to three fruits or 150–200 mL of the fruit juice with symptoms ranging from insomnia and hiccups to confusion and death.[5] The intraperitoneal injection of an aqueous methanol extract of star fruit to male albino mice produced convulsions and cardiopulmonary arrest at doses exceeding 8 g/kg body weight.[6] However, the study did not use an adequate control (normal saline) or analyses of serum chemistries (e.g., sodium, potassium) to determine the effect of such large volumes of fluid and electrolytes on the mice.

TOXICOKINETICS

There are no toxicokinetic data in humans on the specific neurotoxin associated with star fruit intoxication. Although star fruits contain high concentrations of potassium and oxalate, the effect of these substances do not account for all the clinical effects associated with the ingestion of star fruit by renal dialysis patients.

CLINICAL RESPONSE

The ingestion of star fruit or star fruit juice by patients with renal dysfunction can cause acute central nervous system (CNS) disturbances and deteriorating renal function, even in patients without advanced chronic renal failure.[7] Patients typically present within 6–12 hours after the ingestion of star fruit.[8] The rate of progression is highly variable, and death occurs in some patients with altered consciousness. Clinical features of this intoxication include hiccups, nausea, vomiting, fever, agitation, insomnia, lethargy, confusion, muscle weakness, seizures (grand mal, complex partial), and coma.[9] Intractable hiccups and agitation are the most common symptoms associated with this poisoning. The hiccups do not usually respond to haloperidol, metoclopramide, or diazepam. In a series of 32 uremic patients, the classification of the severity of the intoxication associated with star fruit ingestions was as follows: *mild* – hiccups, vomiting, insomnia; *moderate* – agitation, numbness and paraesthesias of the extremities, mild mental confusion; and *severe*– increasing mental confusion progressing to coma, seizures, hypotension, and shock.[8] Altered consciousness or seizures are poor prognostic signs. Recovery may require 7–14 days. A case report associated the development of increasing renal dysfunction and oxalate nephropathy with the chronic ingestion of an undetermined quantity of sour star fruit (i.e., relatively high oxalate content) over 3 years.[10] This 85-year old man had mild pre-existing renal dysfunction; he did not develop any neurological symptoms.

The differential diagnosis of star fruit intoxication in these patients includes hypertensive encephalopathy, dialysis dementia, dysequilibrium syndrome, uremic encephalopathy, CNS infections, hypoglycemia, hypoxia, electrolyte imbalance, cerebral vascular diseases, and drug intoxications. Individuals with normal renal function do not usually develop star fruit intoxication with the exception of individuals ingesting large amounts of sour star fruit juice containing high concentrations of oxalates. These patients develop gastrointestinal distress, back pain, and acute renal failure. However, these individuals do not usually have the CNS disturbances associated with star fruit intoxication in patients with renal dysfunction.[3]

DIAGNOSTIC TESTING

Hyperkalemia occurs in only a few of the patients presenting with star fruit intoxication despite the presence of renal failure and the large amount of potassium in star fruit.[2] Electroencephalograms during the acute illness typically demonstrate diffuse cortical dysfunction consistent with metabolic encephalopathy along with occasional focal regional cortical epileptic activities.[11] Computed tomography (CT) scans of the brain are usually normal, whereas magnetic resonance imaging (MRI) brain scans demonstrate hyperintense T2-weighted images in the thalamus and cortex.[12]

TREATMENT

Patients presenting with toxicity after star fruit ingestion typically require intensive supportive care as a result of CNS disturbances and the metabolic abnormalities (metabolic acidosis, hyperkalemia) associated with worsening renal failure. Seizures may be unresponsive to conventional anticonvulsants (e.g., lorazepam, diazepam) and may require deep sedation (e.g., propofol) or neuromuscular blockade with electroencephalographic monitoring.[13] Patients with mild intoxication (insomnia, intractable hiccups, agitation, slight confu-

sion) usually respond to supportive care. Patients with more severe intoxication require dialysis. Case reports document of the use of plasma exchange in patients with severe star fruit intoxication, but the efficacy of this treatment is unclear because of the lack of toxicokinetic data and the simultaneous use of hemodialysis.[11] Gut decontamination is not recommended. Prompt hemodialysis is the treatment of choice, and most, but not all, patients respond to intensive dialysis within 2–3 days. In severe cases, daily hemodialysis or continuous methods (continuous venovenous hemodialysis, continuous arteriovenous hemodialysis) are preferred because symptoms (hiccups, confusion) recur during severe intoxication. A case report associated improvement in two patients with severe star fruit intoxication with the use of hemoperfusion.[1] However, there are few clinical data to guide treatment.

Chapter 93

TANSY
(*Tanacetum vulgare* L.)

HISTORY

Common tansy (*Tanacetum vulgare* L.) was known to the ancient Greeks. This herb was present in the garden of Charlemagne the Great during the 8th century and in the herb gardens of Swiss Benedictine monks. Traditional uses for common tansy included treatment of gastrointestinal distress, parasitic infections, fever, and rheumatism. In Medieval times, common tansy in large doses was a common abortifacient. During colonial times, common tansy was a food preservative and a component of funeral shrouds and wreaths. In the 19th century, the *United States Pharmacopeia* listed tansy as a stimulant, emmenagogue, and anthelminthic.[1]

BOTANICAL DESCRIPTION

Common tansy is easily confused with tansy ragwort (*Senecio jacobaea* L.), which contains pyrrolizidine alkaloids.

Common Name: Common Tansy, Garden Tansy, Tansy, Golden Buttons

Scientific Name: *Tanacetum vulgare* L.

Botanical Family: Asteraceae (sunflowers, tournesols)

Physical Description: This aromatic plant has fern-like leaves and small, round yellow flowers. Purplish-red stems are hairless or mostly hairless and extensively branched toward the top. Leaves are finely divided into leaflets, ranging from 4–8 in. (~10–20 cm) in length and 1.5–3 in. (~4–8 cm) in width. Characteristic flat-topped clusters of small, button-like, petalless, yellow flowers appear in the summer.

Distribution and Ecology: This perennial herb is a common weed, which grows throughout the northern climate in North America, Europe, and Asia. Common tansy invades disturbed sites on roadsides, fences, pastures, stream banks, and waste areas throughout North America.

EXPOSURE

Sources

The yield of essential oil from tansy is about 1% volume/weight. In a study of 40 plants from wild populations of Norwegian tansy (*Tanacetum vulgare* L.), the average yield of essential oil was 0.81% volume/weight with a range of 0.35–1.90% volume/weight.[2]

Medicinal Uses

Traditional

Traditional uses of tansy include an insect repellant, insecticide, and the treatment of parasitic infection, kidney disease, respiratory infections, migraine headaches, neuralgias, anorexia, headache, diarrhea, sore throat, and rheumatism. The Micmac Indians used tansy as an abortifacient and diuretic.[1]

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Current

Tansy is a spice for cakes, salads, and omelettes as well as an aromatic constituent of some cosmetics, dyes, and insect repellants.

Regulatory Status

There are no standard formulations of essential oils from tansy.

PRINCIPAL INGREDIENTS

Chemical Composition

Tansy contains a variety of compounds including sesquiterpene lactones (parthenolide), flavonoids (methyl ethers of scutellarein and 6-hydroxyluteolin),[3] phenols, coumarins, and polysaccharides (tanacetan TVF).[4] The chemical composition of tansy essential oil is highly diverse with marked geographic variation in monoterpene and sesquiterpene content. There are at least 15 chemotypes with camphor and thujone being the most common chemotypes. A study of 40 plants from wild populations in Norway revealed the following seven chemotypes: β-thujone (55%), camphor (15%), (*E*)-chrysanthenyl acetate/chrysanthenol (7.5%), artemisia ketone/artemisia alcohol (7.5%), α-thujone (5%), chrysanthenone (5%), and 1,8-cineole (5%).[2] The thujone chemotype had high concentrations of thujone (CAS RN: 546-80-5, $C_{10}H_{16}O$) with an average concentration of about 81%. Figure 93.1 displays the chemical structure of thujone. The average camphor concentration in the camphor chemotype was about 31%. In a study of air-dried flower heads from 20 Finnish tansy genotypes, the most common monoterpene was camphor with smaller concentrations of camphene, 1,8-cineole (eucalyptol), pinocamphone, chrysanthenyl acetate, bornyl acetate, and isobornyl acetate.[5] In 13 genotypes, the camphor concentrations ranged from 18.5–69.4%, while the camphor concentration in the remaining 7 genotypes ranged from 0.06–7.15%. The major sterol and triterpene compounds in aerial samples of tansy from Nova Scotia, Canada were β-sitosterol and α-amyrin, respectively, with other sterols including stigmasterol, campesterol, and cholesterol.[1] These samples also contained the triterpene compounds, β-amyrin and taraxasterol.

The composition of the essential oil from tansy depends on a number of factors including the plant part, ontogeny (i.e., chemotype) of the plant, seasonal changes, environmental conditions, and extraction method.[6] The essential oil contains over 100 volatile monoterpene and sesquiterpene compounds with camphor and thujone being the most common. However, the composition of the essential oil varies dramatically with the specific chemotype as indicated above. The essential oil of tansy contains optically pure (−)-camphor, which is a biosynthetic oxidation product of bicyclic monoterpene alcohol, (−)-borneol.[7]

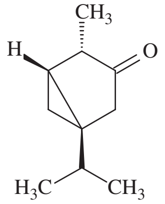

FIGURE 93.1. Chemical structure of thujone.

Physiochemical Properties

Table 93.1 lists some physical properties of thujone.

TABLE 93.1. Some Physical Properties of Thujone

Physical Property	Value
Melting Point	<25 °C/77 °F
Boiling Point	203 °C/~397 °F
Log P (Octanol-Water)	2.650
Water Solubility	408 mg/L (25 °C/77 °F)
Henry's Law Constant	7.00E-05 atm-m³/mole (25 °C/77 °F)
Atmospheric OH Rate Constant	5.12E-12 cm³/molecule-second (25 °C/77 °F)

DOSE RESPONSE

Most of the clinical effects associated with tansy are hypersensitivity reactions. There are few data on the dose response of tansy essential oil.

TOXICOKINETICS

There are few data on the human toxicokinetics of camphor (See Chapter 53, Camphor), thujone, or eucalyptol (1,8-cineole) in tansy essential oil.

CLINICAL RESPONSE

Allergic contact dermatitis and allergic rhinitis are common complications of exposure to tansy in atopic patients with hypersensitivity to plants from the Asteraceae family as a result of substantial cross-reactivity between members of this plant family. In a study of 190 Asteraceae-allergic patients determined by positive skin tests to an Asteraceae mix, feverfew elicited the most (81%) positive responses followed by tansy (77%),

chamomile (64%), and yarrow (41%).[8] Most atopic patients are hypersensitive to allergens other than members of the Asteraceae family, such as nickel.[9] Case reports associated airborne exposure to tansy pollens with allergic contact dermatitis manifest by pruritic, scaly lichenified plaques on the hands, scalp, posterior neck, arms, and legs.[10] Although the presence of oxygenated monoterpene compounds (camphor, thujone, eucalyptol) suggests the possibility of seizures following the ingestion of large doses of the essential oil from tansy,[11] there are no case reports that suggest that seizures are a clinically relevant complication of tansy ingestion.

DIAGNOSTIC TESTING

Gas chromatography[5] and gas chromatographic/mass spectrometry[2] can separate and quantitate the components of tansy essential oils including the main compounds, thujone and camphor.

TREATMENT

Treatment is supportive, including the use of antihistamines and steroids as indicated. Gut decontamination measures are unnecessary.

Chapter 94

VALERIAN
(*Valeriana officinalis* L.)

HISTORY

Valerian was a recognized medicinal herb at least since the writing of *De Materia Medica* by the Greek physician and herbalist Pedanios Dioscorides of Anazarba.[1] In the late 16th century, Fabius Columna reported the effectiveness of valerian as an anticonvulsant, and subsequently this herb was used frequently as a treatment for a variety of nervous diseases. During the 19th century, the Eclectic physicians commonly recommended valerian for a variety of illnesses, including use as an antipyretic, aphrodisiac, sedative, and analgesic.

BOTANICAL DESCRIPTION

The Valerianaceae family contains approximately 250 species of the genus *Valeriana* with *V. jatamansi* Jones (Indian or Pakistan valerian), *V. edulis* Nutt. (Mexican valerian), and *V. officinalis* L. (European valerian) being the most common herbal sources. The latter species is the most common source of valerian extract in North America. Official medicinal sources of valerian include another European valerian species (*V. repens* Host). Adulteration of American valerian with species from other genera is uncommon.

Common Name: Valerian, Garden Heliotrope, Garden Valerian

Scientific Name: *Valeriana officinalis* L.

Botanical Family: Valerianaceae (valarians)

Physical Description: A tall, perennial herb that grows up to 2 m (~7 ft) in height with cylindrical, grooved, hollow stems. The oblong, yellow-brown to dark brown rhizome grows up to about 20 cm (~8 in.) in diameter and 50 cm (~20 in.) in length with a compressed base, one or more stolons, and many thick, brown rootlets. The large, dark green leaves are saw-toothed, and white to pale pink. Strongly scented flowers bloom from June to August; the fruits are oblong to ovate with four ridges and a single seed.

Distribution and Ecology: Valerian is a perennial native herb of western Asia and Europe that prefers streams, damp meadows, scrub, or woodlands. In the United States, valerian is an introduced species that has become naturalized. Valerian is cultivated in several countries including the United States, Eastern Europe, France, Germany, Britain, the Netherlands, Belgium, Russia, and Japan.

EXPOSURE

Sources

The yield of essential oil from the roots of valerian ranges from about 0.4–2.1% depending on seasonal variation, species and strain (genotype), drying and extraction technique, and growing conditions.[2] High-quality valerian contains about 1–1.5% essential oil and ≥0.5% valerenic acid. The crude drug Valerianae Radix consists of roots, stolons, and rhizomes of *Valeriana officinalis* dried at temperatures below 40 °C (104 °F).

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Medicinal Uses

TRADITIONAL

The most common herbal uses of valerian include use as a sedative, sleep aid, and antispasmodic. Other traditional uses include the treatment of muscle cramps, menstrual pain, tension headaches, seizures, yeast infections, sore throat, fluid retention, excessive perspiration, and excessive gastrointestinal gas.

CURRENT

Valerian is a traditional herbal treatment for insomnia and anxiety. Although valerian is generally a safe herb, the efficacy of this herb in the treatment of insomnia and anxiety remains unproven.[3] Several clinical studies suggest that valerian is an effective treatment of insomnia, primarily by reducing sleep latency (i.e., time to fall asleep), night awakenings, and improving the quality of sleep,[4,5] whereas other clinical studies did not demonstrate improvement in these sleep parameters with the use of valerian.[6] The inconsistency of the results and design flaws (small sample sizes, poor assessment measures, inadequate control of confounding variables) limit conclusions about the efficacy of valerian for the treatment of insomnia. A double-blind, randomized crossover, placebo-controlled study compared the effects of single doses of valerian (400 and 800 mg), temazepam (15 and 30 mg), and diphenhydramine (50 and 75 mg) in 14 healthy elderly volunteers.[7] Assessment included validated measures of subjective sedation and mood along with psychomotor performance (manual tracking, digit symbol substitution). There was no statistically significant difference in any of these measures between valerian and placebo.

Frequently herbal sleep preparations combine the use of passionflower, balm, hops, and/or St. John's wort with valerian for the treatment of insomnia or anxiety.[8] There are limited scientific data to support the use of valerian for the alleviation of anxiety.[9,10] In a randomized, placebo-controlled, double-blind, cross-over trial of 10 healthy volunteers receiving single doses of valerian extract (600, 1,200, 1,800 mg), there was no significant difference between valerian treatment and placebo as assessed by questionnaire and psychomotor/cognitive testing (memory, eye–hand coordination, logical reasoning, Digit Symbol Substitution Test).[11] An Internet-based, double-blind, placebo-controlled study of 391 subjects did not detect a statistically significant difference in the scores on the State-Trait Anxiety Inventory State subtest (anxiety) or the Insomnia Severity Index (insomnia), when comparing valerian treatment and placebo groups.[12] The valerian treatment group received two valerian softgel capsules (3.2 mg valerenic acids, 1% valerenic acid in extract) 1 hour before bedtime for 28 days.

REGULATORY STATUS

The US Food and Drug Administration (FDA) lists valerian as a food supplement, and regulatory control of valerian is limited to labeling requirements. The German Commission E approves the use of valerian for the treatment of insomnia and restlessness without any specific contraindications.

PRINCIPAL INGREDIENTS

Chemical Composition

The essential oil of valerian contains over 150 compounds including sesquiterpenes (valerenic acid, valeranone),[13] sesquiterpene derivatives (acetoxyvalerenic acid, 3β,4β-epoxyvalerenic acid, hydroxyvalerenic acid, valerane, valerenal, cryptofauronol),[14,15] bicyclic iridoid esters (valepotriates),[16] decomposition products of valepotriates (baldrinal, homobaldrinal, valtroxal), monoterpenes (bornyl acetate and isovalerate), flavonoids (6-methylapigenin, hesperidin),[17] furanofuran lignans, alkaloids (valerianine, actinidine), and free amino acids (γ-aminobutyric acid, arginine, glutamine, tyrosine). Figure 94.1 displays the chemical structures of the major types of compounds in valerian. Valepotriates are chemically unstable iridoid triesters (valtrate, isovaltrate, homovaltrate, acevaltrate, didrovaltrate). Valtrate and isovaltrate typically account for about 90% of the valepotriate compounds in valerian root.[18] Commercial root extracts of valerian usually contain small amounts of valepotriates (e.g., valtrate) because of their lipophilicity and instability in aqueous solutions. The composition of the essential oil of valerian depends on the chemovar, and the most common compounds include bornyl acetate, valerenal, valeranone, and cryptofauronol.[19] Minor constituents of the essential oil include α-pinene, β-pinene, camphene, β-caryophyllene, terpinolene, limonene, and carvyl acetate.

There is no official standard for herbal preparations of valerian and the content of main sesquiterpene compounds (valerenic acid, hydroxyvalerenic acid, acetoxyvalerenic acid) in these preparations is highly variable. Analysis of six commercial samples of valerian detected valerenic acid and hydroxyvalerenic acid in only one sample in concentrations of 0.54% and 0.13%, respectively.[20] In a study of 31 commercial Australian preparations (capsules, tablets, teas, liquids) of valerian, the total valerenic acid content ranged from <0.01 to 6.32 mg/g with 16% of these products containing

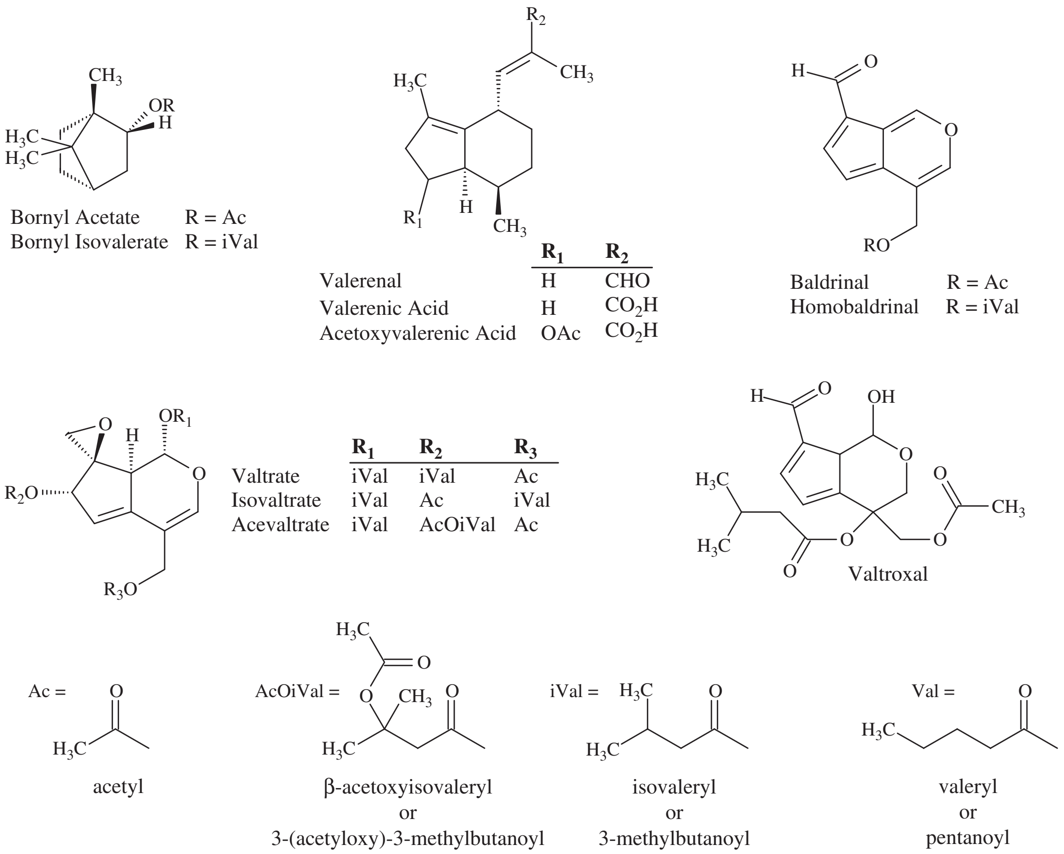

FIGURE 94.1. Chemical structures of major types of compounds in valerian.

<0.1 mg/g or mL.[21] Valepotriate compounds were present in low concentrations (<1 mg/g) in some teas, but most other valerian products did not contain detectable amounts of valepotriate compounds as measured by high performance liquid chromatography (HPLC). Figure 94.2 displays the chemical structure of valerenic acid (CAS RN: 3569-10-6, $C_{15}H_{22}O_2$).

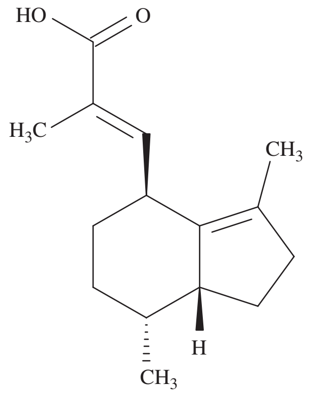

FIGURE 94.2. Chemical structure of valerenic acid.

Physiochemical Properties

Valerenic acids are relatively stable compounds, whereas valepotriate compounds are thermolabile and unstable under acidic or alkaline conditions. Storage of valerian root in high humidity results in the degradation of acetoxyvalerenic acid to hydroxyvalerenic acid. The pungent smell associated with valerian root extract results from hydrolysis during storage and the subsequent formation of isovaleric acid. The fresh root is not typically aromatic. Preservation of the components in the essential oil requires storage in tight containers and a cool, dry, dark place. Exposure of valerian to humidity, high ambient temperatures (>40 °C/104 °F), alcoholic solutions, or acidic conditions (pH < 3) results in the decomposition of valepotriate compounds, and most commercial products do not contain these compounds more than 2 months after extraction.[22] High ambient temperatures also degrade valerenic acids. Exposure of an ethanol extract of dry ground valerian rhizomes to 70 °C/158 °F for 22 hours reduced the total valerenic acid content about 11–12%.[23]

Mechanism of Toxicity

Although valepotriate compounds are frequently cited as the active components of valerian, currently there is no consensus for the mechanism of action for the possible sedative effects of valerian. *In vitro* studies indicate that the flavonoid, 6-methylapigenin in valerian root extract binds to the benzodiazepine binding site of the $GABA_A$ receptor,[17] whereas the lignan, 1-hydroxypinoresinol binds to the $5\text{-}HT_{1A}$ serotonin receptor.[24] These *in vitro* studies also indicate that valerian and valerenic acid are partial agonists of the $5\text{-}HT_{5a}$ receptor.

DOSE RESPONSE

Medicinal Use

The typical herbal dose of valerian is 300–600 mg daily of the valerian root extract. An alternative is the steeping of 2–3 grams dried valerian root in one cup of hot water for 10–15 minutes. The preparation typically is ingested about $^1/_2$–2 hours prior to bedtime.

Toxicity

The ingestion of an estimated 18.8–23.5 g powdered valerian root by an 18-year-old woman caused crampy abdominal pain, chest tightness, lightheadedness, fatigue, fine hand tremor, and mydriasis.[25] All symptoms resolved within 24 hours, and the patient recovered without sequelae.

TOXICOKINETICS

Kinetics

In a study of six healthy adult volunteers receiving a single dose of 600 mg valerian extract (Sedonium™, Lichtwer Pharma, Berlin, Germany), valerenic acid was detectable in the serum for at least 5 hours.[26] The peak serum concentration of valerenic acid occurred 1–2 hours after ingestion in five of the six subjects. The other subject had two peak valerenic acid concentrations occurring at 1 hour and 5 hours after ingestion. The serum elimination half-life for valerenic acid was 1.1 ± 0.6 hours for the five subjects with only a single peak serum valerenic acid concentration.

Drug Interactions

Valerian may potentiate the sedative effects of central nervous system depressants, sedative-hypnotic drugs, and anesthetics, but there are few clinical data to determine the clinical importance of these potential interactions. *In vitro* studies with the ATPase assay suggest that aqueous and ethanol extracts of valerian inhibit CYP3A4 activity,[13] but the clinical significance of this effect also remains unclear. In a study of 12 healthy volunteers using single-time-point phenotypic metabolic ratios to determine the effect of 28 days of valerian root extract (125 mg 3 times daily, no standardization claims) on cytochrome P450 enzyme activities, no changes in phenotypic ratios of CYP2E1, CYP1A2, CYP2D6 or CYP3A4/5 activity was observed when compared with enzyme activities before supplementation.[27] Based on *in vivo* studies on the effect of valerian extract on the activities of CYP2D6 and CYP3A4, valerian is unlikely to produce clinically significant effects on the disposition of medications dependent on the CYP2D6 or CYP3A4 isoenzymes for biotransformation.[28]

CLINICAL RESPONSE

Adverse Reactions

Although most clinical trials to date are small, adverse reactions to valerian in these clinical studies are uncommon and mild, primarily involving headache and gastrointestinal distress.[29] A randomized, controlled, double-blind trial of 102 volunteers receiving 600 mg valerian root extract (LI 156) nightly for 2 weeks did not detect any negative effects on reaction time, alertness, or concentration the morning after intake, when compared with baseline.[30] Adverse reactions associated with the use of valerian reported to the California Poison Control System included nausea, vomiting, drowsiness, agitation, and a probable anaphylactic reaction (urticaria, respiratory distress).[31] Occupational exposure to the dust from valerian causes relatively few hypersensitivity reactions with the exception of nonspecific reactions (conjunctivitis, nasal congestion).[32] Case reports associated liver toxicity with multi-herb preparations containing valerian.[33] However, the contribution of valerian to the development of hepatitis in these cases is not clear because of the potential liver toxicity of other ingredients (skullcap, chaparral) and potential contamination with hepatotoxic herbs.

Acute Effects

A case report about an 18-year-old woman associated the intentional ingestion of up to about 23 g valerian root with mydriasis, fine hand tremor, lightheadedness, chest tightness, abdominal cramps, and fatigue.[25] Her vital signs remained normal (i.e., no tachycardia or tachypnea), and she recovered without sequelae within 24 hours. A case series documented the development of central nervous system depression and anticholiner-

gic symptoms (vomiting, mydriasis, tachycardia, urinary retention, visual hallucination, dry mouth, flushing) after the intentional overdose with an herbal preparation containing 75 mg valerian dry extract, 0.25 mg hyoscine hydrobromide, and 2 mg cyproheptadine hydrochloride.[34] The toxic effects can be attributed to the two drugs other than valerian extract. Follow-up studies detected no evidence of hepatotoxicity.

Chronic Effects

Although some valepotriate compounds demonstrate alkylating activity *in vitro*,[35] these compounds degrade rapidly in stored valerian preparations and there is little known risk of genotoxicity associated with valerian use.[18]

DIAGNOSTIC TESTING

Analytical Methods

Methods to detect valerenic acid and derivatives (acetoxyvalerenic acid, hydroxyvalerenic acid) include thin layer chromatography, gas-liquid chromatography, and high performance liquid chromatography (HPLC) with diode array detection. Limits of detection for sesquiterpene compounds in valerian using capillary electrophoresis are in the range of 6 µg/mL.[20] Degradation products of valerian include hydroxyvalerenic acid, pinoresinol, and hydroxypinoresinol. Hydroxyvalerenic acid is a better marker of deterioration of valerian during storage than valerenic acid because acetoxyvalerenic acid hydrolyzes to hydroxyvalerenic acid during unfavorable storage conditions.[36]

Biomarkers

There are substantial differences in the chemical composition of various *Valeriana* species. The presence of valerenic acid, acetoxyvalerenic acid, and valerenal are biomarkers for valerian prepared from *Valeriana officinalis* rather than other *Valeriana* species (*V. edulis*, *V. jatamansi*). Although *V. officinalis* contains the highest concentration of these valerenic acids, some closely related species (e.g., *V. sitchensis* Bong.) contain small amounts of valerenic acids. Analysis of valerenic acids, flavonoids, and valepotriate compounds by liquid chromatography with UV detection provides unique chemical fingerprints that can separate various *Valeriana* species.[37]

Abnormalities

The complete blood count, serum electrolytes, renal function, and serum hepatic aminotransferases remained normal after the intentional ingestion of up to about 23 g valerian root.[25] In a case series of 23 patients with intentional overdoses of an over-the-counter preparations containing valerian root, there was no evidence of acute hepatitis.[34]

TREATMENT

Treatment is supportive. Adverse reactions to valerian are typically mild and respond to conventional treatment. Decontamination measures are unnecessary.

Chapter 95

YARROW
(*Achillea millefolium* L.)

HISTORY

Yarrow was one of the flowers discovered in an Iraqi tomb of a Middle Paleolithic Shanidar Neanderthal[1] Dioscorides first recorded the medicinal use of yarrow. Allegedly, the Greek hero, Achilles used yarrow leaves to stop the bleeding from the wounds of his soldiers, resulting in the name of the genus, *Achillea*.[2] The dried leaves and flowering tops were officially recommended in the *United States Pharmacopeia* from 1836–1882 as a tonic and emmenagogue. Yarrow leaves were reportedly applied to battle wounds during the US Civil War.

BOTANICAL DESCRIPTION

There are over 100 species in the genus, *Achillea*. Yarrow (*A. millefolium* L.) is a common species used in herbal therapy.

Common Name: Yarrow, Common Yarrow, Bloodwort, Carpenter's Weed, Hierba de las Cortaduras, Milfoil, Soldier's Woundwort, Herbe Militaris, Staunchweed, Plumajillo, Western Yarrow

Scientific Name: *Achillea millefolium* L.

Botanical Family: Asteraceae (sunflowers, tournesols)

Physical Description: This invasive, aromatic weed reaches 10–20 in. (~25–50 cm) in height with many finely divided, feathery dark-green leaves. The leaves are clustered at the base of angular, flowering stems with smaller leaves alternating upward. Flat-topped panicles consisting of numerous small, white to red flower heads appear from June to September.

Distribution and Ecology: Yarrow is an herbaceous perennial widely distributed throughout the temperate climates of the northern hemisphere and, to a lesser extent, in the southern hemisphere with substantial genetic diversity as a result of hybridization and polyploidization.[3] This plant is native to Europe and western Asia, but yarrow has naturalized to temperate areas worldwide including North America, Australia, and New Zealand. Yarrow is commonly found in sunny, disturbed areas along roadsides, old fields, pastures, and meadows in the eastern and central United States and Canada.

EXPOSURE

Sources

The source of yarrow essential oil is typically the aerial parts of *Achillea millefolium* L. The yield of this essential oil is about 0.1–0.3% with the yield increasing during full bloom.[4]

Medicinal Uses

Traditional

Yarrow has traditionally been ingested as a tea and applied as a lotion or poultice. In traditional European herbal medicine, yarrow is a treatment for hepatobiliary disorders, gastrointestinal illness, urinary tract infec-

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

tions, fever, and wounds. Yarrow is also a diuretic, abortifacient, contraceptive, emmenagogue, and uterine stimulant in traditional herbal medicine. North American Indian tribes used yarrow for sprains, contusions, healing wounds, pruritic rashes, pain, and upper respiratory tract infections.[2]

Current

Yarrow is a constituent of experimental herbal preparations for the treatment of cirrhosis[5] and atopic dermatitis,[6] but there is inadequate clinical evidence to conclude that yarrow is an effective treatment for any medical condition. Yarrow is a constituent of some beverages, beers, spices, shampoos, hair-grooming aids, skin fresheners, body lotions, and cosmetics. The essential oil of yarrow is probably not an effective insect repellant.[7]

Regulatory Status

The Council of Europe Committee of Experts classifies yarrow in Group 3 ("safely used in cosmetic products for the purposes stated according to reported use levels").[8]

PRINCIPAL INGREDIENTS

Chemical Composition

The composition of the essential oil from yarrow depends on a variety of factors including season, growing conditions, geographical location or chemotype, plant part, and extraction technique.[9] As the plant matures, the concentrations of α-pinene, β-pinene, and α-thujone increase, while the concentrations of sabinene, borneol, and bornyl acetate decrease.[4] In contrast to steam distillation, solid-phase microextraction of aerial portions of yarrow produces substantial amounts of α-bisabolol, β-bisabolol, and δ-cadinene. The essential oil of yarrow contains over 100 compounds including monoterpenes (camphor, 4-terpineol, α- and β-pinene, α-thujone, sabinene), sesquiterpenes (β-caryophyllene, caryophyllene oxide, [*E*]-nerolidol, germacrene D, α-farnesene), sterols (β-sitosterol, stigmasterol, campesterol),[10] chlorogenic acid and related isomers, dicaffeoylquinic acids (e.g., cynarin),[11] and flavonoids (apigenin, leuteolin-7-glycoside, artemetin, casticin, centaureidin).[12,13] The major compounds in the essential oil of yarrow are camphor, sabinene, 1,8-cineole, α-pinene, and β-pinene.[14,15]

Physiochemical Properties

The estimated tropospheric lifetimes of monoterpene compounds (e.g., *d*-limonene, myrcene, α-pinene, sabinene, γ-terpinene, terpinolene) are relative short (<1–3.5 hours) with related compounds (e.g., 1,8-cinoeole, *p*-cymene) having somewhat longer half-lives.[16] Yarrow extract (CAS RN 84082-83-7) is a clear to brownish-green liquid with a faint herbal odor. This solution is soluble in water with a density ranging from 1.030–1.050 g/mL. The occurrence of bluish coloration to yarrow extract indicates the presence of azulene and related compounds (e.g., chamazulene).

Mechanism of Toxicity

Most adverse reactions to yarrow result from hypersensitivity responses.

DOSE RESPONSE

Medicinal Use

A typical herbal dose of yarrow is 2 to 4 grams dried herb in capsules or a tea (1–2 teaspoons dried herb in boiling water, steeped for 3–5 minutes) up to 3 times daily. However, there are no clinical studies to determine an efficacious dose.

Toxicity

A study of adult male Wistar rats receiving up to 1.2 g/kg body weight of an aqueous crude extract of yarrow leaves daily for 90 days did not detect any systemic or reproductive toxicity.[17]

TOXICOKINETICS

There are few data on the absorption or metabolism of constituents of yarrow following the ingestion of extracts from this herb.

CLINICAL RESPONSE

The most common complications associated with exposure to yarrow are hypersensitivity reactions. These adverse effects include allergic contact dermatitis, contact urticaria, rhinoconjunctivitis, and bronchial asthma.[18–20] There is substantial cross-reactivity between members of the Asteraceae family.[21] In a study of 190 Asteraceae-allergic patients determined by positive skin tests to an Asteraceae mix, feverfew elicited the most (81%) positive responses followed by tansy (77%), chamomile (64%), and yarrow (41%).[22] However, hypersensitivity reactions to yarrow are relatively uncommon, even in patients with multiple contact reactions, photosensitivity, or atopic dermatitis.[23] Rare case reports also associate sore throat, stomach aches, facial

edema, and pruritus with the ingestion of yarrow tea.[24] Rodent studies suggest that high doses of yarrow (>50 times typical herbal doses) can produce fetal toxicity without maternal toxicity,[25] but the clinical significance of extrapolating this fetal toxicity in animals to humans remains unclear. This study detected no increase in fetal demise following the ingestion of yarrow before or after implantation suggesting that yarrow was neither an abortifacient nor a contraceptive; there was no increase in the rate of malformations when the treatment group was compared with controls.

DIAGNOSTIC TESTING

Analytical methods for the separation and identification of the constituents of the essential oil of yarrow include gas chromatography,[14] high performance liquid chromatography (HPLC) coupled with diode-array and fluorescence detectors,[26] and gas chromatography/mass spectrometry.[4,27] Methods for the detection and quantitation of flavonoids and phenolic compounds (e.g., dicaffeoylquinic acids) in yarrow include solid-phase extraction coupled with HPLC and UV detection.[28]

TREATMENT

Treatment is supportive. Most adverse reactions are hypersensitivity responses, which respond to cessation of use and antihistamines and/or steroids. Gut decontamination measures are unnecessary.

Chapter 96

YOHIMBE BARK and YOHIMBINE
(*Pausinystalia yohimbe* Pierre ex Beille)

HISTORY

Yohimbe is a native plant of western Africa, where Pygmies and Bushmen of the region traditionally used this plant as an aphrodisiac, antipyretic, and stimulant. German missionaries brought yohimbe bark from Africa to Europe during the late 19th century, where the plant became popular as the "love tree." Pharmaceutical manufacturers isolated yohimbine from the bark, and this drug has been available by prescription before the US Food and Drug Administration (FDA) began approving drugs in 1938. The popularity of this drug as an aphrodisiac has decreased since the introduction of Viagra® (Pfizer Pharmaceuticals, New York, NY) and similar drugs in the 1990s.

BOTANICAL DESCRIPTION

The main ingredient (yohimbine) of yohimbe bark is also present in other *Pausinystalia* species (e.g., *P. microceras* (K. Schum.) Pierre ex Beille, *P. trillesii* Beille). Although yohimbine and yohimbe are often used interchangeably, the term yohimbe refers to the yohimbe tree and yohimbine is a specific chemical compound.

Common Name: Yohimbe Tree, Corynine, Aphrodine, Quebrachine, Hydroaerogotocin

Scientific Plant Name: *Pausinystalia yohimbe* Pierre ex Beille (*Corynanthe yohimbi*)

Botanical Family: Rubiaceae (madders)

Physical Description: The yohimbe tree is a tall evergreen tree with gray-brown bark and oblong and elliptical leaves. This tree reaches up to 30 m (~100 ft) in height and 8 m (~25 ft) wide with erect, branching stems.

Distribution and Ecology: This tree (*Pausinystalia yohimbe*) is a native plant of western Africa including Nigeria, Cameroon, Congo Gaboon, and Nigeria.

EXPOSURE

Sources

Yohimbe bark (CAS RN: 85117-22-2, corynanthe yohimbe extract) consists of the dried bark of the trunk and/or branches of the yohimbe tree. Yohimbe bark extracts, which contain variable amounts of yohimbine, are available in health food stores and through direct-mail companies as capsules, tablets, and liquids. Yohimbine is also found in *Rauwolfia* root. Yohimbine hydrochloride is available as an FDA-approved prescription drug [Yocon® (Glenwood LLC, Englewood, NJ), Yohimex® (Kramer Laboratories, Miami, FL)] in 2 mg and 4.5 mg tablets.

Medicinal Uses

Traditional

Yohimbe bark is a traditional treatment for a variety of disorders in addition to the treatment of sexual dysfunction. These uses include the treatment of dementia, diabetic complications (e.g., neuropathy), exhaustion,

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

fevers, insomnia, leprosy, low blood pressure, obesity, and syncope.

CURRENT

Health food stores have promoted the use of yohimbe bark extracts as an aphrodisiac for many years, but recently the use of this extract to enhance athletic performance and weight loss has become more popular. In veterinary medicine, yohimbe bark extract is a treatment for impotence in breeding stallions. There are inadequate data to support the use of yohimbe or yohimbine as a dieting agent,[1] and the results of the few clinical studies to date are conflicting.[2]

The main medical indication for yohimbine hydrochloride is the treatment of male impotence. Other suggested medical uses for yohimbine include the treatment of orthostatic hypotension secondary to autonomic failure,[3] dry mouth during tricyclic antidepressant therapy,[4] and the induction of lipid mobilization in obese subjects.[5] In a pilot study of 12 methadone-maintained, opiate-addicted patients, the daily administration of 30 mg yohimbine reduced the symptoms scores of naloxone-precipitated opiate withdrawal an average of 30%.[6] However, vital signs and objective measures of withdrawal were unaffected by yohimbine treatment. Yohimbine is a potential drug of abuse ("yo-yo") because of its alleged aphrodisiac properties.[7]

REGULATORY STATUS

The FDA classifies yohimbe as an unsafe herb, containing "the toxic alkaloid, yohimbine, and other alkaloids." In Germany, the expert panel that evaluates herbal medicines (Commission E) did not recommend the therapeutic use of yohimbe bark and its preparations because of insufficient proof of efficacy.

PRINCIPAL INGREDIENTS

Chemical Composition

The yohimbine concentration in commercial yohimbe products is highly variable. Chemical analysis of 26 commercial yohimbe products indicated that nine products contained no yohimbine and eight products contained only trace amounts (0.1–1 ppm) of yohimbine.[8] The concentrations of yohimbine ranged from <0.1 to 489 ppm compared with 7,089 ppm in the authentic yohimbe bark material. Analyses of authentic yohimbe bark indicate that the average total indole alkaloid content is about 3–6% with approximately 10–15% of the alkaloids being yohimbine. In addition to yohimbine and its isomers (α-yohimbine, β-yohimbine, allo-yohimbine), these alkaloids include ajmalicine, dihydroyohimbine, corynantheine, dihydrocorynantheine, and corynanthine (rauhimbin).

Physicochemical Properties

Yohimbine (CAS RN: 146-48-5, $C_{21}H_{26}N_2O_3$) is an indolealkylamine alkaloid extracted from the bark of the yohimbe tree. Figure 96.1 displays the chemical structure of yohimbine. Yohimbine is a selective α_2-adrenergic receptor antagonist with weak α_1-antagonist activity based on pharmacological studies and radioreceptor ligand binding assays.[9] Yohimbine potentiates the release of norepinephrine from noradrenergic nerve terminals. Additionally, yohimbine reduces the ability of norepinephrine to decrease cAMP and intracellular calcium at postsynaptic noradrenergic receptors, whereas the stimulation of postsynaptic noradrenergic receptors mediated by other adrenoceptor subtypes is unaffected.[10]

In animal studies, yohimbine is a pharmacological stressor, which is commonly used to produce anxiety-like effects.[11] The administration of yohimbine to humans causes elevated plasma catechol and cortisol concentrations, nausea, increased subjective feelings of anxiety, increased startle responses, and panic attacks.[12] Yohimbine is highly lipophilic and easily crosses the blood–brain barrier. Yohimbine is sparingly soluble in water, but soluble in alcohol and chloroform. Yohimbe bark extract is odorless with a bitter taste. Table 96.1 lists some identifying characteristics and physical properties of yohimbine.

Mechanism of Toxicity

Yohimbine is a selective α_2-adrenergic antagonist that produces tachycardia, mydriasis, elevated blood pressure, salivation, diaphoresis, nausea, vomiting, and facial flushing after intravenous administration.[13] The intravenous administration of yohimbine promotes unimpeded norepinephrine flow to α_1 and β receptors in the postsynaptic effector cells, resulting in a rise in blood

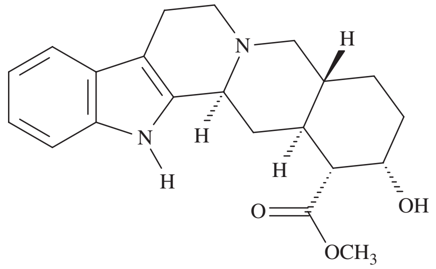

FIGURE 96.1. Chemical structure of yohimbine.

TABLE 96.1. Identifying Characteristics and Physical Properties of Yohimbine

Property	Value
CAS Registry Number	146-48-5; 65-19-0 (Hydrochloride salt)
CAS Names	Yohimban-16-carboxylic acid, 17-hydroxy-, methyl ester, (16α, 17α)
Synonyms	Aphrodyne; corynine; quebrachine
Melting Point	241 °C/~466 °F
log P (Octanol-Water)	2.73
Water Solubility	277 mg/L (25 °C/77 °F)
Vapor Pressure	1.61E-12 mmHg (25 °C/77 °F)
Henry's Law Constant	2.90E-17 atm-m^3/mole (25 °C/77 °F)
Atmospheric OH Rate Constant	2.74E-10 cm^3/molecule-second (25 °C/77 °F)

pressure and an increase in plasma norepinephrine. Yohimbine may also exert a partial block at α_1 receptor sites, dopamine receptor sites, and serotonin receptor sites.[9,14]

DOSE RESPONSE

In clinical studies on the treatment of sexual dysfunction, typical daily doses of yohimbine are 15–30 mg divided into three doses with patients tolerating daily doses up to 100 mg.[15] Side effects in these studies at doses of 20–45 mg include increased heart rate and blood pressure, anxiety and urinary frequency. A study of 20 commercial yohimbe bark preparations sold over the Internet as aphrodisiacs indicated that the maximum daily dose of yohimbine in these products ranged from about 1–23 mg.[16] Case reports indicate that the ingestion of approximately 200–250 mg yohimbine produces transient tachycardia, hypertension, tremulousness, diaphoresis, and anxiety, which resolve spontaneously without serious complications.[17,18]

There are few data on the dose of yohimbe bark when used as an herbal medicine. One preparation of a tea involves the simmering of 25–50 mL (5–10 teaspoons) of yohimbe bark in 360 mL (1 pint) water with the addition of up to 500–1,000 mg vitamin C to improve solubility as needed.

TOXICOKINETICS

The absorption and elimination of oral doses of yohimbine are rapid. Following the ingestion of therapeutic doses (e.g., 8–10 mg) of yohimbine, peak plasma concentrations occur within 45–60 minutes.[19] Oral bioavailability of pharmaceutical preparations of yohimbine is relatively low with substantial variability. In a study of seven healthy volunteers, the mean bioavailability of a 10-mg dose of yohimbine was 33% with a range of 7–87%.[20] The estimation of the volume of distribution (V_d) is complex as a result of the interaction of high protein binding, rapid metabolism, and high lipid solubility. Following therapeutic doses of yohimbine, the mean protein binding of yohimbine, 11-OH-yohimbine, and 10-OH-yohimbine was 82%, 43%, and 32%, respectively.[21] Elimination of yohimbine occurs primarily by hepatic metabolism with very small amounts (<1%) of yohimbine excreted unchanged by the kidneys.[15] The major hepatic metabolite in plasma is the active metabolite, 11-OH-yohimbine. Although the α_2-adrenoceptor binding of 11-OH-yohimbine is less than yohimbine, the α_2-adrenergic antagonist activities of these two compounds are similar because of the relatively lower protein binding of 11-OH-yohimbine.[21] The minor, inactive metabolite, 10-OH-yohimbine, is usually detectable only in urine samples. Following therapeutic doses of yohimbine, elimination of yohimbine is relatively rapid with a half-life ($t_{1/2}$) of about 1.5 hours compared with approximately 6 hours for the active 11-OH-yohimbine metabolite.[22] In a pharmacokinetic study of 16 healthy male participants receiving yohimbine tartrate and L-arginine glutamate in a single pharmaceutical preparation, the plasma elimination half-life of yohimbine was 1.0 ± 0.34 hours with a range of 0.40–6.0 hours.[23] Consequently, the duration of the pharmacological effects of yohimbine may result from the prolonged half-life of 11-OH-yohimbine. The biotransformation of yohimbine in some subjects (i.e., slow metabolizers) with debrisoquine oxidative polymorphism is limited compared with other subjects.[22]

CLINICAL RESPONSE

Adverse effects associated with the use of yohimbe as a medicinal herb include anxiety, urinary frequency, agitation, headache, and elevated blood pressure.[15,24] A case report associated the development of severe hypertension (blood pressure 240/140 mmHg, headache, weakness) with the use of yohimbe as an herbal treatment for impotence.[25] The absorption of yohimbine is relatively rapid with symptoms of intoxication beginning within 1–2 hours. Clinical features of yohimbine intoxication include nausea, vomiting, anxiety, tremulousness, palpitations, diaphoresis, transient hypertension, and mild tachycardia. A 16-year-old girl developed a severe headache, weakness, paresthesias, poor coordination, tremors, and a dissociative state about 20–30 minutes after ingesting an estimated yohimbine dose of 250 mg.[18] Within 4 hours, she developed the sensation of severe pressure-like substernal chest pain that resolved

after 2 hours. The electrocardiogram revealed a sinus tachycardia, but no evidence of ischemia or dysrhythmias. Other clinical features that resolved over the next 36 hours included palpitations, tachypnea, erythema, nausea, diaphoresis, tremulousness, anxiety, mild hypertension, and tachypnea. The ingestion of an estimated yohimbine dose of 200 mg with ethanol by a 62-year-old man produced vomiting, anxiety, lightheadedness, lower extremity paresthesias, mild hypertension, and tachycardia that resolved within 24 hours without complication.[26] Yohimbine intoxication may produce an acute dissociative reaction with anxiety, paresthesias, weakness, and incoordination.

DIAGNOSTIC TESTING

Methods for the quantitation of yohimbine include gas chromatography/nitrogen phosphorus detection[8] and high performance liquid chromatography (HPLC),[27] and HPLC with ultraviolet detection/mass spectrometry with atmospheric pressure chemical ionization and electrospray ionization.[16] During yohimbine intoxication, most laboratory tests (e.g., liver/kidney function, electrolytes) are normal, though serum catecholamine concentrations (norepinephrine, epinephrine) may be slightly elevated during the acute phase of intoxication.[18] The distribution of yohimbine between serum and red blood cells is uneven with only 20% of the yohimbine in whole blood residing in the erythrocytes.[19]

TREATMENT

Management of yohimbine intoxication is supportive. Decontamination measures (i.e., activated charcoal) are usually unnecessary, but the use of activated charcoal within one hour of ingestion of excessive doses of yohimbine is a therapeutic option. However, there are no clinical data to document the efficacy of decontamination measures in this setting. Benzodiazepines (diazepam, lorazepam) are the drugs of choice to alleviate anxiety and the initial sympathomimetic symptoms associated with yohimbine intoxication.[28]

There are few data on the efficacy of specific drugs to treat yohimbine intoxication. Clonidine is a *potential* antagonist of the effects of yohimbine. Clonidine acts centrally by stimulating alpha adrenergic receptors, causing a reduction in sympathetic outflow, and peripherally by agonist effects on α-adrenergic receptors, causing a reduction in vascular activity. However, clonidine possesses weak α_1-agonist activity (i.e., peripheral vasoconstriction) that may exacerbate hypertension following the administration of low clonidine doses during yohimbine intoxication. Consequently, sodium nitroprusside is safer than clonidine for the treatment of hypertensive emergencies associated with yohimbine toxicity.

Chapter 97

CITRONELLA OIL
[*Cymbopogon nardus* (L.) Rendle]

HISTORY

At the end of the 19th century, citronella was first used as an insecticide. At the beginning of the 20th century, the isolation of the aldehyde, hydroxycitronellal from citronella oil helped to launch the perfume industry.

BOTANICAL DESCRIPTION

Common Name: Citronella Grass, Ceylon Citronella, Nardus, Nard Grass, Nardus Grass, Mana Grass, Geranium Grass

Scientific Name: *Cymbopogon nardus* (L.) Rendle

Botanical Family: Poaceae (grass family)

Physical Description: Citronella grass is a perennial, coarse, clump-forming tropical grass that can reach 5–6 ft (~1–2 m) in height. The surface of the leaf-blade is smooth or scaberulous (small raised areas of roughness) and gray-green. The leaves droop for one-third of the length and are aromatic when crushed. Flowers are borne in terminal and axillary racemes.

Distribution and Ecology: Citronella grass is native to southeastern Asia, and this grass is grown commercially in Sri Lanka, India, Burma, Indonesia, and Java. This plant is an ornamental grass in southern Florida and California as well as a naturalized grass in tropical Asia.

EXPOSURE

Sources

Citronella oil is a steam distillation product of the fresh or partially dried leaves from citronella grass (*Cymbopogon nardus*) or Java citronella grass (*Cymbopogon winterianus* Jowitt). The latter is called Java-type citronella oil, whereas the former is called Ceylon-type citronella oil. The yield of essential oil from the leaves is approximately 0.4–1.4% volume/weight.

Medicinal Uses

TRADITIONAL

Traditional herbal treatments with citronella oil include use as a rubefacient (redness of skin), antispasmodic, and diaphoretic (increase sweat). Animal studies suggest that citronella oil produces some sedation and analgesic effects.[1]

CURRENT

Citronella oil and citronella candles are traditional mosquito repellants and household fumigants.[2,3] Citronella oil is also a strong food flavoring agent, which occurs in low concentrations in alcoholic and nonalcoholic beverages, baked goods, breakfast cereals, soft and hard

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

candies, frozen dairy products, gelatins, and puddings. Additionally, this oil is a component of deterrents for dogs seeking to mate.

Regulatory Status

In the United States, citronella oil is listed as generally recognized as safe (GRAS), and the Flavor and Extract Manufacturers' Association (FEMA) approved GRAS status for citronella oil. The Council of Europe placed the Java type citronella oil in Category 1 (items are not considered a safety concern at levels consumed) and the Ceylon-type citronella oil in Category 3 (items with a safety concern associated with the active ingredient) based on the presence of isomethyleugenol.

PRINCIPAL INGREDIENTS

Chemical Composition

Both Ceylon- and Java-type citronella oils contain over 80 constituents, primarily monoterpene compounds and minor amounts of sesquiterpenes [(E)-nerolidol, β-caryophyllene, germacren-4-ol].[4] The major constituents vary in these two types of citronella oil depending on geographic location, climate, and strain. Citronellal (CAS RN: 106-23-0, $C_{10}H_{18}O$) and citronellol (RN: 106-22-9, $C_{10}H_{20}O$) are the main compounds in Ceylon-type citronella oil, accounting for about 30–45% of the total constituents depending on the source.[5] Figure 97.1 shows the chemical structure of citronellal. Geraniol is the other major constituent (i.e., about 25–35%) with minor amounts of geranyl acetate, citronellyl acetate, and limonene. Ceylon-type of citronella oil contains lower concentrations of citronellal and citronellol and higher concentrations of isomethyleugenol compared with Java-type citronella oil.

Physiochemical Properties

Ceylon-type of citronella oil is a pale-yellow to yellowish-brown liquid that has a characteristic citronellal-like smell, whereas Java-type is a clear, light-yellow to brownish liquid with a strong citrus smell. Table 97.1 lists some physical properties of citronellal.

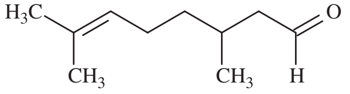

FIGURE 97.1. Chemical structure of citronellal.

Mechanism of Toxicity

The main constituents of citronella oil are citronellol, citronellal, and geraniol, but the specific toxic constituents have not been identified; therefore, the mechanism of action is unknown.

DOSE RESPONSE

The ingestion of citronella causes relatively low toxicity in the absence of pulmonary aspiration. The ingestion of an estimated 25 mL of citronella oil by a 16-month-old child was not associated with any systemic toxicity.[6]

TOXICOKINETICS

There are few data on the toxicokinetics of the major components of citronella oil.

CLINICAL RESPONSE

Most accidental ingestions of citronella oil do not produce symptoms, provided pulmonary aspiration does not occur.[6] The older medical literature associates the ingestion of citronella oil with respiratory distress, hypotension, and death.[7] However, the use of unconventional treatment, the possible role of pulmonary aspiration, and the lack of adequate documentation of medical events prevents conclusions about the causal role of citronella oil in the development of these serious effects. Contact dermatitis occurs following exposure to cosmetics containing the closely related compound, hydroxycitronellal (CAS RN: 107-75-5).[8,9] Long-term carcinogenesis studies in rodents with doses up to 2,000 mg/kg food-grade geranyl acetate containing approximately 29% citronellyl acetate did not detect evidence of carcinogenicity.[10]

DIAGNOSTIC TESTING

Methods to analyze the content of monoterpene compounds in citronella oil include gas chromatography and gas chromatography/mass spectrometry.[5]

TABLE 97.1. Some Physical Properties of Citronellal

Physical Property	Value
log P (Octanol-Water)	3.530
Water Solubility	70.2 mg/L (25 °C/77 °F)
Vapor Pressure	0.280 mmHg (25 °C/77 °F)
Henry's Law Constant	2.62E-04 atm-m^3/mole (25 °C/77 °F)
Atmospheric OH Rate Constant	1.21E-10 cm^3/molecule-second (25 °C/77 °F)

TREATMENT

Treatment is supportive. Accidental ingestions of citronella oil do not require decontamination. Patients should be evaluated carefully for the presence of pulmonary aspiration (cough, dyspnea, pulmonary infiltrates, reduced oxygen saturation).

Chapter 98

CITRUS OIL and LIMONENE

HISTORY

Both the *d*- and *l*-isomers of limonene and the racemic mixture (dipentene) occur naturally. In Florida in the early 1940s, *d*-limonene was discovered as a by-product of citrus molasses production.[1] Since the 1980s, *d*-limonene has been an alternative to chlorinated hydrocarbon solvents and degreasing agents. In 2004, the US Food and Drug Administration (FDA) banned the use of ephedra products, and synephrine-containing herbal products of bitter orange have been promoted as alternative dietary supplements for energy enhancement and weight loss.

BOTANICAL DESCRIPTION

Bergamot is a variety of bitter orange cultivated on a variety of rootstocks.

Common Name: Bergamot Orange

Scientific Name: *Citrus* X *aurantium* L. subsp. *bergamia* (Risso & Poit.) Wight & Arn. ex Engler

Botanical Family: Rutaceae (rues, rutacées)

Physical Description: The bergamot orange is a small pear-shaped fruit that is a cross-product of the sour orange and the pear lemon.

Distribution and Ecology: This cultivar was originally developed in Italy. This acidic orange is now grown in the Ivory Coast, Brazil, and Argentina as a source of bergamot oil rather than a food.

Common Name: Sour Orange (Seville Orange, Bitter Orange, Green Orange, Zhi Shi)

Scientific Name: *Citrus* X *aurantium* L. ssp. *aurantium* (*Fructus aurantii*)

Botanical Family: Rutaceae (rues, rutacées)

Physical Description: This evergreen tree reaches up to 3–9 m (~10–30 ft) in height with a more erect and compact crown than the sweet orange. The trunk has smooth, brown bark, and the young, green twigs have relatively long thorns. The compound, ovate, pointed green leaves alternate on broad-winged, relatively long petioles compared with the sweet orange. Highly fragrant flowers appear singly or in small clusters in the leaf axils with widely separated petals surrounding a tuft containing many yellow stamens. The round, oblate or oblong-oval fruit has a rough surface and a thick, aromatic, bitter peel that becomes bright red-orange on maturity.

Distribution and Ecology: The sour orange is native to southeastern Asia. This orange was distributed widely to warm areas of the Pacific Islands (Guam, Samoa, Fiji), North Africa, Europe, and North America.

Common Name: Orange, Sweet Orange

Scientific Name: *Citrus* X *sinensis* (L.) Osbeck (pro sp.) [maxima X reticulata]

Botanical Family: Rutaceae (rues, rutacées)

Physical Description: The sweet orange is an old hybrid between the tangerine and similar fruit.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

This evergreen reaches about 10 m (~33 ft) in height with alternate, ovate, waxy green leaves that are pointed. Fragrant, white flowers appear in May, usually singly. There are several cultivars of the sweet orange including the Washington navel, Valencia (juice orange), and blood orange.

Distribution and Ecology: Sweet oranges are cultivated widely in warm climates throughout the world, where temperatures during winter do not persist below freezing.

Common Name: Tangerine

Scientific Name: *Citrus reticulata* Blanco

Botanical Family: Rutaceae (rues, rutacées)

Physical Description: The tangerine is a small (<6–7 cm/2–3 in.), oblate, loose-skinned, deep orange fruit.

Distribution and Ecology: Some tangerine trees (e.g., Satsuma tangerine) can tolerate cool subtropical environments incompatible with sweet oranges, where temperatures reach 15 °F–18 °F (~−9 °C to ~−8 °C).

Common Name: Key Lime, Mexican Lime

Scientific Name: *Citrus* X *aurantiifolia* (Christm.) Swingle (pro sp.) [medica X sp.]

Botanical Family: Rutaceae (rues, rutacées)

Physical Description: Limes grow on relatively small, much branched citrus trees. The Key lime is a round, green fruit about 3–5 cm (~1–2 in.) in diameter with a thin peel and an acid pulp.

Distribution and Ecology: The lime grows in most citrus-producing areas.

Common Name: Lemon

Scientific Name: *Citrus* X *limon* (L.) Burm. f. (pro sp.) [medica X aurantifolia]

Botanical Family: Rutaceae (rues, rutacées)

Physical Description: Lemon trees grow somewhat more rapidly than orange trees with more widespread branches than grapefruit or sweet oranges. The oval fruit is slightly oblong and turns yellow during maturity. The diameter of the lemon is about 6 cm (~2 in.).

Distribution and Ecology: The lemon grows in most citrus-producing areas, although this tree is slightly less resistant to cold than sweet oranges.

Common Name: Grapefruit, Paradise Citrus

Scientific Name: *Citrus* X *paradisi* Macfad. (pro sp.) [maxima X sinensis]

Botanical Family: Rutaceae (rues, rutacées)

Physical Description: The grapefruit tree has larger, thicker leaves than the sweet orange tree, and the grapefruit grows more vigorously than orange, particularly during the early years of growth. The relatively large (8–10 cm/~3–4 in.) fruit is round to oblate with a thick rind that turns yellow on maturity. Some varieties are seedless, and the pulp is white or pink.

Distribution and Ecology: The grapefruit grows in most citrus-producing areas.

EXPOSURE

Sources

There are a variety of sources for citrus oil including sweet orange (*Citrus sinensis*), mandarin (*Citrus deliciosa* Tenore), grapefruit (*Citrus paradisi*), lemon (*Citrus limon*), and sour or bitter orange (*Citrus aurantium*). *d*-Limonene is a non-nutritive dietary component of the essential oils of citrus fruits that occurs in smaller concentrations in turpentine, tea tree oil, and other essential oils including eucalyptus, lavender, rosemary, caraway, and peppermint. Commercial use of *d*-limonene includes the synthesis of spearmint oil and use as a lemon fragrance in soaps, detergents, creams, lotions, and perfumes as well as a lemon flavoring agent in foods, beverages and chewing gum. Commercial production processes for *d*-limonene involve alkalinization and steam distillation of citrus peel and pulp remaining from the production of citrus juice or cold-pressed citrus peel oils. Commercial production of *l*-limonene involves acid treatment of pinene or the purification of monoterpene compounds in pine oils. Synthetic processes for the racemic mixture include thermal isomerization of α-pinene or the removal of dipentene as a by-product of synthetic pine oils. As a result of the ubiquitous presence of *d*-limonene in commercial products, this compound is a common constituent of indoor air. In a study of indoor air samples from commercial office buildings in the midwestern United States, *d*-limonene was one of the five most prevalent volatile organic compounds present in concentration up to about 3 $\mu g/m^3$.[2] Outdoor air samples from Houston, Texas contained limonene concentrations varying from 0–32 $\mu g/m^3$ (0–5.7 ppb).[3]

Medicinal Uses

Traditional

Common herbal uses for extracts of sour or bitter orange (zhi shi) include sedation and the treatment of

gastrointestinal disorders, such as anorexia, abdominal pain, constipation, and nausea.[4]

Current

d-Limonene is an experimental chemotherapeutic compound undergoing testing as chemopreventative agent to enhance the detoxification of carcinogens by the induction of Phase II carcinogen-metabolizing enzymes.[5,6] The role of *d*-limonene in preventing cancer in humans is unproven. *Citrus aurantium* contains beta agonists, and herbal extracts of *C. aurantium* are used as weight-reduction agents.[7] Although extracts of Seville orange (*Citrus aurantium*) are marketed as a safe alternative to ephedra in herbal weight-loss products, there are few clinical data to support the efficacy of this product as a means to lose weight.[8,9] A study of 13 elderly patients with dementia did not support the use of sweet orange (*Citrus aurantium*) to reduce combative, resistive behaviors in individuals with dementia.[10] Of about 30 terpene compounds studied, *d*-limonene had the most desirable properties for the dissolution of gallstones in a Japanese study,[11] but there has been little use of this compound to solubilize gallstones in clinical practice. *d*-Limonene is a common constituent of home cleaning products, industrial hand cleaners, deodorants, disinfectants, wax and paint strippers, and lubricating oils, as well as some animal shampoos and topical insecticides.[12,13] In many histological laboratories, *d*-limonene is a substitute for xylene.

Regulatory Status

d-Limonene is on the US Food and Drug Administration's (FDA) list of compounds generally recognized as safe (GRAS), and the FDA approves the use of *d*-limonene as a food additive. *d*-Limonene is a common flavoring agent and fragrance in perfumes, soaps, beverages, and foods.

PRINCIPAL INGREDIENTS

Chemical Composition

The composition of essential citrus oils depends on the process (steam distillation, vacuum distillation, solvent extraction, cold pressing) as well as the place of origin, species, season, and weather. The most common methods for obtaining essential oils from citrus (bitter orange, sweet orange, mandrin, grapefruit, lime, lemon, bergamot) are cold mechanical pressing and steam distillation. The composition of various citrus oils is similar, consisting of 85–95% of the monoterpene *d*-limonene along with small quantities of terpene hydrocarbons (myrcene, α-pinene, sabinene), alcohols, aldehydes, phenolic acids, esters, and ketones. *d*-Limonene occurs naturally in both the dextrorotatory and levorotatory forms with the racemic mixture of the two isomers being known as dipentene. Figure 98.1 displays the chemical structure of limonene. About 90% of orange peel oil is *d*-limonene (1-methyl-4-isopropenyl-1-cyclohexene, CAS RN: 138-86-3). Synonyms for limonene include 4-isopropenyl-1-methyl cyclohexene, 1-methyl-4(1-methy lethenyl)cyclohexene, p-mentha-l,8-diene, carvene, cinene, and cajeputene. Citronella and lemon grass oils contain primarily *l*-limonene.

The presence of valencene as the principal sesquiterpene compound distinguishes sweet orange peel oil from other types of citrus oils. Compared with other citrus oils, the concentration of limonene in lemon peel oil is relatively low (70–80%) with higher concentrations of α-pinene, β-pinene, and γ-terpinene. The oxygenated fraction of lemon oil contains relatively high concentrations of the aldehyde, citral, which imparts the aroma of lemon oil. The *d*-limonene concentration in bergamot oil is substantially lower (25–32%) compared with other citrus oils, while the content of linalool and linalyl acetate are very high. A sample of lemonade juice contained about 0.5 mg *d*-limonene/mL.[14] Typical commercial products containing *d*-limonene include nonalcoholic beverages (31 ppm), ice cream (68 ppm), candy (49 ppm), baked goods (120 ppm), gelatins and puddings (48–400 ppm), and chewing gum (2,300 ppm).[15]

Extracts of *Citrus aurantium* (Seville orange, bitter orange) contain synephrine (*p*-synephrine, oxedrine), which is an indirect-acting sympathomimetic amine structurally similar to ephedrine and phenylpropanolamine.[8] Figure 98.2 displays the similarity between ephedrine, the neurotransmitter, epinephrine, and synephrine. Dry extracts of bitter orange contain about 3% synephrine as measured by high performance liquid chromatography (HPLC).[16] There are six possible isomers of synephrine including the *ortho*-, *meta*-, and

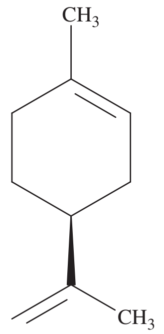

FIGURE 98.1. Chemical Structure of Limonene.

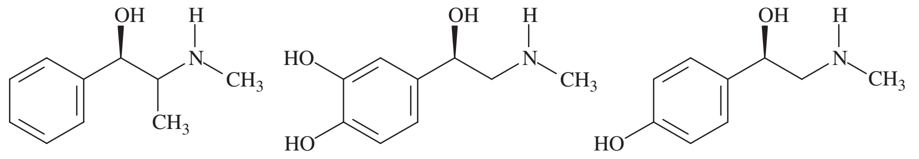

Ephedrine **Epinephrine (adrenalin)** **Synephrine**

FIGURE 98.2. Similarity of synephrine, ephedrine, and epinephrine.

para- isomers along with two optical isomers or chiral forms for each of these three positional isomers. At least some dietary supplements of bitter orange also contain *m*-synephrine (phenylephrine), which is a common over-the-counter nasal decongestant.[17] The exact composition of each isomer in citrus oils is not well defined. Bitter orange also contains other stimulant amines including *d*,*l*-octopamine and *N*-methyltyramine.[18] The low-volatile fraction of *Citrus* essential oils contains flavonoid (rutinosides, neohesperidosides) and coumarin compounds including neoeriocitrin, narirutin, naringin, hesperidin, neohesperidin, naringenin, aurapten, bergamottin, bergapten, nobiletin, tangeritin, and hesperetin.[19] In general, lime oil contains the highest concentration of furocoumarin compounds compared with other citrus oils.[20] High concentrations of bergapten occur in bergamot oil and lime oil; the concentration of oxypeucedanin is high in lime oil and undetectable in bergamot oil. Bergapten and oxypeucedanin are the main phototoxic furocoumarin compounds in lemon oil with the latter being about one-fourth as potent as bergapten in animal models of phototoxicity.[21] The concentration of these furocoumarin compounds varies substantially in lemon oil samples, ranging from 4–87 ppm and 26–728 ppm, respectively, in 13 samples from various parts of the world.[21] Most flavonoids in citrus are flavanones (rutinosides, neohesperidosides) bound as glycosides attached at the C7 position. The predominant flavanone in sweet orange, mandarin, lemon, and tangerine is the rutinoside compound, hesperetin, which is a relatively tasteless flavanone. Lime and lemon oils also contain substantial amounts of eriocitrin.[22] Sour or bitter orange and grapefruit contain different flavanones compared with sweet orange and mandarins. The neohesperidoside glycosides predominate in grapefruit (naringin, narirutin) and bitter orange (naringin, neohesperidin).[23] In one study, the concentration of naringin and neohesperidin in samples of bitter orange ranged from approximately 2–26 mg/g and 4–15 mg/g, respectively.[16] These neohesperidoside glycosides are intensely bitter and contribute to the characteristic taste of bitter orange and grapefruit. Linalool is a major terpene alcohol that contributes to the floral aroma of citrus peel oils.[24]

TABLE 98.1. Physical Properties of *d*-Limonene

Physical Property	Value
Conversion Factors	
1 ppm	5.56 mg/m^3
1 mg/m^3	0.18 ppm
Molecular Weight	136.26
Molecular Formula	$C_{10}H_{16}$
Density	0.8411 g/cm^3 (20 °C/68 °F)
Melting Point	–74.3 °C/–101.7 °F
Boiling Point	176 °C/~349 °F
Density (4 °C–20 °C)	0.8402
log P (octanol-water)	4.57
Water Solubility	13.8 mg/L (25 °C/77 °F)
Vapor Pressure	1.55 mmHg (25 °C/77 °F)
Henry's Law Constant	0.032 atm-m^3/mole (25 °C/77 °F)
Atmospheric OH Rate Constant	1.49E-10 cm^3/molecule-second (35 °C/95 °F)

Physiochemical Properties

Limonene is a colorless to slightly yellow liquid with a pleasant, lemon-like odor and a citrus taste. *d*-Limonene is the pharmacologically active isomer. Table 98.1 lists some of the physical properties of *d*-limonene. The high vapor pressure and low water solubility of limonene indicates a relatively high rate of evaporation. This compound is flammable with a flash point of 48 °C (~118 °F). In the atmosphere, ozone, nitrate radicals, and hydroxy radicals rapidly (i.e., few hours) oxidize *d*-limonene to monocyclic terpene compounds (e.g., *cis* and *trans*-limonene-2-hydroperoxide, carvone).[25] Although *d*-limonene is an irritant, the allergenic properties associated with *d*-limonene probably result from oxidation products (e.g., limonene oxide, limonene hydroperoxides, carvone) rather than the parent compound.[26,27] The pH of orange peel oil is about 5.6 compared with about 3.8 for orange juice concentrate.[28]

Mechanism of Toxicity

The contribution of synephrine to the toxicity associated with some case reports of bitter orange supplements is unclear. These supplements contain synephrine,

which is an α_1-adrenergic receptor agonist that produces vasoconstriction and elevated blood pressure in *in vitro* animal preparations.[29] However, herbal preparations contain multiple ingredients including caffeine, and the role of synephrine in these cases remains undefined. A randomized, double-blind, placebo-controlled crossover study did not detect elevated blood pressure in 10 healthy subjects following single doses of synephrine, whereas the ingestion of weight loss supplements containing multiple ingredients including synephrine did produce significant cardiovascular stimulation.[30]

DOSE RESPONSE

Medicinal Use

In clinical trials on the use of *d*-limonene to dissolve gallstones, patients tolerated oral doses of 20 g *d*-limonene without obvious toxicity.[11] The ingestion of 100 mg *d*-limonene/kg did not produce clinically significant toxicity in seven healthy volunteers.[31] In a phase I clinical trial of *d*-limonene in patients with advanced cancer, the maximum tolerated dose was 8 g/m^2 with nausea, vomiting, and diarrhea being the dose-limiting effects.[32]

Toxicity

Based on the significant decreases in body weight gain associated with administration of *d*-limonene to male and female mice and rats and female rabbits, the World Health Organization (WHO) established an acceptable daily intake (ADI) for *d*-limonene of 1.5 mg/kg body weight. The daily intake of *d*-limonene varies considerably depending on the amount and type of citrus products consumed along with the processing procedures. The mean daily intake of *d*-limonene from citrus juices among US consumers in an Arizona study was about 13 mg based on questionnaires.[33]

TOXICOKINETICS

Absorption

Rodent studies indicate that the absorption of *d*-limonene is rapid with peak serum concentrations of this compound occurring within 2 hours of oral administration.[34] However, in a study of 32 patients with locally advanced metastatic solid tumors receiving oral *d*-limonene, the absorption of *d*-limonene was relatively slow with the time to peak concentration (T_{max}) ranging from 1–6 hours.[32] In eight healthy volunteers exposed to 450 mg/m^3 *d*-limonene for 2 hours, the relative pulmonary uptake of *d*-limonene was high (i.e., about 70%).[35]

Biotransformation

d-Limonene undergoes extensive species-dependent biotransformation (Figure 98.3).[34] The major metabolite in humans and guinea pigs is 8-hydroxy-*p*-meth-1-en-9-yl-β-D-glucopyranosiduronic acid (M-VI), whereas perillic acid-8,9-diol (M-IV) is the major metabolite in rats and rabbits.[36,37] In a phase I clinical trial of patients with advanced cancer, the predominant circulating metabolites of *d*-limonene were perillic acid, dihydroperillic acid, uroterpenol, limonene-1,2-diol, and an isomer of perillic acid.[32] *In vitro* studies indicate that CYP2C9 and, to a lesser extent, CYP2C19 catalyze the 6-hydroxylation of *d*-limonene to carveol and the 7-hydroxylation of *d*-limonene to perillyl alcohol.[38]

Elimination

The metabolism of *d*-limonene is extensive with relatively small amounts (<0.01%) of *d*-limonene excreted unchanged in the urine.[35] Animal studies indicate that renal excretion is the main route of elimination of *d*-limonene with about 75–90% of the absorbed dose eliminated within 2–3 days. Fecal excretion accounts for about 10% of the absorbed dose of *d*-limonene during this period. In a study of nine healthy volunteers ingesting lemonade rich in *d*-limonene, plasma perillic acid concentrations declined rapidly with a mean plasma half-life of 1.38 ± 0.40 hours.[14] Secretion of *d*-limonene occurs in breast milk as a result of nonoccupational exposure to this compound.[39]

Drug Interactions

Botanical supplements containing *C. aurantium* extracts probably do not produce clinical significant interactions with cytochrome P450 enzymes (CYP3A4, CYP1A2, CYP2E1, CYP2D6) in humans.[40]

CLINICAL RESPONSE

Acute Effects

d-Limonene is a skin irritant and skin sensitizer that produces various types of contact dermatitis including irritant, delayed allergic eczematous, immediate vesicular eruption, urticaria, and phototoxicity.[41,42] Case reports associate the topical exposure to *d*-limonene with the development of acute contact dermatitis.[43,44] Although these oxidized *d*-limonene compounds are the most common skin sensitizers in citrus oil, rare case reports associate contact dermatitis with minor components (e.g., geraniol, citral) of citrus peel oil.[45] Berloque dermatitis is a variant of phytophotodermatitis that

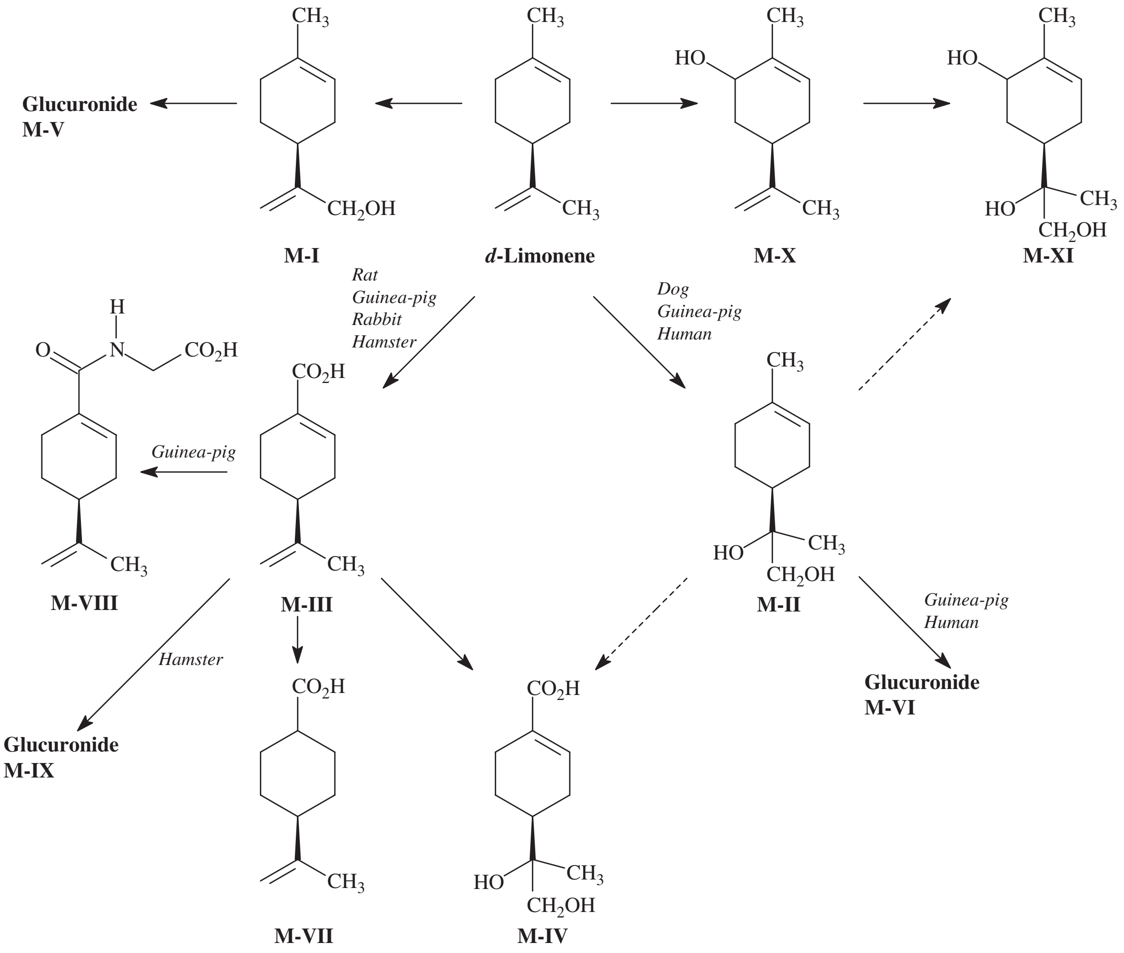

FIGURE 98.3. Major pathways of limonene biotransformation in various animal species. **Metabolites (M): M-I** = *p*-mentha-1,8-dien-10-ol, **M-II** = *p*-menth-1-ene-8,9-diol, **M-III** = perillic acid, **M-IV** = perillic acid 8,9-diol, **M-V** = *p*-mentha-1,8-dien-10-yl-beta-D-glucopyranosiduronic acid, **M-VI** = 8-hydroxy-p-menth-1-en-9-yl-beta-D-glucopyranosiduronic acid, **M-VII** = 2-hydroxy-p-menth-8-en-7-oic acid, **M-VIII** = perillylglycine, **M-IX** = perillyl-beta-D-glucopyrano-siduronic acid, **M-X** = *p*-mentha-1,8-dien-6-ol, **M-XI** = *p*-menth-1-ene-6,8,9-triol. Adapted from International Agency for Research on Cancer. *d*-Limonene. IARC Mongr Eval Carcinog Risk Hum 1999;73:313.

produces painful, red, edematous vesicles and bullae after contact with high concentrations of psoralen-containing fragrances, most commonly oil of bergamot.[46] Sequelae include hyperpigmentation of the affected skin. Although Berloque dermatitis is rarely seen today because of the removal of these fragrances from most cosmetic products, case reports associate these types of skin lesions with the use of bergamot oil during aromatherapy.[47] Gastrointestinal distress (nausea, vomiting, diarrhea) was the main adverse effect in a clinical trial of advanced cancer patients receiving daily *d*-limonene doses of 0.5–12 g/m^2 in 21-day cycles.[32]

Although the FDA banned the use of ephedra-containing products because of safety considerations in 2004, the ephedra ban did not preclude the use of other structurally related sympathomimetic amines. Bitter orange (*Citrus aurantium*) contains the indirect-acting sympathomimetic amine, synephrine, which is a common replacement for ephedra in herbal preparations for weight loss and energy enhancement. Several case reports associate the use of synephrine-containing supplements with adverse cardiovascular and cerebrovascular effects. A 38-year-old man developed an ischemic stroke (memory loss, unsteady gait) 1 week after initiating a weight-loss dietary supplement containing 6–12 mg synephrine.[48] The multivessel distribution of the stroke and normal magnetic resonance angiography suggested a vasospastic origin. A 55-year-old smoker developed an acute lateral myocardial infarction one year after beginning the daily use of 300 mg bitter orange (*C. aurantium*). Although she was hypertensive on presentation, she did not have a history of hypertension or other cardiovascular risk factors. A previously healthy 22-year-old woman developed exercise-induced syncope 1 hour

after ingesting a second dose of an herbal weight loss supplement, which contained 3 mg synephrine.[49] The electrocardiogram demonstrated a prolonged QTc interval (516 milliseconds), which normalized within 24 hours. The exact causal role of synephrine in these case reports is unclear because of the ingestion of multiple ingredients and the lack of pharmacokinetic data on synephrine.

Chronic Effects

In a 2-year gavage study, there was evidence of an increased incidence of tubular cell hyperplasia, adenomas, and adenocarcinomas of the kidney in male F344/N rats receiving 150 mg *d*-limonene (99% pure)/kg 5 days/week.[50] This nephropathy was the only microscopic evidence of *d*-limonene-related toxicity in this study. There was no evidence of carcinogenic activity of *d*-limonene for female F344/N rats receiving 300 or 600 mg/kg, $B_6C_3F_1$ mice receiving 250 or 500 mg/kg, or female $B_6C_3F_1$ mice receiving 500 or 1,000 mg/kg on a similar schedule. *d*-Limonene is one of a diverse group of hydrocarbons, which produce a unique nephropathy in male rats secondary to the accumulation of α_{2u}-globulin following subchronic or chronic exposure. The International Agency for Research on Cancer (IARC) lists *d*-limonene as not classifiable as to carcinogenicity to humans (Group 3) based on the lack of evidence that any human protein can contribute to a renal syndrome similar to the α_{2u}-globulin nephropathy occurring exclusively in male rats.[51]

DIAGNOSTIC TESTING

Methods of analyzing the composition of citrus oils include liquid chromatography, high-speed gas chromatographic separation and time-of-flight mass spectrometry,[52] capillary electrophoresis,[53] and HPLC.[54] In the absence of antioxidants, the concentrations of monoterpene hydrocarbons (e.g., *d*-limonene) decrease during storage at room temperature, but these losses are small during refrigeration or frozen storage. Over one year, the concentration of monoterpene compounds in cold-pressed daidai peel oil decreased from 98% to approximately 66%, while the concentration of sesquiterpene hydrocarbons and alcohols increased.[55]

TREATMENT

Treatment is supportive. Patients with contact dermatitis from citrus oil benefit from topical steroids as a means of reducing the incidence of hyperpigmentation.

Chapter 99

EUCALYPTUS OIL
(*Eucalyptus* Species)

HISTORY

In Western civilization, eucalyptus oil has been an expectorant for cough and colds as well as a skin disinfectant, liniment for myalgias, and a counterirritant. A letter from First Fleet Surgeon Considen to Sir Joseph Banks in 1788 was the first recorded European reference to the medicinal use of eucalyptus oil.[1] *Eucalyptus* species dominate the flora of Australian forests. However, few mammalian herbivores use *Eucalyptus* leaves as a food source, probably as a result of the poor nutritional qualities and high concentration of phenols and terpenes in these leaves. There are four Australian marsupials that feed on *Eucalyptus* leaves including the koala (*Phascolarctos cinereus* Goldfuss), greater glider (*Petauroides volans* Kerr), ringtail possum (*Pseudocheirus peregrinus* Boddaert), and the brushtail possum (*Trichosurus vulpecula* Kerr).[2] The koala bear feeds almost exclusively on eucalyptus leaves from infancy, whereas the other marsupials also feed on leaves from other species.

BOTANICAL DESCRIPTION

There are over 50 species in the genus *Eucalyptus* including *Eucalyptus globules* (Tasmanian bluegum), *Eucalyptus fruticetorum* F. Muell. ex Miq., *Eucalyptus pulverulenta* Sims (silverleaf mountain gum), and *Eucalyptus robusta* Sm. (robust eucalyptus, swamp mahogany).

Common Name: Eucalyptus

Scientific Name: *Eucalyptus* species

Botanical Family: Myrtaceae (myrtle)

Physical Description: These mostly evergreen, hardwood trees produce copious amounts of oil in the leaves. Older leaves are alternate and slender with long petioles, whereas the younger leaves are round and opposite, occasionally without petioles. The distinctive flowers have many showy stamens rather than petals. The woody, cone-shaped fruits release seeds from valves at the end of the fruits. Some species have smooth bark, whereas other species have rough bark ranging from short fibers to deep furrows and long, stringy bark. The Australian Mountain-ash, (*Eucalyptus regnans* F. Muell.) is one of the tallest trees (i.e., up to 92 m/300 ft).

Distribution and Ecology: Eucalyptus species are dominant trees in temperate forests and woodlands in Australia. These trees are cultivated in temperate climates, such as California.

EXPOSURE

Sources

Distillation of *Eucalyptus* leaves is the source of eucalyptus oil. The three types of commercial eucalyptus oil are defined by the following uses: medicinal, perfumery, and industrial. The industrial type is derived from *E. dives* Schauer, but the production of this type of oil is very small. The most important type of eucalyptus oil is the medicinal type derived primarily from *Eucalyptus globulus* Labill. (Tasmanian blue gum) and *E. exserta*

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

F. Muell. (Queensland peppermint). This type of oil has relatively high concentrations of cineole. The sources of perfumery eucalyptus oil are *E. citriodora* Hook. (lemon-scented gum) and, to a lesser extent, *E. staigeriana* F. Muell. ex Bailey (lemon-scented ironbark). Other plant species contain substantial amounts of the major ingredient, eucalyptol, in eucalyptus oil including *Artemisia pontica* L. (Roma mugwort), *Rosmarinus officinalis* L. (rosemary), *Salvia officinalis* L. (sage), *Hedychium flavum* Robx. (garland flower), and *Mentha piperita* L. (peppermint).[3]

Medicinal Uses

In Australia, eucalyptus oil is a discrete product and a component of vaporized liquids, candy, cough drops, ointments, salves, and cleaning products.[4] Australian Aborigines[5] and indigenous Brazilian people[6] traditionally used eucalyptus oil to treat upper respiratory tract infections, asthma, viral illness, fever, and bronchial infections as well as diarrhea, toothaches, snake bites, and skin lesions. Experimental studies suggest that eucalyptus-containing solutions have mosquito repellant properties.[7] Eucalyptol is approved by the US Food and Drug Administration (FDA) for use as a food additive and is a component of some mouthwashes (Listerine®, Johnson & Johnson, New Brunswick, NJ) and dental preparations. In Germany, eucalyptol is a licensed medicinal product (Soledum™ capsules–100 mg; Cassella-med, Cologne, Germany) for the treatment of bronchitis, sinusitis, and respiratory infections. A small clinical trial suggested that eucalyptol has mucolytic and anti-inflammatory properties.[8]

PRINCIPAL INGREDIENTS

Chemical Composition

About 10% of the dry leaf mass of eucalyptus leaves contain essential oils consisting primarily of terpene and phenolic compounds. Eucalyptus oil is a steam distillation product of eucalyptus leaves and terminal branches from varied species of *Eucalyptus*. The major constituent of eucalyptus oil is the 10-carbon bicyclic ether, 1,8-cineole (eucalyptol), and the concentration of eucalyptol varies with *Eucalyptus* species. In general, the essential oils from the leaves of *Eucalyptus globulus* contain high concentrations (70–80%) of eucalyptol. Figure 99.1 displays the chemical structure of saturated monoterpene compound, eucalyptol, which is an isoprenoid (C_5) compound consisting of two isoprene subunits (C_{10}). This essential oil also contains small amounts of hydrocyanic (prussic) acid as well as phellandrene, α-pinene, linalool, α-terpineol, eudesmol, and other terpene compounds.[9]

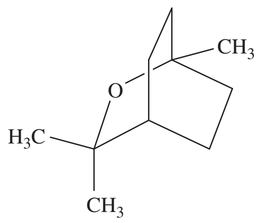

FIGURE 99.1. Chemical structure of eucalyptol.

TABLE 99.1. Some Physical Properties of Eucalyptol

Physical Property	Value
CAS RN	470-82-6
Molecular Weight	154.24
Molecular Formula	$C_{10}H_{18}O$
Melting Point	1.5 °C/~35 °F
Boiling Point	176.4 °C/~350 °F
log P (Octanol-Water)	2.74
Water Solubility	3,500 mg/L (21 °C/~70 °F)
Vapor Pressure	1.9 mmHg (25 °C/77 °F)
Henry's Law Constant	1.10E-04 atm-m^3/mole (25 °C/77 °F)
Atmospheric OH Rate Constant	1.11E-11 cm^3/molecule-second (25 °C/77 °F)

Analysis of leaves from *Eucalyptus ovata* demonstrated four flavonol glycosides, such as quercetin 3-*O*-β-arabinsoside, and nine tannins including catechin and gallocatechin.[10] The stem bark of *E. globulus* contains a variety of compounds including catechin, ellagic acid rhamnosides, engelitin, eriodictyol, methyl gallate, pinoresinol, quercetin, rhamnazin, rhamnetin, taxifolin, vomifoliol, and 3,4,5-trimethoxyphenol 1-*O*-beta-D-(6′-*O*-galloyl)glucopyranoside.[11]

Physiochemical Properties

Eucalyptus oil is a clear to pale-yellow liquid with a distinctive camphor-like odor and pungent taste. This steam-distillation product is water-insoluble and contains at least 70% 1,8-cineole. Synonyms for eucalyptol include cineole, 1,8-cineolcajeputol, 1,3,3-trimethyl-2-oxabicyclo(2.2.2.)octane, and 1,8-epoxy-*p*-menthane. Table 99.1 lists some physical properties of eucalyptol.

DOSE RESPONSE

Medicinal Use

The combination of 2 g eucalyptus oil, 3 g chloroform, and 40 g castor oil was a treatment for parasites in the early 20th century.[12] The recommended therapeutic dose of eucalyptus oil is up to 0.2 mL (184 mg) or 5 mL

in a hot steam vaporizer. Topically, eucalyptus oil is applied in a 0.5–3% ointment. The daily oral dose of eucalyptol for the treatment of upper respiratory tract infections is 600 mg.

Toxicity

There are limited data on the correlation between the dose of eucalyptus oil and toxicity. The estimated tolerable daily intake (TDI) for eucalyptol is 0.1 mg/kg.[3] Because these data are from case reports, there is a wide range of reported toxic and fatal doses of eucalyptus oil. Case reports and a retrospective review of case histories of children admitted to an Australian hospital with the diagnosis of eucalyptus oil poisoning suggested that significant central nervous system depression may occur after the ingestion of 5–10 mL of eucalyptus oil.[13,14] This retrospective study used no biomarkers to document exposure to eucalyptus oil. In a retrospective review of 41 pediatric visits to emergency departments for eucalyptus oil poisoning, there was no correlation between estimated dose and clinical symptoms.[15] Approximately 80% of these cases were asymptomatic including four children with estimated doses of eucalyptus oil exceeding 30 mL. The suicidal ingestion of 200–250 mL eucalyptus oil by a 73-year-old woman was associated with coma, hypotension, seizures, and aspiration pneumonia.[16] The patient developed persistent pneumonia and died 3 months after ingestion.

TOXICOKINETICS

Eucalyptus oil usually contains at least 70% 1,8-cineole (eucalyptol), which is absorbed rapidly from the gastrointestinal tract. The dermal application of eucalyptus oil does not usually cause systemic symptoms.[17] A case report suggests that the dermal application of large amounts (i.e., compress applied to whole body continually for 2 days) may cause ataxia, obtundation, muscle weakness, and slurred speech.[18] However, the solution also contained ethanol, and no serum ethanol concentration was reported to document the role of ethanol in the development of signs of intoxication. There are few data on the toxicokinetics of eucalyptol in humans. Following the oral administration of 800 mg eucalyptol to rats, the main metabolites were 1,8-dihydroxy-10-carboxy-p-methane, 2-hydroxy-cineole, and 3-hydroxy-cineole.[19] Other potential metabolites include 3-hydroxycineole. In studies of rats, eucalyptol crosses the placenta, but not the blood–milk barrier.[20] *In vitro* testing suggests that the inhibitory activity of eucalyptus oil on several cytochrome P450 enzymes including CYP1A2 CYP2C8 CYP2C9 CYP2C19 CYP2D6 and CYP3A4 is relatively weak,[21] but there are limited data to confirm any drug interactions. The main potential drug interaction is the enhancement of the sedation associated with the use of eucalyptus oil and other sedatives.

CLINICAL RESPONSE

Most dermal and pulmonary exposures to eucalyptus oil do not produce systemic complaints.[17] The clinical features of poisoning from the ingestion of eucalyptus oil vary depending on the dose and the presence of complications (e.g., aspiration pneumonia). Mild poisoning typically involves burning of the mouth and throat, nausea, vomiting, and abdominal pain. Central nervous system symptoms include lightheadedness, slurred speech, ataxia, headache, and drowsiness.[22] More severe ingestions involve obtundation, coma, convulsions, hypotension, and respiratory distress.[16] Cutaneous reactions following the ingestion of eucalyptus oil include generalized erythema, pruritus, urticaria, eczema, and vesicular lesions.[18] In sensitized individuals, inhalation of eucalyptus pollen or the ingestion of eucalyptus infusions can exacerbate underlying asthma and/or rhinoconjunctivitis.[23] A case report suggests that vocal cord dysfunction mimicking asthma can occur in sensitive individuals following airborne exposure to dried eucalyptus leaves.[24] Testing indicated that *this* reaction results from irritation rather than an immune response.

DIAGNOSTIC TESTING

Methods to detect 1,8 cineole include gas chromatography with flame ionization detection[25] and isocratic high performance liquid chromatography.[26] The limit of detection for the latter method in solid material is 100 µg/g material.

TREATMENT

Treatment primarily is supportive. There are few data to guide the use of decontamination measures. Patients with eucalyptus oil ingestion should not receive syrup of ipecac because of the risk of seizures and aspiration pneumonia. The efficacy of activated charcoal is also equivocal because of the rapid onset of seizures and coma as well as the lack of data on the adsorption of the major ingredient in eucalyptus oil (1,8-cineole) to activated charcoal. Patients with central nervous system depression should be observed for the development of aspiration pneumonia and respiratory insufficiency.[12] The treatment of seizures includes airway control as needed, supplemental oxygen and anticonvulsants (diazepam, lorazepam).

Chapter 100

NEEM OIL (MARGOSA OIL)
(*Azadirachta indica* Adr. Juss.)

HISTORY

Neem oil (margosa oil) has a long history of use in Indian folk medicine as a treatment for upper respiratory tract infections, leprosy, and intestinal parasites. Since ancient times, Hindus have used an extract of the neem tree as a panacea and as a bitter additive to seeds to reduce insect infestations in the seeds.

BOTANICAL DESCRIPTION

The neem tree (*Azadirachta indica*) is sometimes confused with the chinaberry (*Melia azedarach* L.) However, these two species from the Mahogany (Meliaceae) family are easily distinguished by their leaves. *Azadirachta* species have simple pinnate leaves, in contrast to the 2- to 3-pinnate leaves from *Melia* species.

Common Name: Indian Neem Tree, Indian Lilac, Neem Tree, Margosa Tree

Scientific Name: *Azadirachta indica* Adr. Juss. (Melia Azadirachta L., Melia indica Margosa)

Botanical Family: Meliaceae (mahogany)

Physical Description: This fast-growing, evergreen tree reaches 15–20 m (~49–66 ft) in height with long spreading branches. The leaves are alternate, spiral, compound and pinnate with the leaf blade being glabrous. The white flowers are arranged in inflorescences with all sepals joined. The yellow, fleshy fruit grows to about 1–2 cm (~0.4–0.8 in.) and contains one (rarely, two) seeds.

Distribution and Ecology: The neem tree is native to India and the Indo-Pakistan subcontinent, and is currently distributed throughout southern Malaysia, Thailand, and southeastern Asia. This tree is a cultivated plant species in many semiarid areas of Asia, Africa, Australia, Philippines, Central America (Nicaragua), and southern United States below 700 m (~2,300 ft) elevation.

EXPOSURE

Neem (margosa) oil is an extract from the seeds of the neem tree that is used as a traditional medicine by Indians in India, Burma, Thailand, Malaysia, Indonesia, and Sri Lanka, primarily for external applications (scabies, sores, leucoderma, pruritus, bacterial/fungal infections, local contraceptive). There are over 700 herbal preparations in Ayurveda, Amchi, Siddha, and Unani health traditions.[1] Other uses include the treatment of diabetes, fever, respiratory disorders, constipation, rheumatism, intestinal parasites, and decreased libido.[2] Neem oil also is a folk remedy in Africa and other parts of Southeast Asia for the treatment of fever and parasitic infections as well as the prevention of insect bites.[3,4] Neem oil extracts (e.g., Neemix®, W.R. Grace and Co., Baltimore, MD) are used for the insecticidal properties of the bioactive tetranortriterpenoid compounds (e.g., azadirachtin A, B, H) that include growth regulation, fecundity suppression and sterilization, oviposition, repellence, changes in biological fitness, and blocking development of vector-borne pathogens.[5,6] The neem oil for these natural alternatives to synthetic pesticides and mosquito repellants is a methanolic

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

extract of the defatted neem (*Azadirachta indica* Adr. Juss.) seed kernels.[7–9]

PRINCIPAL INGREDIENTS

Chemical Composition

Neem seeds contain about 45% oil. Margosa oil is synonym for neem oil (CAS RN: 8002-65-1). Neem oil is a yellowish, fatty acid-rich extract of neem tree seeds (*Azadirachta indica*) that contains at least 35 pharmacologically active compounds (triterpenoid, tetranortriterpenoid) as well as glycerides, flavonoids (kaempferol, myricetin, quercetin), fatty acids, and sulfur-containing compounds.[10] Bitter components of neem oil include the major sulfur-containing compound, nimbin, which accounts for about 1.5% weight/weight.[11] In addition to nimbin, azadirachtin-A, azadirachtin-B, and azadirachtin-H, other compounds in neem oil include azadirachtin-D, azadirachtin-I, deacetylnimbin, deacetylsalannin, and salannin.[12] Minor bitter constituents include nimbinin, nimbidin, gedunin, nimolicinol, epoxyazadiradione, and nimbidol. Commercial insecticidal formulations of neem oil typically list the concentration of azadirachtin A ($C_{35}H_{44}O_{16}$, CAS RN: 11141-17-6). The concentration of the other major tetranortriterpenoid compounds as listed in Figure 100.1 vary in these formulations depending on the source of the neem oil. The azadirachtin content in neem seeds depend primarily on genetic differences among neem trees rather than climatic factors. In a study of 28 neem trees in India, the azadirachtin A and B concentrations in kernels ranged from approximately 550–3,000 mg/kg and 40–590 mg/kg, respectively.[13] The major long-chained saturated and unsaturated fatty acids in neem oil are stearic, oleic, linoleic, and palmitic with smaller concentrations of arachidic, myristic, and behenic fatty acids.[14]

Physicochemical Properties

Neem oil is a yellow, malodorous extract with an unpleasant taste as a result of the presence of sulfur compounds. Tetranortriterpenoid compounds (e.g., azadirachtin, salannin, and deacetylgedunin) extracted from neem oil disrupt the metamorphosis of insects.[15] Although azadirachtin A decomposes in sunlight, acid/alkaline media, heat, and moisture, this compound is the currently accepted reference standard for neem-based products.[16]

Mechanism of Toxicity

The administration of neem oil from local commercial sources to mice produces fatty infiltration of the liver, cerebral edema, mitochondrial changes in the hepatocytes, and proximal renal tubule necrosis similar to Reye's syndrome. In animal models, the administration of neem oil (margosa oil) to mice produces the rapid onset of microvesicular liver steatosis and glycogen depletion as a result of mitochondrial injury manifest histologically by swelling, pleomorphism, loss of dense bodies, and loss of ribosomes.[17] Postmortem examination of children dying after the ingestion of margosa oil demonstrates swelling of hepatocytes, fatty metamorphosis of the liver, glycogen depletion, mitochondrial pyknosis, increased numbers of peroxisomes, and proliferation of smooth endoplasmic reticulum.[18] The ingredient(s) or contaminant(s) responsible for the hepatic effects of the neem oil have not been defined.

DOSE RESPONSE

Medicinal Use

There are no uses of neem oil approved by US health agencies. The estimated safe daily dose of azadirachtin is 15 mg/kg body weight.[19]

Toxicity

Typically, infants who developed encephalopathy received doses of neem oil (margosa oil) in the range of 5–30 mL.[20] The role of individual hypersensitivity, contaminants, and concomitant illness in the development of the encephalopathy remains undefined. Few of these case reports analyzed the ingredients in the neem oil involved with these poisonings. Common adverse effects of the medicinal use of neem oil include nausea and diarrhea. A dose of 10 mg/kg in rats produced stupor tremulousness, seizures, and death in 4 of 5 rats.[21] In subchronic rodent studies, the no-observed-effect level (NOEL) of azadirachtin technical 12% was 1,500 mg/kg per day for 90 days.[22] The intentional ingestion of one liter of neem leaf extract by a 24-year-old woman was associated with ventricular fibrillation and cardiac arrest in the emergency department that responded to standard measures of resuscitation.[23] She developed pulmonary edema in the hospital, but she responded to supportive care and she was discharged on the seventh hospital day.

TOXICOKINETICS

There are few data on the toxicokinetics of the toxic ingredients of neem oil including azadirachtin compounds.

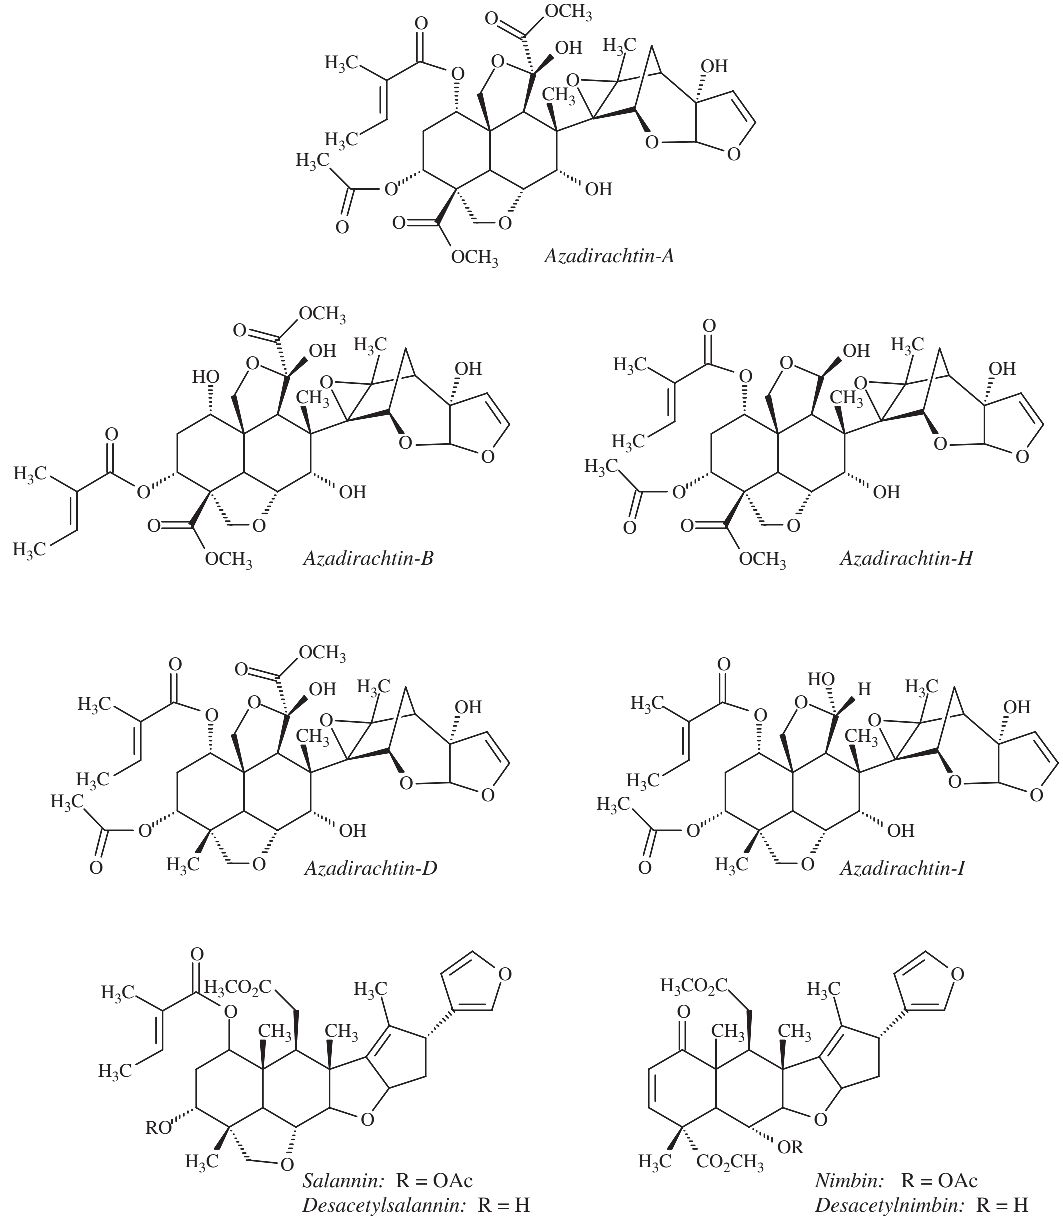

FIGURE 100.1. Chemical structures of major constituents of neem oil.

CLINICAL RESPONSE

Acute Effects

Case reports associate the onset of an encephalopathy similar to Reye's syndrome with the ingestion of neem oil (margosa oil) by infants and young children.[24,25] Clinical features include vomiting, drowsiness, tachypnea, and recurrent seizures that progress to coma or cardiopulmonary arrest.[26,27] These episodes typically involved the ingestion of unrefined neem oil that, at least in some cases, was contaminated with camphor.[24] Vomiting usually starts 15 minutes to 4 hours after ingestion. Although mild elevation of serum hepatic transaminases may occur, liver failure is unusual.[20] Common adverse effects from the use of neem oil as an herbal remedy include nausea and diarrhea.[26]

Chronic Effects

Animal studies suggest that the oral toxicity of azadirachtin compounds, the main biopesticides in neem oil, is relatively low.[22] In rodent studies, the daily administration of 1,500 mg azadirachtin technical 12%/kg during

gestation days 6–15 did not produce evidence of embryo/fetotoxicity or teratogenic effects.[28] A three-generation rat study indicated that debitterized neem oil does not produce adverse reproductive or systemic effects after the ingestion of doses similar to the doses ingested by humans.[29]

DIAGNOSTIC TESTING

Analytical methods for separating and identifying compounds in neem extracts include enzyme-linked immunosorbent assay (ELISA),[30] reversed-phase liquid chromatography,[31] liquid chromatography/mass spectrometry with UV detection,[12] and high performance liquid chromatography/atmospheric pressure chemical ionization/mass spectrometry.[32] The limit of detection of the latter method for azadirachtin compounds is about 0.2 μg/mL. The most common laboratory abnormalities during serious cases of neem oil toxicity include leukocytosis, hypoglycemia, electrolyte imbalance, and metabolic acidosis.[24] Postmortem findings resemble Reye's syndrome with fatty infiltration of liver and proximal renal tubules, mitochondrial damage, and cerebral edema.[18] Fatty infiltration does not occur in Indian childhood cirrhosis, and the histological features of this disease differ markedly from neem oil poisoning.[33]

TREATMENT

Treatment is supportive. Decontamination measures are unnecessary because of the presence of vomiting and the rapid absorption of the liquid. Immediate management usually involves the control of seizures and associated hypoxemia with traditional anticonvulsants (diazepam, lorazepam) and respiratory support. Other serious abnormalities that require evaluation and treatment include hypoglycemia, metabolic acidosis, and dehydration. Cerebral edema may complicate the clinical course. The effect of neem oil on fatty acid metabolism suggests the L-carnitine as a potential antidote,[34] but there are inadequate clinical data to evaluate the efficacy of this substance during neem oil poisoning. The presence of a concomitant infection (sepsis, meningitis) should be excluded with appropriate laboratory tests.

Chapter 101

PEPPERMINT OIL
(*Mentha* x *piperita* L.)

HISTORY

Peppermint has a long history of medicinal use dating back to ancient Egypt, Greece, and Rome. The scientific name for peppermint (*Mentha* x *piperita*) derives from a mythological Greek nymph, Mintha, who transformed herself into the plant, and from the Latin word for pepper (*piper*). Peppermint is a hybrid plant; the first hybrids were propagated in Mitcham, England in 1696.[1]

BOTANICAL DESCRIPTION

Commercial peppermint is a sterile hybrid between spearmint (*Mentha spicata* L.) and water mint (*Mentha aquatica* L.). The sterility of this plant requires the spread of this clonal plant by vegetive propagation.

Common Name: Peppermint

Scientific Name: *Mentha* x *piperita* L. (pro sp.)

Botanical Family: Lamiaceae (menthes, mints)

Physical Description: This low-spreading plant grows up to 2–3 ft (~0.6–0.9 m) in height during the bloom of purple flowers. The lance-shaped, aromatic leaves are deeply notched when mature.

Distribution and Ecology: Peppermint is a perennial plant widely cultivated in Europe and North America. The northwestern United States is a major commercial area for growing peppermint as a result of favorable climatic conditions for this hybrid.

EXPOSURE

Sources

Products of *Mentha piperita* (peppermint) include *Mentha piperita* oil (peppermint oil, CAS RN: 8006-90-4), *Mentha piperita* leaf extract (peppermint leaf extract, CAS RN: 84082-70-2), *Mentha piperita* (peppermint) leaf, and *Mentha piperita* (peppermint) leaf water. American and European peppermint oils are volatile oils, steam distilled from the aerial parts of the flowering peppermint plant (*Mentha* x *piperita* L.). These oils are primarily fragrance components (i.e., 0.02–3%) of cosmetic formulations, such as dentifrices, mouthwash, breath fresheners, and skin-cleansing agents. The leaf water previously was used as a flavoring agent and fragrance component, but currently this formulation is not used. (–)-Menthol is the principal component of peppermint oil because this oil is not dementholized. Peppermint oil is available as enteric-coated capsules, soft gelatin capsules, a liquid, and bulk herb oil. Japanese peppermint oil is a steam distillation product of *Mentha arvensis* L. var. *piperascens*. This oil is primarily a source of menthol because of the poor flavor of the oil compared with American and European peppermint oils. (–)-Menthol is also prepared synthetically and crystallized from the essential oil of cornmint (*Mentha arvensis* var. *piperascens*).

The biosynthesis of (–)-menthol is a complex chemical process that involves eight enzymatic steps, beginning with the formation and cyclization of the monoterpene precursor, geranyl diphosphate, to the parent olefin,

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

(−)-(4S)-limonene.[2] Monoterpene synthesis occurs in highly specialized secretory cells of the epidermal oil glands during two temporally distinct periods. The early biosynthetic process is the filling of the epidermal oil glands with (−)-menthone. During the late period of leaf development coincident with flower initiation, reduction of the C3-carbonyl of menthone by NADPH-dependent ketoreductases yields (−)-menthol and (+)-neomenthol.[3] Formation and storage of the essential oil of peppermint occurs in the oil glands (peltate glandular trichomes) on the aerial surfaces of *Mentha* species.

Medicinal Uses

Traditional

Traditional herbal uses of peppermint oil include the treatment of dyspepsia, bile duct disorders, bronchial spasm, cholelithiasis, intestinal colic, common cold, cough, cramps, dysmenorrhea, flatulence, inflammation of oral mucosa, influenza, and urinary tract infections. Caraway oil [(−) carvone] is frequently added to peppermint oil as a flavoring agent, particularly in preparations for the treatment of indigestion.

Current

The major monoterpene, menthol, is a constituent of many pharmaceutical and oral health care products, teas, tobacco products, cosmetics and confectionary goods (chewing gum, candies). The use of peppermint oil is possibly efficacious for the treatment of irritable bowel syndrome.[4] A meta-analysis of five placebo-controlled, double-blind, clinical trails demonstrated a statistically significant ($P < 0.001$) global improvement in the symptoms associated with irritable bowel syndrome in patients treated with peppermint oil when compared with placebo groups.[5] However, the small number of patients ($n = 175$), short-term follow-up (<1 month), and methodological design flaws limit definitive conclusions regarding the efficacy of peppermint oil for the treatment of irritable bowel syndrome.

Regulatory Status

The US Food and Drug Administration (FDA) approves the use of peppermint oil as a food additive and dietary supplement with GRAS (generally recognized as safe) status.

PRINCIPAL INGREDIENTS

Chemical Composition

(−)-Menthol is the major component (30–55%) of peppermint oil. Other constituents include menthyl acetate (2.8–10%), (−)-menthone (14–32%), (+)-isomenthone (1.5–10%), (+)-menthofuran (1–9%), 1,8-cineole (3.5–14%), along with minor amounts of *l*-limonene, *p*-menthane, α-pinene, phellandrene, menthyl isovalerate, amyl alcohol, acetaldehyde, dimethyl sulfide, α- and β-thujone, citronellol, γ-terpinene, and valeric acid.[6,7] Menthol usually refers to (−)- or *l*-menthol, which is one of eight possible stereoisomers of 1-methyl-4-(1-methylethyl)cyclohexan-3-ol. Figure 101.1 displays the chemical structure of (−)-menthol (CAS RN: 1490-04-6, $C_{10}H_{20}O$). Menthol accumulation in peppermint leaves occurs in leaves younger than 3 weeks with low catabolic losses after maximal leaf expansion. In general, high-quality peppermint oil (i.e., high menthol/menthone ratio) develops during full bloom.[8] This ratio increases somewhat during storage at room temperatures (i.e., 22 °C–24 °C/~72–75 °F).[9] The less desirable ketones (pulegone, carvone) are present in trace amounts during this period, and the concentration of pulegone in most commercial products is usually below 1% as a result of safety considerations.

Peppermint also contains (+)-pulegone, particularly during early plant development. In several samples of dried peppermint leaves from Italy, the (+)-pulegone concentration was approximately 7 mg/kg, whereas the concentration in several samples of peppermint oil was about 1–2.5%.[10] In the samples isolated from natural sources, (+)-pulegone represented about 99% of the isomers compared to about 1% for (−)-pulegone. The pulegone content in peppermint oil depends on season, growing conditions, extraction processes, and harvesting practices. In a 3-year study of pulegone content in American peppermint oil, the (+)-pulegone concentration ranged from 1.2–5.7% with a mean of about 3.6% ($n = 17$).[11] Isopulegone is usually present in smaller concentrations.

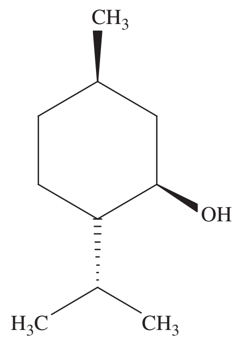

FIGURE 101.1. Chemical structure of (−)-menthol.

TABLE 101.1. Some Physiochemical Properties of Menthol

Physical Property	Value
Molecular Weight	156.26
log P (Octanol-Water)	3.380
Water Solubility	420 mg/L (25 °C/77 °F)
Atmospheric OH Rate Constant	2.41E-11 cm^3/molecule-second (25 °C/77 °F)

Physiochemical Properties

Peppermint oil is a colorless to pale yellow liquid with a strong, penetrating peppermint odor and a pungent taste. The enantiomer, (+)- or *d*-menthol has a musty, unpleasant odor; therefore, this enantiomer has little commercial value. Table 101.1 lists some physiochemical properties of (−)-menthol.

Mechanism of Action

In vitro studies in animal preparations suggest that menthol reduces intraluminal pressures in the colon by relaxing intestinal smooth muscle as a result of the calcium channel blocking properties of this compound.[12] However, the actual mechanism of action is unclear because some observational studies indicate that intraluminal administration of peppermint oil does not reduce directly measured intraluminal pressures in the colon of volunteers.[13]

DOSE RESPONSE

Typical oral doses of peppermint oil for indigestion are 0.2–0.4 mL in enteric-coated capsules or suspensions three times daily. Topical use of 10% peppermint oil (in methanol) involves the application of this solution to the forehead several times daily for relief of headache. The traditional use of peppermint leaves as an infusion entails the use of 3–6 grams of peppermint leaf daily. Doses of peppermint oil exceeding 1 g/kg body weight are considered potentially toxic, but there are few clinical data of the dose-response of peppermint oil. Concentrated peppermint oil is irritating to the oral mucosa, and high concentrations of peppermint oil can cause burns.

TOXICOKINETICS

Kinetics

The monoterpenes in peppermint oil are rapidly absorbed orally (i.e., maximum concentrations about 2 hours after ingestion) as a result of their high lipid solubility, and pharmaceutical preparations typically contain a sustained-release formulation to deliver these compounds to the lower gastrointestinal tract.[14] Following absorption, menthol undergoes conjugation with glucuronic acid to form menthol glucuronide, which is excreted by the kidney.[15] In a study of four fasted volunteers receiving 180 mg enteric-coated peppermint oil, about 40% of the menthol dose was recovered as total (free + conjugated) menthol within the first 14 hours after ingestion.[16] Menthol glucuronide also undergoes enterohepatic recirculation.[6]

Drug Interactions

Peppermint oil (K_i = 36 ± 3 µmol/L), menthol (K_i = 87 ± 7 µmol/L), and menthyl acetate (Ki = 124 ± 7 µmol/L) are moderately potent reversible inhibitors of *in vitro* CYP3A4 activity. In a study of 12 healthy volunteers, the use of peppermint oil (600 mg daily) increased the bioavailability of felodipine, CYP3A4-dependent drug by a mean of 140% (range: 77–262%) when compared with placebo (water).[17] However, the use of peppermint oil did not alter the $AUC_{0\text{-}8}$; therefore, the clinical relevance and underlying mechanism (e.g., inhibition of presystemic metabolism) remain undetermined.

CLINICAL RESPONSE

Adverse Reactions

Adverse effects associated with the use of peppermint oil include heartburn, headache, dizziness, and anal burning. Peppermint is a rare cause of hypersensitivity reactions following the use of personal care products, such as toothpaste.[18,19] The allergic reactions associated with the use of products containing peppermint oil include eczematous contact dermatitis, urticaria, recurrent intra-oral ulcerations, and lichenoid reaction.[20,21] Constituents (e.g., α-pinene, dipentene, phellandrene) other than menthol are usually the sensitizers, despite the high concentration of menthol in peppermint oil.[22] Case reports also associate chronic, excessive use of peppermint-containing compounds with stomatitis and hypertrophy of papillae on the tongue.[23]

Acute Effects

The intravenous injection of peppermint oil can produce adult respiratory distress syndrome (ARDS) and hypoxia as a result of increased pulmonary vascular permeability. An 18-year-old woman injected 5 mL of peppermint oil intravenously during a suicide attempt.[24] Within 4 hours she developed fulminant pulmonary edema and hypoxemia requiring ventilatory support for

9 days. After discharge from the hospital, she was lost to follow-up. The ingestion of pure peppermint oil can cause mucosal burns. A 49-year-old woman developed multiple burns in the entire oropharynx and edema of the tongue, soft palate, and epiglottis after ingesting 40 drops of pure peppermint oil.[25] She required endotracheal intubation, but she was extubated 24 hours later. The chemical burns resolved within 2 weeks.

DIAGNOSTIC TESTING

Methods for the detection and quantitation of menthol include gas chromatography with flame ionization detection,[16] reverse-phase high-performance liquid chromatography, and capillary gas chromatography/mass spectrometry.[10] The use of supercritical fluid chromatography and electrochromatography allows the enantioselectivity required to individually quantitate isomers of the chiral compounds in peppermint oil.[26]

TREATMENT

Treatment is supportive. The most serious adverse effects are anaphylactic reactions and chemical burns involving the oropharynx and epiglottis. Patients should be evaluated carefully for the adequacy of the airway and ventilation, and treated with standard measures (epinephrine, antihistamines, intubation) as needed.

Chapter 102

TEA TREE OIL
(*Melaleuca* Species)

HISTORY

Indigenous populations in Australia used extracts of the Australian tea tree (*Melaleuca alternifolia*) for the treatment of skin infections many centuries before the arrival of the Europeans. During the late 1800s, Captain James Cook documented the use of the leaves from this tree to brew tea. Commercial production of tea tree oil began in Australia during the 1920s after the publication of reports by Penfold and Grant on the antimicrobial properties of Australian essential oils.[1] These studies suggested that tea tree oil was a more efficacious antibacterial agent than phenol, which was the most common antimicrobial agent during this period. For several decades, tea tree oil was produced by the hand cutting the plant material followed by distillation in mobile, wood-fired bush stills. Production of tea tree oil declined during the 1940s as effective antibiotics became available.[2] As natural products became more popular during the 1970s and 1980s, high-density, commercial plantations of tea trees were established in Western Australia, Queensland, and New South Wales that produced the essential oil after extraction from cut and chipped plant material.

BOTANICAL DESCRIPTION

There are at least 100 species in the genus *Melaleuca*, and most of these species are indigenous to Australia. Although *Melaleuca alternifolia* (Maiden and Betche) Cheel is the common commercial source of tea tree oil, the hydro-distillation of other *Melaleuca* species can produce essential oils similar to tea tree oil including *M. linariifolia* Sm. (cajeput tree), *M. dissitiflora* F. Muell. and *M. uncinata* R.Br (broom honeymyrtle). Other *Melaleuca* species producing essential oils include *Melaleuca cajuputi* Powell (cajuput oil) and *Melaleuca quinquenervia* (Cav.) Blake (niaouli oil).

Common Name: Australian Tea Tree, Narrow-Leaved Paperbark

Scientific Name: *Melaleuca alternifolia* (Maiden and Betche) Cheel

Botanical Family: Myrtaceae (myrtles, myrtacées)

Physical Description: This hardwood tree grows to 5–8 m (~16–26 ft) in height. The bark of the tree is flaky (paperbark), and the lower bark becomes charred as a result of wildfires. Loose, white to cream-colored terminal spikes of small flowers appear from October to November. The stamens of these flowers are prominent, and the petals are small and inconspicuous.

Distribution and Ecology: The Australian tea tree is a native plant of eastern Australia. Other species of *Melaleuca* inhabit forests, woodlands, and swamps in New Zealand, New Guinea, New Caledonia, Indonesia, and Malaysia. The typical habitat of this tree is swampy, low-lying subtropical coastal areas of northeastern New South Wales and southern Queensland.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

EXPOSURE

Sources

Steam distillation or hydro-distillation (i.e., immersion in boiling water) of leaves and terminal branches of *M. alternifolia* produce tea tree oil (melaleuca oil) with a typical yield of about 1–2% weight of wet plant material. This essential oil should not be confused with essential oils from other *Melaleuca* species, such as cajuput oil, manuka oil, kanuka oil, or niaouli oil. These essential oils differ significantly in the composition of cyclic hydrocarbons when compared with tea tree oil.

Medicinal Uses

Traditional

Bundjalung Aborigines of northern New South Wales inhaled vapors from crushed tea tree leaves; they applied a poultice made of tea tree leaves to treat coughs, colds, insect bites, abrasions, and skin infections. An infusion of tea tree leaves was a traditional treatment for skin diseases and sore throats. The essential oil was not used until the publication of the reports by Penfold and Grant as mentioned earlier. Tea tree oil was added to cutting oils as a method to reduce infections associated with skin trauma during the use of these oils.

Current

Tea tree oil is an active ingredient of many topical preparations for the treatment of cutaneous infections including wound infections,[3] fungal dermatoses,[4] otitis media,[5] and acne.[6] However, there are presently inadequate clinical data to support the use of tea tree oil for any of these conditions.[7] Although several clinical studies suggest that tea tree oil possesses antimicrobial activity,[8] the poor quality of the studies (low numbers, lack of blinding due to the characteristic odor of tea tree oil, lack of statistical significance testing, absence of comparison to current therapy) prevent conclusions regarding the efficacy of tea tree oil as an antimicrobial agent.[2] Tea tree oil is present in a variety of household products including moisturizing cream, laundry detergents, fabric softeners, mouthwashes, massage oils, and candles, often as a substitute for nutmeg oil. Tea tree oil is an investigational drug as an antimicrobial, anti-inflammatory, and chemotherapeutic agent.

Regulatory Status

Current standardization recommendations suggest that tea tree oil preparations contain >30% terpinen-4-ol (terpinenol-4) and <15% 1,8-cineole (see Table 102.1).

TABLE 102.1. Typical Composition and International Organization for Standardization (ISO) Standard Composition of Tea Tree Oil

Compound	ISO Standard (%)[a]	Composition (%)[b]
Terpinen-4-ol	≥30	40.1
γ-Terpinene	10–28	23.0
α-Terpinene	5–13	10.4
1,8-Cineole	≤15	5.1
Terpinolene	1.5–5	3.1
ρ-Cymene	0.5–12	2.9
α-Pinene	1–6	2.6
α-Terpineol	1.5–8	2.4
Aromadendrene	Trace-7	1.5
δ-Cadinene	Trace-8	1.3
Limonene	0.5–4	1.0
Sabinene	Trace-3.5	0.2
Globulol	Trace-3	0.2
Viridiflorol	Trace-1.5	0.1

[a]ISO standard no. 4730.
[b]Mean composition of about 800 tea tree oil samples from Russell, 2003.[9]

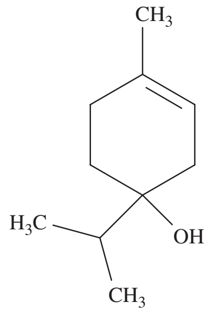

FIGURE 102.1. Chemical structure of terpinen-4-ol.

PRINCIPAL INGREDIENTS

Chemical Composition

Tea tree oil (melaleuca oil) contains over 100 compounds, consisting primarily of monoterpene and sesquiterpene hydrocarbons with their associated tertiary alcohols. A majority of the oil consists of terpinen-4-ol (CAS RN: 562-74-3, $C_{10}H_{18}O$) and γ-terpinene (CAS RN:8013-00-1, $C_{10}H_{16}$). Figure 102.1 displays the chemical structure of terpinen-4-ol. The composition and toxicity of tea tree oil varies with chemotype, season, growing conditions, and extraction techniques.[9,10] The leaves of seedlings contain higher concentrations of terpinolene, α-pinene, and β-pinene than mature leaves, while the concentrations of terpinen-4-ol, sabinene, and *cis*-sabinene hydrate are lower in the leaves of seedlings than in mature leaves.[11] The concentration of 1,8-cineole

(eucalyptol) remained constant during the studied growing period. The chemical composition of mature and seedling leaves were similar when the seedling reached 4 months. Table 102.1 lists the average composition of terpinen-4-ol (terpinenol-4) chemotype of tea tree oil based on over 800 samples analyzed by gas chromatography/mass spectrometry (GC/MS).[12] This table also lists the standards set by the International Organization for Standardization (ISO) for the composition of 14 components of "oil of Melaleuca–terpinen-4-ol type."[13] The species of *Melaleuca* is not stipulated by the ISO standard, and potential sources of tea tree oil other than *M. alternifolia* include *M. dissitiflora, M. linariifolia*, and *M. uncinata*. However, essential oils from some *Melaleuca* species differ dramatically from the essential oils derived from *M. alternifolia*. For example, the essential oil from *Melaleuca ericifolia* Sm. (swamp paperbark) contains about 97% methyl eugenol,[14] and the leaves have unique phenolic compounds (ericifolin, 2-*O*-*p*-hydroxybenzoyl-6-*O*-galloyl-(α,β)-4C1-glucopyranose, 3-methoxyellagic acid 4-*O*-rhamnopyranoside).[15] There are at least six varieties (chemotypes) of *M. alternifolia* that produce unique essential oils including the terpinen-4-ol, terpinolene, and four types of 1,8-cineole (eucalyptol).[16] Terpinen-4-ol is the most common chemotype of tea tree oil in commercial production.

Physiochemical Properties

Tea tree oil is a transparent, colorless to pale yellow oil with a characteristic odor. This oil is soluble in nonpolar solvents and has a specific gravity ranging from about 0.885–0.906 g/mL.[13] Although terpinen-4-ol is soluble in water, α- and γ-terpinene are poorly water soluble. Table 102.2 lists some physical properties of the major component of tea tree oil, terpinen-4-ol. Tea tree oil undergoes photo-oxidation when exposed to light, moisture, heat, or air during storage. Under these conditions, the concentrations of α- and γ-terpinene decrease over a few days to several months, while the concentration of ρ-cymene increases.[12] *In vitro* studies suggest that tea tree oil has antimicrobial properties (terpinen-4-ol, α-terpineol) as a result of the disruption of bacterial cell wall integrity and respiration.[17] The estimated tropospheric lifetimes of monoterpene compounds (e.g., *d*-limonene, myrcene, α-pinene, γ-terpinene, terpinolene) is relatively short (<1–3.5 hours) with the lifetimes of related compounds (e.g., 1,8-cinoeole, *p*-cymene) being longer.[18]

TABLE 102.2. Some Physical Properties of Terpinen-4-ol

Physical Property	Value
Boiling Point	209 °C/~408 °F
Water Solubility	1491 ppm
log P (Octanol-Water)	3.26
Atmospheric OH Rate Constant	1.04E-10 cm^3/molecule-second (25 °C/77 °F)

Mechanism of Toxicity

The Melaleuca tree is probably not a significant source of aeroallergens.[19] The specific sensitizing agent or agents in tea tree oil are not well defined, but several compounds both in the monoterpene and sesquiterpene fractions probably are involved.[20] Potential sensitizing compounds in tea tree oil include *d*-limonene, α-pinene, α-terpinene, terpinen-4-ol, α-phellandrene, terpinolene, aromadendrene, and ρ-cymene.[21] Based on animal studies, fresh tea tree oil is a very weak sensitizing agent compared with degradation products, such as peroxides, epoxides and endoperoxides including ascaridol and 1,2,4-trihydroxy menthane.[22,23] 1,8-Cineole (eucalyptol) is probably not a major irritant or sensitizing agent in tea tree oil.[24]

DOSE RESPONSE

Medicinal Use

The use of tea tree oil typically involves the topical application of 5–10% solutions to the affected area with the exception of burns. The use of oral preparations is not recommended.

Toxicity

There are few data on the dose-related toxicity of tree tea oil in humans. The ingestion of an estimated volume of <10 mL of pure tea tree oil was associated with disorientation and ataxia that resolved spontaneously 5 hours after ingestion.[25] The ingestion of about 10 mL of pure tea tree oil by a 4-year-old child produced ataxia and respiratory depression that required intubation.[26] The patient was discharged 24 hours after ingestion with no sequelae. The ingestion of an estimated 0.5–1 mL/kg body weight by an adult was associated with coma for 12 hours followed by hallucinations and persistent, colicky diarrhea.[27]

TOXICOKINETICS

There are few human data on the toxicokinetics of components of tea tree oil.

CLINICAL RESPONSE

Cutaneous Reactions

Allergic reactions to tea tree oil include irritant and allergic contact dermatitis, systemic hypersensitivity reactions, and erythema multiforme-like eruptions, particular after the use of improperly stored oil on damaged skin. Case reports also associate the ingestion of tea tree oil with systemic contact dermatitis[28] and the inhalation of essential oil vapors with airborne contact dermatitis.[29] The typical skin lesion of the contact dermatitis associated with tea tree oil is an eczematous plaque in the area of topical application, but bullous lesions and an erythema multiforme-like reaction (target lesions distal to the initial dermatitis) can also occur after dermal use of tea tree oil.[30,31] Skin biopsy from these target lesions distal to the contact dermatitis demonstrated spongiotic dermatitis rather than the histological features of erythema multiforme.

Systemic Effects

Most accidental ingestions of tea tree oil cause no or minor symptoms as reported to US Poison Control Centers.[32] Case reports of accidental and intentional ingestions of tea tree oil indicate that the main complications of exposure result from central nervous system depression, loss of coordination, and respiratory insufficiency. The most common symptom following accidental ingestion of tea tree oil is central nervous system depression manifest by ataxia, drowsiness, and unsteady gait. Symptoms usually resolve within 6–12 hours depending on the dose of tree oil ingested.[33] Anaphylactic reactions may occur in sensitized individuals. Case reports associate the topical application of tea tree oil with the development of anaphylactic reactions manifest by facial erythema, throat constriction, lightheadedness, and pruritus.[34]

Chronic Effects

There is little evidence to suggest that tea tree oil is genotoxic or carcinogenic.[35]

DIAGNOSTIC TESTING

GC/MS methods are available to separate and quantitate the monoterpene hydrocarbons, sesquiterpene hydrocarbons, and related alcohols in tea tree oil.[12,36]

TREATMENT

Treatment is supportive. Because of the potential for central nervous system depression associated with the ingestion of tea tree oil, patients should be observed closely for evidence of respiratory insufficiency during the first few hours after ingestion. Decontamination measures are not recommended because of the lack of documented efficacy and the risk of pulmonary aspiration. Symptoms usually resolve within 6–12 hours with supportive care.

Chapter 103

TUNG OIL
(*Aleurites fordii* Hemsl.)

HISTORY

Tung oil is an important raw material in the dye and oil-based paint industries. Prior to World War II, the major producers of tung oil were China, Japan, the United States, Mexico, and Indonesia. After the War, production of the oil increased in Africa (Madagascar, Malawi) and South America (Argentina, Brazil, Paraguay).

BOTANICAL DESCRIPTION

Misidentification of tung nuts as chestnuts has been associated with acute tung nut poisoning.[1]

Common Name: Tung Nut, Tung Oil Tree, China Wood Oil Tree

Scientific Name: *Aleurites fordii* Hemsl.

Botanical Family: Euphorbiaceae (spurge)

Physical Description: The tung oil tree reaches 12 m (~39 ft) in height with a wide trunk and smooth bark. The dark green leaves are up to 15 cm (~6 in.) wide with heart-shaped or occasionally lobed-shaped. The foliage turns yellow in the fall. White flowers appear in clusters during early spring with male and female flowers in same inflorescence. The green to purple fruits are pear-shaped at maturity with four to five individual seeds consisting of a hard outer shell and a kernel. The latter is the source of tung oil.

Distribution and Ecology: This tree is indigenous to central and western China. In 1932, tung oil trees were introduced into the southeastern United States and these trees are now present from eastern Texas to Florida. The current distribution of the tung oil tree also includes Japan, Taiwan, and India. Cultivation of tung oil trees requires long, hot summers with abundant moisture.

EXPOSURE

Sources

The thick, woody endocarp layer of the tung nut is the source of tung oil. The oil-rich seeds are produced inside a thick, woody endocarp layer of the tung nut, and these seeds are the source of tung oil used on fine furniture.

Medicinal Uses

Traditional

The tung oil tree and the oil extract are traditional herbal treatments for parasitic infections, scabies, burns, skin infections (erysipelas), congestion, constipation, mental illness, and metal poisoning.

Current

Tung oil is a component of lacquers, varnishes, paints, inks, dyes, linoleum, resins, artificial leather, felt-base floor coverings, polishing compounds, and greases. The commercial use of tung oil primarily results from the unique ability of this oil to dry to a clear, hard finish following oxidation of α-eleostearic acid in the oil.[2]

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Additionally, tung oil is a constituent of insulating wires, metallic surfaces, and coatings for beverage, food, and medicine containers.

PRINCIPAL INGREDIENTS

Chemical Composition

Tung oil contains 75–80% α-eleostearic acid (CAS RN:13296-76-9; 9,11,13-*cis, trans, trans*-octadecatrienoic acid), 10–15% oleic acid, and 4% palmitic acid as well as tannins, phytosterols, and a saponin.[3] Figure 103.1 displays the chemical structure of eleostearic acid. Tung Δ^{12} oleate desaturase catalyzes the formation of α-eleostearic acid from linoleic acid.[4]

Physiochemical Properties

Tung oil is a viscous, dark yellow, opalescent oil with a specific gravity of 0.9341 at 15 °C–25 °C (59 °F–77 °F). This oil is relatively insoluble in alcohol and chloroform. The development of gastroenteritis after the ingestion of food cooked in tung oil suggests that the toxic constituent of tung oil is heat stable.[5] The conjugated triene in α-eleostearic acid is an intrinsic chromophore, which causes strong UV absorbance (269 nm) and mild fluorescent properties.[6]

Mechanism of Toxicity

The toxic components of tung oil have not been identified. Animal studies suggest that the tung nut contains the gastrointestinal toxin, but tung oil does not contain this toxin.[7] However, cooking food in tung oil has been associated with gastrointestinal toxicity.

DOSE RESPONSE

The ingestion of 6–15 tung nuts produces a severe gastroenteritis including colicky abdominal pain, protracted vomiting, and diarrhea.[1,8] Patients usually recover uneventfully with supportive care.

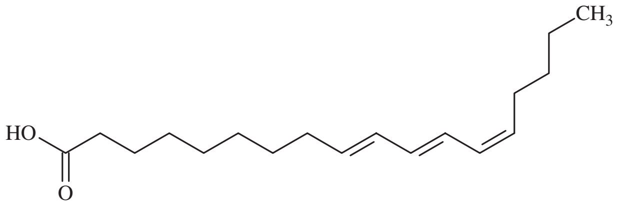

FIGURE 103.1. Chemical structure of eleostearic acid.

TOXICOKINETICS

The toxic component in tung oil has not been identified, and there are no data on the toxicokinetics of components in tung oil.

CLINICAL RESPONSE

Rarely, acute hypersensitivity reactions occur after exposure to dust from the tung nut including conjunctivitis, urticaria, rhinitis, and acute bronchospasm.[9] The ingestion of tung nuts causes severe gastrointestinal irritation.[10] In addition, the ingestion of tung oil or food cooked in tung oil produces a severe gastroenteritis. Profuse vomiting, diaphoresis, and palpitations developed within 15 minutes after the ingestion of food cooked in tung oil followed by abdominal pain and diarrhea.[5] Nonspecific symptoms include malaise, fatigue, lightheadedness, somnolence, sore throat, and chills.[1] Older medical reports suggest that central nervous system depression, mydriasis, respiratory insufficiency, and renal dysfunction can occur after the ingestion of tung oil,[7] but the etiology of these symptoms remains unclear because of poor documentation and the use of unconventional treatment methods by current medical standards.

DIAGNOSTIC TESTING

The primary laboratory abnormality associated with acute tung nut poisoning is electrolyte imbalance due to gastrointestinal losses. Occasionally, mild hyperglycemia and glucosuria occurs.[8] Typically, serum creatinine and hepatic aminotransferases are normal.

TREATMENT

Treatment is supportive, primarily involving the evaluation of the patient for fluid and electrolyte imbalances and the treatment of vomiting, diarrhea, and fluid/electrolyte disturbances caused by the gastroenteritis. Gastrointestinal decontamination measures are unnecessary.

Chapter 104

TURPENTINE and PINE OIL
(*Pinus* Species)

HISTORY

Oil of turpentine (terebinthinates) has been an herbal treatment for a variety of illnesses since ancient times. Hippocrates (460–370 BC) mentioned the value of turpentine oil as an emmenagogue (stimulant of menstrual flow) and inhibitor of nasal discharge.[1] The Greek physician, Dioscorides used turpentine oil as an aphrodisiac, diuretic, decongestant, and antiarthritic agent. The Romans used this oil for a wide variety of internal and external diseases including stroke, lethargy, depression, and pleurisy. From the late 17th century through the US Civil War, surgeons used turpentine in the treatment of wounds and amputations. In the Confederate Army, the external application of turpentine was a substitute for quinine in the treatment of malaria.[2] During the 18th and 19th centuries, turpentine oil was administered for the treatment of a variety of infections including croup, yellow fever, typhus, dysentery, and various parasites. Turpentine enemas were a treatment for abdominal distension, hysteria, and amenorrhea during the late 19th century.[3]

BOTANICAL DESCRIPTION

Common Name: Pines

Scientific Name: *Pinus* species

Botanical Family: Pinaceae

Physical Description: Pine trees have distinctive bundles of long, narrow needles and large, woody cones with tough scales. Branches commonly grow in rings around the trunk.

Distribution and Ecology: Pines are coniferous species, which are native to Central and North America, Europe, Asia, and small areas of North Africa. Pines are widely cultivated around the world including in Africa and South America. There are a variety of *Pinus* hybrids, and *Pinus* species are the most common conifers worldwide.

EXPOSURE

Sources

Oil of turpentine (gum turpentine) is the volatile, oily, liquid fraction derived from the steam distillation of pine resin. The latter material is obtained by tapping living species in the genus *Pinus* including *P. brutia* Tenore (calabrian pine), *Pinus elliottii* Engelm. (slash pine), *P. halepensis* P. Miller (Aleppo pine), *P. massoniana* D. Don (Masson pine, Chinese red pine), *P. merkusii* Junghuhn & Vriese ex Vriese (Merkus pine), *P. pinaster* Aiton (maritime pine), *P. radiata* D. Don (Monterey pine), and *P. sylvestris* L. (Scots pine). Other sources of turpentine include the extraction or destructive distillation of wood (wood turpentine) and by-products of chemical pulping of pine trees. Although technically not a petroleum distillate, most reviews include turpentine with petroleum distillates because turpentine is an aromatic hydrocarbon with properties, toxic effects, and uses similar to petroleum distillates. The skin sensitizer, colophony, is the nonvolatile, solid residue (rosin, gum rosin) that remains after the evaporation of volatiles from the distillation of crude turpentine.[4] Both

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

colophony (rosin) and turpentine oil are distillation products of *Pinus* species, and the rosin used on violins and equestrian equipment includes both products. The high-temperature distillation of turpentine or other pine oil resins produces pine oil. Tall oil is dark-brown, liquid rosin, which is a by-product of pinewood in the wood pulp industry.

Uses

Traditional

Traditional uses of turpentine include use as an abortifacient,[5] antihelminthic agent,[6] rubefacient, decongestant, antipyretic, insect repellant,[7] and a treatment for human myasis (i.e., infection with dipterous larvae, such as maggots).[8] A tea brewed from the tips of pine branches was a substitute for coffee.

Current

Turpentine is a constituent of paint and other coatings, paint thinners, and solvents. The use of turpentine for these applications has decreased as other, less-expensive solvents have become available. However, the use of turpentine as a solvent remains common in developing countries. Other products containing turpentine include perfumes, liniments, and cleaning products. Turpentine is a raw product for the isolation of chemicals (e.g., camphor, citral, citronellal, isobornyl acetate, linalool, menthol, pine oil) in a wide range of commercial products. Pine oil is a solvent for varnish and polish, and synthetic pine oil is a constituent of fragrances and flavorings. Purification of monoterpene compounds in pine oil or the acid catalysis of pinene produces *l*-limonene, whereas citrus pulp or peels are the sources for the *d*-isomer of limonene. More recent formulations of pine oil-cleaning products contain smaller concentrations of pine oil and higher concentrations of constituents that reduce the viscosity and aspiration potential of the product.

PRINCIPAL INGREDIENTS

Chemical Composition

Turpentine is the volatile, predominantly terpenic, fraction or distillate resulting from the solvent extraction of softwoods (e.g., pine). The exact composition of turpentine oil depends on a variety of factors including extraction and refining methods, plant part, species, geographical location, and season. The major constituents of turpentine (CAS RN:8006-64-2) are terpene compounds ($C_{10}H_{16}$), such as α-pinene, β-pinene, camphene, 3-carene, and dipentene (*d*,*l*-limonene).[9,10] Other constituents include other acyclic, monocyclic, or bicyclic terpenes, oxygenated terpenes, and anethole. Monoterpenes in turpentine are volatile substances that occur naturally in air as a result of the emission of these substances from vegetation.[11] *d*-Limonene is a minor constituent of turpentine, but this compound is a major constituent of caraway, dill, celery, and oil from several fruits of the genus *Citrus* (lemon, orange, grapefruit).

Pine oil contains highly lipophilic secondary and tertiary cyclic terpene alcohols. Depending on the source of turpentine and the production methods, pine oil can contain terpene ethers and other hydrocarbons. Analysis of a sample of pine oil demonstrated 57% α-pinene, 26% carene, 8% β-pinene, 6% limonene, and 3% other hydrocarbons as measured by gas chromatography/mass spectrometry.[12] Individual constituents of the essential oil vary with *Pinus* species, extraction methods and plant parts. Table 104.1 lists the common constituents of the essential oil from the Balkan pine (*Pinus peuce* Gris.), North American pine (*Pinus ponderosa*, subspecies not reported), red pine (*Pinus resinosa* Aiton), and the eastern white pine (*Pinus strobus* L.).[13,14] Pine oil is usually present in household products along with other constituents (e.g., isopropyl alcohol, chloroxylenol), which may increase CNS and pulmonary toxicity.[15] Pine bark extract contains a variety of phenolic acid glucosides with anti-inflammatory properties, catechin compounds, taxifolin and taxifolin derivatives, procyanidins, and lignan glucosides.[16]

Physiochemical Properties

d-Limonene is an excellent solvent, but air oxidation of this substance produces potent sensitizing agents.[17] Turpentine also contains the strong sensitizer, Δ-3-carene.[18] These unsaturated cyclic hydrocarbons are very lipophilic. Turpentine is soluble in ether and alcohol, but insoluble in water. The water solubility of turpentine at 20 °C–25 °C (68 °F–77 °F) is 0.023% by weight and the vapor pressure at 25 °C (77 °F) is 5 mmHg.[19] The ingestion of turpentine produces a violet-like odor of the breath and urine. The viscosity of pine oil is greater than turpentine, and therefore the aspiration hazard of pine oil is less than the aspiration hazard of the turpentine. The terpene compounds present in turpentine are released into the air both from natural (bark, cortex of conifers) and anthropogenic (wood processing) sources. Monoterpenes (α-pinene, β-pinene, 3-carene) are highly photoreactive in the atmosphere with relatively short atmospheric half-lives.[20,21] Some evaporation of monoterpene compounds occurs during the use of cleaning products containing pine oil, particularly α-phellandrene, terpinolene, γ-terpinene, *d*-limonene, camphene, and α-pinene.[22]

TABLE 104.1. Most Common Constituents as a Percentage of the Total Essential Oil from Several *Pinus* Species

[b]Needle oil.
[+]Includes limonene.
NR, not reported.

Mechanism of Toxicity

In vivo animal experiments indicate that the central nervous system is the primary organ of toxicity, whereas alveolar damage results from the aspiration of less volatile gums and resins.[23] Hence, lower volatility means aspiration risk is much lower for turpentine than with more volatile petroleum distillates. Colophony is also a potent skin sensitizer that previously contaminated turpentine. Older preparations of turpentine contained irritants (formic acid, aldehydes) and relatively high concentrations of skin sensitizers (δ-3-carene, α-pinene).[24,25]

DOSE RESPONSE

Ingestion

The toxic dose of turpentine or pine oil is not well defined because of the effects of aspiration, the variable composition of essential oils, and the presence of other toxic compounds in most turpentine and pine oil products. Most accidental exposures to turpentine or pine oil produce mild symptoms, if any, provided pulmonary aspiration does not occur. Ingestions exceeding 2 mL/kg probably are potentially serious.[26] The ingestion of the equivalent of about 200 mL pure pine oil by an adult was associated with coma, whereas the ingestion of the equivalent of approximately 30 mL by an 18-month-old child caused lethargy and ataxia.[27] Both patients recovered without sequelae. A 14-month-old child developed tachypnea, lethargy, and seizures after reportedly ingesting 120 mL turpentine.[28] Within 24 hours, the child was asymptomatic.

Inhalation

Volunteer studies indicate that eye, nose, and throat irritation occurs following exposure to turpentine concentrations in the range of 125–175 ppm.[29] Following exposure of volunteers to turpentine vapors at 75 ppm, several subjects developed mild nasal and throat irritation. Although 175 ppm was intolerable, most subjects could tolerate daily exposure to 100 ppm. The American Conference on Governmental and Industrial Hygienists (ACGIH) recommends a threshold limit value–time weighted average (TLV-TWA) of 100 ppm to minimize the potential for upper respiratory tract irritation. There is no short-term exposure limit (STEL) because of limited data. Both the US Occupational Safety and Health Administration permissible exposure limit (OSHA PEL) and the National Institute for Occupational Safety and Health recommended exposure limits (NIOSH REL) are consistent with the TLV-TWA. The NIOSH immediately dangerous to life or health (IDLH) value is 1500 ppm. There are no well-recognized chronic effects from inhalational exposure to turpentine other than contact dermatitis.

TOXICOKINETICS

The main components of turpentine are monoterpenes (e.g., α-pinene, β-pinene, 3-carene, *d*-limonene). The high solubility of monoterpenes in blood indicates that these compounds are rapidly absorbed from the lungs and stored in adipose tissues.[30] Based on volunteer studies, the respiratory uptake of these monoterpenes ranges from about 60–70%. In a study of eight volunteers exposed to turpentine at 450 mg/m^3 for 2 hours, the mean relative uptakes of α-pinene, β-pinene, and 3-carene were 62%, 66%, and 68%, respectively.[31] Metabolism accounts for most of the elimination of the ingested monoterpenes with relatively small amounts of unchanged monoterpenes appearing in the urine and in exhaled air. During experimental studies, the amount of unchanged α-pinene,[32] 3-carene,[33] and *d*-limonene[36] excreted in expired air were 8%, 3%, and 1%, respectively, whereas the amount of unchanged monoterpene excreted in the urine was <0.001%. Following the ingestion of pine oil, the metabolism and renal elimination of monoterpenes is relatively slow. The peak urinary excretion of the main metabolite, bornyl acetate, occurred approximately 5–6 days after the ingestion of pine oil.[34] Following exposure of volunteers to α-pinene, the kidneys eliminated about 4% of the dose as *cis*- and *trans*-verbenol.[35] Although a slow terminal elimination phase exists, volunteer studies indicate that most of a single, ingested dose of these monoterpenes is eliminated within 3–4 days.[36] α-Terpineol glucuronide disappeared rapidly from the urine of an 18-month-old child who was surreptitiously administered pine oil, and this compound was not detectable in urine samples obtained 12 days after admission.[37]

CLINICAL RESPONSE

Adverse Effects

Turpentine oil is both an irritant and a sensitizer. As reported to the German Information Network of Departments of Dermatology Multicentre Project, the rate of sensitization to oil of turpentine was approximately 2% in tested patients with a slight decline in recent years.[38] Although relatively rare, allergic contact dermatitis results from exposure to turpentine oil, particularly in atopic individuals working as painters, potters, perfumery workers, or violinists (fiddler's neck).[39,40] A painter with prior sensitization to colophony developed hand eczema after handling lottery tickets that contained colophony.[41] Cross-reaction occurs between turpentine and a variety of other essential oils including tea tree oil, peppermint, balsam of Peru, pyrethrum, chrysanthemum, and ragweed.[42,43]

Acute Toxicity

Most internal human exposures to turpentine or pine oil involve the accidental ingestion of turpentine-containing products by children. Turpentine oil is a marked gastrointestinal irritant that produces more gastrointestinal and central nervous system symptoms than a similar ingestion of a petroleum distillate.[37] However, the ingestion of turpentine products produces a significantly lower incidence of pneumonitis compared with petroleum distillates.[44] Clinical features following the ingestion of mixtures containing *Pinus* distillates (turpentine oil, pine oil) include mucosal irritation (nausea, vomiting, abdominal pain, sore throat, chest pain), mild respiratory tract irritation (cough, transient shortness of breath) and central nervous symptoms (headache, elation, confusion, ataxia, lethargy).[27] A violet-like odor to the breath and urine suggests ingestion of pine oil, although this odor is not always present. Coma, seizures, and death can result from large, intentional ingestions of turpentine or pine oil.[45] Symptoms usually develop within 2–3 hours following ingestion, and the toxic effects typically resolve within 24 hours.[26] Rare complications of turpentine or pine oil aspiration include acute respiratory distress syndrome (ARDS), bronchopleural fistula, pneumatoceles, lung necrosis, empyema,[46] pneumothorax, sepsis, and multiorgan failure.[47,48] Urinary tract irritation (dysuria, hematuria, frequency) may also occur.[49,50] The parenteral injection of approximately 5 mL of turpentine was associated with the development of hypoxemia and noncardiogenic pulmonary edema, followed by cellulitis and a sterile abscess at the injection site.[51] Similar respiratory abnormalities occurred in horses injected with pine oil for malicious purposes.[52]

Chronic Toxicity

Preliminary animal studies indicate that turpentine oil has weak tumor promoting properties.[53] Neither the International Agency for research on Cancer (IARC) nor the US Toxicology Program list turpentine oil or major ingredients in turpentine oil as suspected carcinogens.

DIAGNOSTIC TESTING

Analytical Methods

Turpentine oil contains many compounds. Terpenoid compounds increased the flexibility of the oil binders in oil paintings.[54] Analysis of these compounds in pine resins (e.g., Venice turpentine from *Larix decidua* Mill.) by gas chromatography (GC) and mass spectrometry

(MS) helps determine the best compounds for restorations of old paintings.[55]

Biomarkers

The blood turpentine concentration in an 85-year-old woman as measured by GC with flame ionization detector was 28 µg/mL, when compared with a standard consisting of the material involved with the poisoning.[56] At the time the sample was drawn, she was comatose, hypotensive, and apneic. 1-α-Terpineol is a major constituent of pine oil and a biomarker for ingestion of substances containing pine oil.[52] Postmortem blood from a 89-year-old Alzheimer's patient, who was found at home in cardiac arrest after drinking about 100 mL Pine-Sol® (Uline, Waukegan, IL), contained 25 mg/dL 1-α-terpineol as measured by gas chromatography/mass spectrometry.[57] Pine oil composed about 17–22% of this product, and about 50% of the pine oil consisted of 1-α-terpineol.

Abnormalities

Complications of the ingestion of turpentine include hematuria, thrombocytopenia,[58] and pneumatoceles.[59] The typical course of the pneumatocele is slow, progressive resolution of the radiographic changes over a period of weeks. Laboratory abnormalities following the ingestion of mixtures of monoterpene compounds can also include leukocytosis and mild elevation of hepatic aminotransferases.[12]

TREATMENT

The treatment of accidental exposures to turpentine is similar to the treatment of petroleum distillates. Patients should be observed for the development of signs of aspiration because the ingestion of turpentine frequently causes vomiting. Decontamination measures are not recommended because of the lack of documented efficacy and the risk of pulmonary aspiration. These patients should be admitted for observation for the development of respiratory depression and seizure activity. Asymptomatic children may be discharged after 3–4 hours of observation if the 2-hour postingestion chest x-ray is normal. Because monoterpenes are lipophilic compounds with relatively low blood concentration, the use of hemodialysis and hemoperfusion probably does not alter clinical outcome.[34]

Chapter 105

PLANT DERMATITIS

The plant kingdom represents a highly diversified biological system containing over 300,000 plant species. Based on the plant taxonomy developed by the Swedish botanist, Linné, Latin names describe families (capitalized, plural, no italic), genus (capitalized, italic, singular), and species (italic, singular). Exposure of humans to chemicals in plants causes several types of dermal lesions, collectively called phytodermatitis. Based on the mechanism of action, phytodermatitis is divided in the following classifications: (1) irritant contact dermatitis, (2) allergic contact and airborne allergic dermatitis, (3) phytophotodermatitis, (4) pharmacological injury, and (5) mechanical injury.[1] The stinging nettle (*Urtica dioica* L.) causes a mechanical injury secondary to contact with tiny, type-like bristles followed by a transitory (few minutes to hours) pruritic, urticarial rash. These lesions result from the injection of chemicals (e.g., histamine, serotonin, acetylcholine, leukotriene B_4, leukotriene C_4) following penetration of the skin by these bristles.[2,3] Isolated mechanical injuries result from contact with nontoxic bristles and spines (e.g., cactus) that may cause the formation of slow healing, foreign body granulomas.[4] Other sources of skin lesions following exposure to plants include pseudophytodermatitis (e.g., contact with arthropods or insecticides on the plant) and pseudophytophotodermatitis (e.g., contact with phototoxic chemicals from fungal infections in the plant).

Skin eruptions occur during all seasons, particularly during the warmer months when exposure to plants and pollens are high. Weeds, ornamental flowers, native vegetation, vegetables, sawdust, and plant products contain thousands of chemicals that can produce a contact dermatitis either by direct irritation or by an allergic reaction.[5] Host susceptibility and variation in the concentration of sensitizing chemicals caused by genetic factors, plant parts, environmental conditions, and season result in different clinical responses to dermatitis-inducing plants. Potent plant sensitizers (e.g., castor bean, western red cedar) can produce both contact dermatitis and asthma in the occupational setting.[6,7]

IRRITANT CONTACT DERMATITIS

Plant dermatitis (phytodermatitis) results both from allergic reactions and from direct irritation (i.e., nonallergic mechanisms). Irritant dermatitis is the most frequent dermatitis associated with plant exposure, and this type of dermatitis involves chemical and physical injury rather than an immunological response.[8,9] Table 105.1 lists the common plants that cause primarily irritation following direct exposure. The most common plant families involved with irritant contact dermatitis are Agavaceae (*Agave*) Brassicaceae (*Brassica*, *Eruca*, *Raphanus*, *Sinapis)*, Ranunculaceae (*Aconitum*, *Anemone*, *Ranunculus)*, Euphorbiaceae (*Croton*, *Euphorbia*, *Hippomane)*, and Rutaceae. Skin lesions

TABLE 105.1. Common Plant Irritants

Family	Genus and Species	Common Name
Agavaceae	*Agave americana* L.	Century plant, American aloe, maguey
Araceae	*Dieffenbachia seguine* (Jacq.) Schott	Dumb cane
	Philodendron cordatum Kunth ex Schott	Philodendron
Amaryllidaceae	*Narcissus jonquilla* L.	Jonquil
	Narcissus pseudonarcissus L.	Daffodil
	Narcissus poeticus L.	Pheasant's eye
Brassicaceae (Cruciferae)	*Armoracia rusticana* P.G. Gaertn., B. Mey. & Scherb.	Horseradish
	Brassica nigra (L.) W.D.J. Koch	Black mustard
	Sinapis alba L.	White mustard
	Rorippa nasturtium-aquaticum (L.) Hayek	Watercress
	Raphanus sativus L.	Radish
Euphorbiaceae	*Codiaeum variegatum* (L.) Blume	Croton
	Euphorbia helioscopia L.	Sun spurge
	Euphorbia pulcherrima Willd. ex Klotzsch	Poinsettia
	Euphorbia milii var. splendens (Bojer ex Hook.) Ursch & Leandri	Crown-of-thorns
	Hippomane mancinella L.	Manchineel tree
Liliaceae	*Hyacinthus orientalis* L.	Hyacinth
Ranunculaceae	*Anemone hupehensis* (hort. ex Lem.) Lem. ex Boynton	Japanese anemone
	Clematis vitalba L.	Clematis, Ol' man's beard
	Pulsatilla vulgaris Miller	Pasqueflower
	Ranunculus acris L.	Buttercup

Source: Adapted from Ref 1.

result from the combined effects of mechanical trauma by sharp plant parts and chemical reactions. These reactions involve low molecular weight acids (acetic, citric, formic, malic), glycosides, proteolytic enzymes, or calcium oxalate crystals that may become embedded in the skin as a result of trauma (e.g., use of chain saws).[8] In contrast to allergic contact dermatitis, almost all exposed individuals develop skin lesions after exposure to direct irritants. Reaction begins soon after exposure, and the clinical response depends both on the concentration of the irritant and on the condition of the skin. Clinical manifestations of irritant contact dermatitis resemble a chemical burn and include erythema with or without edema, hyperkeratosis, linear crusty abrasions, pruritic erythematous papules,[10] vesicles, urticaria, pruritic subepidermal bullae, purpura,[11] necrotic ulcers, and granulomas. Typically, these cutaneous lesions develop within minutes to several hours after exposure. Common histological findings include spongiosis, eosinophils, superficial perivascular lymphocytic infiltrates, and subcorneal pustules. Irritant and allergic types of reactions are not mutually exclusive, and mixed reactions may occur because some chemicals are both sensitizers and irritants. Although systemic symptoms are unusual, severe cases may be associated with headache, diarrhea, myalgias, fever, and leucocytosis.[12] Treatment is supportive.

ALLERGIC PHYTODERMATITIS

Oleoresins (essential oils) occur in a variety of plants and plant parts depending on genetic background, growing conditions, and season. These compounds are complex mixtures of aldehydes, aromatic alcohols, aliphatic and aromatic esters, phenols (catechol, hydroquinone, resorcinol), and terpenes.[1] These low-molecular-weight compounds are haptens that induce cell-mediated inflammatory reactions involving prior sensitization and the priming of memory and effector T lymphocytes.

The distribution and shape of eczematous skin lesions suggests the possibility of allergic contact dermatitis. Plant sources of allergic contact dermatitis include species in the Anacardiaceae (poison oak, ivy, sumac), Asteraceae (ragweed, feverfew, wormwood, burdock, chamomile, artichoke, chrysanthemum, yarrow, tansy) and Primulaceae (primrose) families as well as genera of liverwort (*Frullania*) and lichens (*Cladonia, Evernia, Parmelia, Usnea*).[13,14] Occupational exposure to the latter two group produces a chronic, lichenified, dermatitis of the hands, forearms, face, and neck in forest workers and

wood cutters (e.g., wood cutter's dermatitis).[15] These lesions often are photosensitive. Common plants associated with skin reactions in the occupational settings include Christmas cactus (*Schlumbergera* hybrids), barberton daisy (*Gerbera* hybrids), poinsettia (*Euphorbia pulcherrima* Willd. ex Klotzsch), Chinese hibiscus (*Hibiscus rosa-sinensis* L.), *Campanula* spp., marguerite daisy (*Argyranthemum frutescens (L.)* Sch. Bip.), geranium (*Pelargonium* hybrids), tomato plant (*Solanum lycopersicum* var. *lycopersicum* L.), spathe flower (*Spathiphyllum* spp.), weeping fig (*Ficus benjamina* L.), primrose (*Primula* spp.), and *Begonia* hybrids.[16–18] Although allergic rhinitis and bronchial hyperreactivity as a result of exposure to *Asteraceae* pollens are common, immediate-type hypersensitivity responses to contact with these plants are relatively rare.[19]

Table 105.2 and Table 105.3 list common sensitizing agents in plants and trees. Typically, linear streaks of erythema, papules, and vesicles appear on the exposed skin of sensitized patients after a latent period up to 5–6 days. The severity of the dermatitis depends on the degree of exposure to the sensitizing agent as well as individual sensitivity. Cross-reactivity to antigens within the same plant genera (e.g., *Toxicodendron*) often occurs, but the presence of contact dermatitis does not correlate to symptoms of allergic rhinitis. In Oriental medicine, ingestion of lacquer from *Toxicodendron* species is a general health supplement and a treatment for gastrointestinal symptoms.[20]

TOXICODENDRON DERMATITIS (POISON OAK, SUMAC, AND IVY)

BOTANICAL DESCRIPTION

Poison ivy, poison sumac, and poison oak are indigenous to the United States, Canada, and northern Mexico. Although poison oak and poison ivy can grow in most

TABLE 105.2. Common Plant Sensitizers

Family	Plant	Common Name	Sensitizing Agent
Alliaceae	*Allium sativum* L. *Allium triquetrum* L.	Garlic onion	Diallyl disulfide, allylpropyldisulfide, allicin
Alstroemeriaceae	*Alstroemeria* spp.	Peruvian lily	Tulipalin A
Anacardiaceae		Poison ivy, poison oak, poison sumac, cashew nut (un-roasted), oriental lacquers, ginkgo tree, mango (stem, skin of fruit only), Brazilian pepper	Catechols (e.g., urushiol)
Araliaceae	*Dendropanax trifidus* (Thunb.) Makino ex Hara		Falcarinol
Brassicaceae		Wild garlic, horseradish, black mustard, winter cress, candy tuft, wild mustard	
Caryophyllaceae		Carnation, cauzeflower	
Asteraceae[a]	*Tanacetum parthenium* (L.) Schultz-Bip. *Inula helenium* L. *Chrysanthemum* spp.	Feverfew Elecampane Chrysanthemum, gerbera daisy	Parthenolide Alantolactone Sesquiterpene lactone
Euphorbiaceae		Spurge, castor bean	
Liliaceae	*Tulip* spp. *Hyacinthus* spp. *Lilium longiflorum* Thunb.	Tulip Hyacinth Easter lily	Tulipalin A
Primulaceae	*Primula* spp.	Primula	Primin (2-methoxy-6-pentylbenzoquinone)
Proteaceae	*Grevillea robusta* A. Cunningham ex R. Br.	Silky oak	Urishiol
Rutaceae		Citrus fruit (lime, orange, grapefruit)	

[a]The main sensitizers in the Asteraceae family are sesquiterpene lactones with the α-methylene-γ-butyrolactone moiety.[21] These compounds also occur in other families including magnolias, laurel bay (*Laurus nobilis* L.),[22] and liverworts.

TABLE 105.3. Common Sensitizing Agents in Trees

Sensitizing Agent	Sources	Common Name
Deoxylapachol, lapachol	*Tectona grandis* L. f.	Teak
(R)-3,4-Dimethoxy-dalbergione	*Machaerium scleroxylon* Tul.	Caviuna vermelha
2,6-Dimethoxy-1,4-benzoquinone	>50 Plant sources	Mahogany, macoré
Chlorophorin	*Chlorophora excelsa* Benth.	Kambala
Mansonone A	*Mansonia altissima A.* Chev.	Mansonia bété
Obtusaquinone	*Dalbergia retusa* Hemsl.	Cocobolo
Thymoquinone	*Cedar* species	Cedar
Cardol, anacardic acid	*Anacardium occidentale* L.	Cashew tree
Urushiol	*Toxicodendron vernicifluum* (Stokes) F. Barkley	Japanese lacquer trees
Ginkgolic acid	*Semecarpus anacardium* L. f.	Marking nut tree
	Mangifera indica L.	Mango tree
	Schinus terebinthifolius Raddi	Florida holly
	Ginkgo biloba L.	Ginkgo tree, Maidenhair tree
	Grevillea robusta A. Cunningham ex R. Br.	Silky oak

temperate zones throughout North America under the proper climatic conditions, these plants are not usually found in the deserts of Texas, Arizona, and central Mexico, the rain forests of Washington, Hawaii, Alaska, elevations above 4,000–5,000 feet (~1,200–1,500 m), or northern Canada.[23] These plants do not usually exist in the Rocky or Sierra Nevada Mountains or in the high plateaus of Nevada and Idaho.[24] Identification of poison oak and poison ivy is complicated by the regional variation of these plants, such as deviations from the clusters of three leaves. All plants in the genus *Toxicodendron* have pinnate leaves (i.e., multiple leaflets arranged along a midrib), but the number of leaves varies with species. Plants with an appearance similar to *Toxicodendron* species include squawbash (*Rhus trilobata* Nutt.), fragrant sumac (*Rhus aromatica* Ait.), Virginia creeper (*Parthenocissus quinquefolia* (L.) Planch.), and Boston ivy (*Parthenocissus tricuspidata* (Sieb. & Zucc.) Planch.).[25]

Poison Ivy

Common Name: Poison Ivy, Poison Vine, Mark Weed, Three-Leaved Ivy

Scientific Name: *Toxicodendron radicans* (L.) Kuntze

Physical Description: Although occasionally an erect shrub reaching 15–20 ft (~5–6 m) in height, poison ivy commonly grows as a woody vine. Hair-like, aerial rootlets anchor the vines of eastern poison ivy (*T. radicans*) to supporting structures. Northern or western poison ivy [*T. rydbergii* (Small ex Rydb.) Greene] grows as small shrub without aerial rootlets. The bright green, hairless, serrated or smooth leaves are pointed and grow in three leaflet clusters on a short stalk. In the fall, the leaves become various shades of red, yellow, and brown. Small greenish white flowers produce clusters of grayish brown fruit. Cultivated varieties of garden ivies belong to different botanical families than poison ivy.

Distribution and Ecology: Poison ivy is found in North and South America as well as eastern Asia. This species is found in every state except California and Nevada. Poison ivy is most abundant along the rocky coasts of New England, sandbars off New Jersey and Long Island, and throughout the Carolinas.

Eastern Poison Oak

Common Name: Eastern Poison Oak, Oakleaf Ivy

Scientific Name: *Toxicodendron quercifolium* (Michx.) Greene

Physical Description: This erect, deciduous, woody shrub has triple leaflets similar to those of poison ivy, but the leaf edges are sinuate like oak leaves.

Distribution and Ecology: This plant is present less commonly than poison ivy, and eastern poison oak inhabits an area bounded by Texas, northern Florida, and New Jersey.

Western Poison Oak

Common Name: Western Poison Oak, Pacific Poison Oak

Scientific Name: *Toxicodendron diversilobum* (Torr. & Gray) Greene

Physical Description: This woody, deciduous shrub grows to about 3–6 ft (~1–2 m) in wooded areas below 4,000–5,000 ft (~1,200–1,500 m). Many thornless woody stems arise from the underground roots. The lobed leaves usually appear in clusters of three, similar to oak leaves. Small white flowers appear from August to November followed by relatively large (7.5 mm) fruit that resemble cherries. In contrast to eastern poison oak (*T. pubescens* P. Mill.), western poison oak has aerial rootlets to anchor the vines to supporting structures (e.g., trees).

Distribution and Ecology: The habitat of western poison oak is the Pacific Coast from Canada to Mexico, particularly in canyons with abundant water.

Poison Sumac

Common Name: Poison Sumac, Poison Elder, Poison Ash, Swamp Sumac, Thunderwood

Scientific Name: *Toxicodendron vernix* (L.) Kuntze

Physical Description: Grows as a wood shrub (5–8 ft/~1–2 m) or as a small tree (up to 25 ft/~8 m) with light gray bark. Leaves appear as 7- to 13-leaflet clusters arranged in pairs, with a terminal leaflet at the end of the stem. Leaflet margins are smooth and pointed. The fruit is red.

Distribution and Ecology: Poison sumac occurs primarily in the southeastern and northeastern United States and in some midwestern areas, particularly in swamps and bogs east of the Mississippi River. This plant grows primarily in undisturbed areas where human activity is minimal.

ALLERGEN

Physiochemical Properties

Urushiol compounds are the oleoresin components of *Toxicodendron* species that cause contact dermatitis. Inside the undamaged plant, urushiol is a transparent oil that contains a mixture of diphenols (catechols) with long, hydrophobic alkyl side chains at C3 on the catechol ring. Upon exposure to oxygen, urushiol polymerizes to become a shiny, black lacquer. The volatility of urushiol is low, and this compound remains antigenic after drying on fomites.[26] The length of the side chain varies with species. Although the genetic and environment factors alter the concentration of catechols between different species and individual plants, all catechols in the family *Anacardiaceae* are structurally similar.[27] The antigenic structure in this family is the side chain at the C3 position of the orthocatechol, which is a pentadecyl (15-carbon) chain in poison ivy, a heptadecyl (17-carbon) side chain in poison oak, and a 13-carbon side chain in poison sumac. Although the chemical structure of urushiols differs between various species, sensitization to one species of *Toxicodendron* usually results in cross-sensitivity to other *Toxicodendron* species. Reducing the saturation and increasing the length of the side chain causes greater antigenicity. On the skin, the reduction of urushiol at the C1 and C2 positions produces highly reactive quinones, which are transformed into potent contact allergens.

In moist aerobic environments, urushiol oxidizes and polymerizes to form a brown-black lacquer. The sap from poison ivy, poison oak, and poison sumac turns dark brown within about 10 minutes and black by about 24 hours.[28] Urushiol adheres to many surfaces, including gloves, skin, clothes, equipment, and animal fur. Because of the solubility of catechols in rubber, urushiol penetrates rubber gloves, but not heavy-duty vinyl gloves.[29] Soap and water degrade urushiol, and a thorough machine washing removes dried urushiol from clothes. Once the urushiol-protein complex forms in the skin, washing will not reduce the antigenicity of the complex. Urushiol is nonvolatile; therefore, airborne contact dermatitis occurs only when smoke carries the urushiol on dust particles. Many members of the Anacardiaceae family of tropical and subtropical plants contain urushiol or similar substances. Cardol in mango (*Mangifera indica* L.) and urushiol demonstrate cross-reactivity with contact allergens of a variety of species from this family including poison oak and ivy (*Toxicodendron* species), rengas or black varnish tree (*Gluta renghas* L.), cashew nut tree (*Anacardium occidentale* L.), and the Indian marking nut tree (*Semecarpus anacardium* L. f.), and the Chinese lacquer tree [*Toxicodendron vernicifluum* (Stokes) F. Barkley].[26]

Sensitizers

Urushiol occurs throughout poison ivy and poison oak plants including the stems, roots, leaves, and vines. During the fall, the red, brittle leaves contain high concentrations of urushiol. In the winter season, the bare twigs of poison oak and poison ivy retain significant concentrations of urushiol in the sap. In a study of seasonal urushiol content of poison oak leaves, the urushiol content remained relatively stable (0.02–0.4%) from Spring to early November, when the urushiol content increased to 0.9–2.6%.[30] By December when the leaves fell, the urushiol content was low; therefore, fallen leaves are not allergenic. Urushiol flows through the resin channels under the exocarp of the fruit and diffuses into the leaves, stems, and roots. At high concentrations, urushiol is a contact irritant.

Mechanism of Action

Hypersensitivity to urushiol compounds in *Toxicodendron* species is a delayed cell-mediated immunological reaction that involves T lymphocytes. Urushiol, the immunogenic hapten of *Toxicodendron* species, elicits a predominantly $CD8^+$ T-cell response in the epidermis. Catechols from *Toxicodendron* plants are haptens that penetrate the skin to form reactive quinones. These compounds bind to a ligand on Langerhans cells in the epidermis and to macrophages and dendrocytes in the dermis.[31] $CD4^+$ T lymphocytes in the regional lymph nodes process the antigen presenting cells and begin to divide into effector and memory T cells that circulate throughout the body. Subsequent exposure to urushiol produces a cytotoxic response from the release of a variety of cytokines by the memory T-cells. The amount of redness, swelling, vesiculation and pruritus depends on the balance between the effector T cells and the T suppressor lymphocytes. Subsequently, a delayed hypersensitivity reaction occurs.

Susceptible Populations

Of all members of the animal kingdom, only humans and some other primates are sensitive to *Toxicodendron* species. The severity of the reaction to these plants depends on the degree of sensitization, the site of exposure (i.e., skin thickness, sun-exposed skin), and the quantity of antigen in contact with the skin. Children under the age of 5 years do not usually develop sensitivity to *Toxicodendron* species. Beyond 6–8 years of age, experimentally induced hypersensitivity is possible in up to 85% of that population.[32] Based on experimental studies in healthy volunteers, about 50% of the adult population develops hypersensitivity dermatitis following a transient contact (i.e., approximately 2.5 μg purified urushiol) to *Toxicodendron* species.[33] Increasing the dose of urushiol to 50 μg produces contact dermatitis in an additional 30–40% of the population. Consequently, about 15% of the population does not develop reactions to urushiol despite exposure to doses far exceeding the amount of urushiol normally present following exposure to *Toxicodendron* plants. Occupational groups with a high incidence of sensitivity to *Toxicodendron* species include farm workers, forestry workers, and fire fighters.[24] The high incidence of urushiol sensitivity in children of urushiol-sensitive parents suggests a significant genetic predisposition.[34]

CLINICAL RESPONSE

Typically, contact dermatitis produces a burning pruritic erythema over the area of contact in the configuration of linear scratch marks about 2–4 days after exposure to *Toxicodendron* species.[35] Highly sensitized patients may react to contact with *Toxicodendron* species within 8 hours, and patients without previous skin lesions may require 5–6 days to react. New lesions can appear up to 14 days after exposure.[36] The erythematous lesions progress to papules and vesicles. The skin lesions usually appear first on exposed areas in the configuration of contact (e.g., linear scratch marks). Secondary lesions may develop on areas distal from the initial contact as a result of repeated contact with oleoresins on animal fur or clothing. These lesions may develop in clumps because of variation in skin sensitivity (e.g., the eyelids and dorsum of the hand are more sensitive than the palm and hairy areas) and in the amount of secondary exposure. The fluid in the skin vesicles does not contain sensitizing agents. Rarely, black spots or linear lesions appear on the skin as a result of the deposition of urushiol on the skin that oxidizes and polymerizes to form a black lacquer.[37] Nausea, vomiting, diarrhea, and abdominal pain may accompany the skin lesions in highly sensitive individuals. Typically, the skin lesions resolve within approximately 10–14 days. The development of new skin lesions 2–3 weeks after initial contact suggests re-exposure to antigen reservoirs (e.g., pets, equipment, tools, clothing, fingernails). Sensitivity to urushiol decreases with age. In general, the onset of the hypersensitivity reaction is longer and the severity of the reaction is milder in older patients compared with a similar exposure in younger individuals.[38]

The most common complication following the development of contact dermatitis is secondary infection. Rarely, the systemic absorption of catechols causes urticaria, scarlatiniform eruptions, and erythema multiforme. A rare case report associated membranous nephropathy, proliferative glomerulonephritis, and arteritis with *Toxicodendron* exposures, particularly following the administration of commercial poison oak extract.[39] Hyperpigmentation and vitiligo may occur, particularly in dark-skinned races.

Ingestion of leaves may produce a severe gastroenteritis and pruritus ani. The development of immunity to *Toxicodendron* species following the chewing of its leaves by American Indians has not been documented.[40] Rarely, *Toxicodendron* species may produce urticaria, allergic rhinitis, and asthma. Differential diagnosis includes phytophotodermatitis, nummular eczema, chemical-induced irritant dermatitis, bedbugs (*Cimex lectularius* L.), Portuguese jellyfish envenomation, and caterpillar dermatitis. Skin lesions associated with the ingestion of *Toxicodendron* plants as herbal remedies include generalized maculopapular rash, erythroderma, vesiculobullous lesions, and erythema multiforme.[20]

TREATMENT

Decontamination

Urushiol binds quickly to the skin (i.e., <30–60 minutes), and the skin should be rinsed immediately with cool water beginning with the hands or other contaminated areas first. Urushiol is neutralized by alkaline soap, such as ordinary face soap or dishwashing liquid (pH 8.8–10.5); the affected skin should be washed with soap and water after the initial rinse, particularly the palms of the hands.[36] Vigorous scrubbing of the affected area should be avoided. Volunteer studies suggest that the removal of urushiol with soap or solvents reduces the severity of urushiol-induced lesions when initiated within 2 hours of exposure, but decontamination does not eliminate reactions in sensitized individuals.[41,42] The use of an organic solvent [acetone, isopropanol, Tecnu® outdoor skin cleanser (Tec Laboratories, Inc., Albany, OR)] may leach some of the urushiol from the skin up to 4–6 hours after an exposure; however, further exposure to urushiol must be avoided immediately after the use of these solvents because these solvents reduce the protective skin lipids and the natural barrier to urushiol. Following the use of these solvents, the affected skin should be washed with soap and water to remove any urushiol remaining on the surface of the skin. The addition of hydrogen peroxide or sodium hypochlorite to the water increases the oxidation of urushiol. All clothing should be changed and the contaminated clothing washed with soap and water.

Topical Steroids

High-potency fluorinated steroid gels 2–3 times per day are appropriate for localized skin lesions, but medium-potency steroid gels are more appropriate for large lesions. Topical steroids should be started before the appearance of the vesicles and continued for 2–3 weeks.[36] Moderate-strength topical steroids should be avoided on the face and genitalia.[26] Systemic steroids (adult dose 1–2 mg/kg daily for 7–10 days) may be required for more severe lesions.

Soaks

Cold water compresses or soaks 3–4 times daily for 15 minutes are recommended for weeping or pruritic lesions during the acute phase. The addition of aluminum subacetate [Burow's solution, Domeboro™ solution (Bayer HealthCare, Morristown, NJ)] may provide additional relief when applied as wet compresses of a 21/2% solution. Tepid (32 °C/90 °F) showers are preferred to hot showers because heat may cause vasodilatation, erythema, and edema.

Shake Lotions

Shake lotions (e.g., calamine) are topical preparations, which are combinations of powders and liquids that require physical agitation (i.e., shaking) prior to application. Calamine lotion helps dry oozing, wet skin lesions after the application of soaks. Shake lotions used to sooth the dermal lesions associated with poison ivy or poison oak should not contain antihistamines because of potential sensitization. Additionally, these topical products should not contain zirconium because of the potential to cause granulomas. Over-the-counter (OTC) soap mixtures (e.g., Zanfel™; Zanfel Laboratories, Inc., Morton, IL) are available to reduce the pruritus associated with *Toxicodendron* hypersensitivity reactions.

Systemic Steroids

Adequate doses of systemic corticosteroids given early in severe, edematous cases provide quick relief and may blunt the natural course of the skin lesions. At least 40 mg (0.5–0.75 mg/kg) of prednisone daily is often necessary. The dose is tapered during the second and third weeks. The dose is tapered by 10 mg every 4 days until the daily dose is 20 mg. If no rebound occurs after the administration of 20 mg every other day for one week, the prednisone is discontinued. At times, prolonged therapy (i.e., 5–6 weeks) is required.

Oral Antihistamines

Although the use of oral antihistamines may reduce the sensation of itch and sedate the patient, these drugs do not alter the course of the skin lesions.

Supportive Care

All contaminated clothing and domestic animals should be washed with soap and water. The lesions of poison oak are not usually covered with an occlusive dressing (i.e., left open), but large bullous lesions may require protection by a bulky dressings [e.g., Kerlix® (Kendall Company, Mansfield, MA) and nonadherent dressing]. These bullous lesions should not be lanced. The dressing may be soaked off with cool water to prevent disruption of the bullae. The skin lesions should be observed carefully for signs of secondary infection (i.e., increasing redness, warmth, pain).

Hyposensitization

No well-controlled clinical trials have demonstrated the efficacy of commercial extracts, and potential adverse reactions (gastrointestinal distress, pruritus ani, local

inflammation) limit the usefulness of hyposensitization methods.[43] US Food and Drug Administration-approved barrier cream (IvyBlock®; Enviroderm Pharmaceuticals, Louisville, KY) is available when exposure of sensitized individuals to *Toxicodendron* plants is anticipated. These organoclay barrier compounds reduce, but do not eliminate hypersensitivity reactions.[44]

BULBS

There are approximately 250 genera of bulbous plants that are divided into true bulbs (daffodils, onions), tubers (dahlia), rhizomes (*Iris*), and corms (*Crocus, Gladiolus*). Bulbs commonly producing dermatitis include tulip, narcissus, hyacinth, and members of the Alliaceae (Allium) family (garlic, onion, chives).[45] Rare causes of contact dermatitis include contact with species from the family Ranunculaceae[46] and the genera *Iris, Ornithogalum*,[45] and *Scilla*.[47] These skin lesions usually result from irritation rather than an allergic reaction.

TULIP

The genus *Tulipa* is member of the Liliaceae family that is native to southwestern central Asia (Turkey). In 1593, the French botanist and physician, Carolus Clusius started the bulb trade in Holland by introducing *Tulipa gesneriana* L. into the medical garden of the University of Leiden. During severe food shortages in Holland at the end of World War II, tulips were a food source. Now there are over 2500 cultivars of *Tulip*. Contact dermatitis occurs following exposure to the plant sap, pollen, and the hard outer skin (tecta) of the tulip bulb, particularly in professional growers (digging, peeling, packaging, sorting) and to a lesser extent in florists.[48]

Typical features of contact dermatitis produced by tulips range from paronychia and dry erythematous, hyperkeratotic plaques on the finger tips to more extensive eczema.[49] The characteristic fissured, hyperkeratotic finger tips and pustular lesions under the nail are termed "tulip finger."[50] Paresthesias and discomfort ("tulip fire") may develop in the fingertips of exposed worker within several hours of handling tulip bulbs.[51] Occasionally, contact urticaria and bronchial hyperreactivity develop following exposure to tulips.[52,53] Hydrolysis of tuliposides in the tulip bulbs forms tulipalin A (α-methylene-γ-butyrolactone) and tulipalin B with the former being the primary sensitizer.[54] Although tulipalin A occurs throughout the tulip plant, the bulb and the pistils contain the highest concentrations.[55] Patch testing suggests that tulipalin A penetrates vinyl and latex gloves, but not nitrile gloves.[56] Tulipalin A also occurs in other members of the Liliaceae and Alstroemeriaceae families including *Alstroemeria* species (Peruvian lily),[57] glacier lily (*Erythronium grandiflorum* Pursh),[58] and *Lilium longiflorum* Thunb. (Easter lily).[59] Contact with the sap from these plants produces a contact dermatitis similar to tulip finger and, rarely, bronchial hyperreactivity.[60,61] The tulip does not contain clinically significant quantities of calcium oxalate crystals. Patch tests are available to determine individual sensitivities to allergens in bulbs.[62]

NARCISSUS

Narcissus is a native plant of the Mediterranean, North Africa, and southwest Asia. The source of most cultivars is *Narcissus pseudonarcissus* L. (wild daffodil), *N. jonquilla* L. (joquil), *N. poeticus* L. (pheasant's eye), *N. tazetta* L. (tazetta), and *N. triandrus* L. (angel's tears).[45] Narcissus bulbs contain needle-shaped calcium oxalate crystals as well as several weak sensitizers (homolycorine, masonin).[63] These sensitizers are not present in the stems and leaves of narcissus. True contact allergen to narcissus is relatively rare, and almost all skin lesions following exposure to narcissus results from an irritant dermatitis.[63] Consequently, most severe reactions result from the contact of the sap with damaged skin.

HYACINTH

The native habitat of hyacinth is the eastern Mediterranean. There are many cultivars, probably derived from *Hyacinthus orientalis* L. The brown outer covering (tecta) of the hyacinth bulb has several layers that contain high concentrations (i.e., up to 6%) calcium oxalate crystals. Mechanical microtrauma caused by these crystals produces skin irritation and "hyacinth itch." Although there is substantial individual variation, most individuals develop an irritant dermatitis following exposure. Pruritus and urticaria are the most common features of hyacinth itch, primarily in the volar surface of the forearms, the face, thighs, or inguinal region.[64] The itching usually resolves following removal of the irritant from the skin. Eczema, hyperkeratosis, and fissuring of the finger tips occur occasionally. True allergic dermatitis or occupational asthma as a result of exposure to hyacinth is rare.[65]

ONION AND GARLIC (*Allium Species*)

Important species in the genus *Allium* include chives (*A. schoenoprasum* L.), garlic (*A. sativum* L.), and onion (*A. cepa* L.). Bulbs from many *Allium* species contain

irritant sulfur compounds (isothiocyanates). Potential allergens in garlic include diallyldisulfide, allylpropyldisulfide, and allicin.[45] Most skin lesions from exposure to onions cause an irritant dermatitis rather than allergic contact dermatitis.

TREES

Table 105.3 lists common sensitizing compounds in trees. The oil between the inner kernel and the outer layer of the cashew nut from the cashew tree (*Anacardium occidentale* L.) contains a variety of antigenic substances, including cardol and anacardic acid.[66] Roasting destroys these sensitizing agents. Contact dermatitis, stomatitis, or pruritus ani may result from the consumption of inadequately processed cashew nuts[67] or from exposure of sensitized individuals to swizzle sticks or voodoo dolls made from the cashew nut tree.[68] Cross-reactivity to *Toxicodendron* species occurs in patients sensitized to cashew nut oils because of the structural similarity between cardol and catechols in *Toxicodendron* species.[39] The antigenic oleoresins (urushiol, cardol) in mango demonstrate cross-reactivity with similar compounds in *Toxicodendron* species.[69]

Oriental lacquers derived from lacquer trees contain the same sensitizers (urushiols) that are present in *Toxicodendron* species.[70,71] These lacquers retain sensitizing properties indefinitely, but the sensitizing agent is sensitive to heat.[72] The fruit from the marking nut tree (*Semecarpus anacardium* L. f.) also contains an urushiol that produces contact dermatitis. The oil hardens into a black substance used by the laundrymen (dhobis) of India to mark clothes. The dhobi mark remains indefinitely despite repeated washings. A case report associated the development of acute renal failure and acute cortical necrosis with exposure to sap of the marking-nut tree (*Semecarpus anacardium* L. f.).[73] The fruit pulp of the maidenhair tree and ginkgo tree (*Ginkgo biloba* L.) contains catechols that produce cheilitis, stomatitis, pruritus ani, and proctitis in sensitized individuals. The sensitizing agents are not present in the seeds.

AIRBORNE CONTACT PHYTODERMATITIS

During dry windy conditions, sensitizing chemicals (e.g., monoterpenes, sesquiterpene lactones) concentrate in dried portions of the plant and subsequently these chemicals become airborne.[74,75] Occupational exposure accounts for most cases of airborne allergic phytodermatitis. Sources of airborne contact dermatitis include plants from the Asteraceae (Aster) family including ragweed (*Ambrosia* species), feverfew (*Tanacetum parthenium* L.),[76] and *Parthenium hysterophorus* L. (wild feverfew), garlic, sunflower, citrus fruits, thyme, soybean, rosewood, tea tree oil, essential oils, colophonium, yarrow, and lichens.[77] Seasonal peaks of allergic rhinitis and airborne allergic dermatitis are similar. Airborne allergic dermatitis may develop following fires as a result of the adsorption of sensitizing oleoresins to airborne ash. The deposition of these allergenic particles on exposed skin surfaces (upper eye lid, neck, upper chest, hands, wrists) produces pruritic macules and papules on exposed areas. Vesicles and bullae are uncommon. Lesions may appear on the trunk and lower extremities as a result of contact with contaminated clothing. In contrast to the linear lesions of direct contact dermatitis, airborne allergens produce a more uniform involvement of the hands, face, and other exposed areas. Although airborne contact phytodermatitis commonly occurs with a prominent demarcation at the midbiceps line and the upper sternal V line similar to phytophotodermatitis, airborne allergic dermatitis often involves the submental and postauricular regions, whereas phytophotodermatitis does not typically produce lesions in these areas. Airborne allergic dermatitis also involves other shaded portions of the body (e.g., upper eyelids, scalp covered by hair).[78] The treatment of airborne contact dermatitis and allergic contact dermatitis are similar depending primarily on the severity of the skin lesions.

PHYTOPHOTODERMATITIS

The ability of plants to cause hyperpigmentation was recognized by the ancient Egyptians, who used juice from *Ammi majus* L. (false Bishop's weed) and sunlight to treat vitiligo.[79] Phytophotodermatitis is a skin eruption that results from vigorous contact with crushed plants containing heterocyclic furan compounds including linear furocoumarin (psoralen, 5-methoxypsoralen, 8-methoxypsoralen) and angular furocoumarin (angelicin, pimpinellin). In the presence of sunlight (UVA), these compounds form covalent bonds with pyrimidine bases that result in single DNA adducts and cross-linked DNA strands. The cross-linking of DNA in the epidermis causes a rapid, temporary decline in RNA and DNA synthesis.

Clinically, the combination of sunlight, exposure to furocoumarin compounds, and moist skin produces a burning erythema in irregular patches on sun-exposed skin followed by edema and vesicles. This reaction involves a toxic rather than an immunological response, and most patients respond in a similar fashion to the same dose of psoralens.[80] A variety of plant families contain furocoumarin compounds (psoralens) including Brassicaceae (Cruciferae or mustard), Moraceae (figs), Ranunculaceae (buttercup), Rutaceae (bergamot, common rue, gas plant, lemon, lime), and Apiaceae or Umbelliferae (angelica, carrots, celery, dill, fennel, giant hogweed, wild parsnip).[8] Some of these plant species contain photosensitizing coumarin compounds other than psoralens, such as bergapten and xanthotoxin present in limes.[81] Table 105.4 lists the common causes of phytophotodermatitis. This disease occurs in occupational settings, such as food processing (celery, parsley)[82] and gardening (wild parsnip, gas plant).[83] Fresh, healthy celery plants do not contain clinically significant amounts of psoralen.[84]

The appearance of phytophotodermatitis is similar to severe sunburn[85] or jellyfish envenomation.[86] Typically, linear, burning macules develop soon after exposure and these lesions progress to papules and, in severe cases, bullae over 12–36 hours. The occurrence of maximal photosensitivity depends on the toxicokinetics of the involved furocoumarin range from 2–3 hours (5-methoxypsoralen) to approximately 32–36 hours for 8-methoxypsoralen. These lesions persist several days and often hyperpigmentation begins about 1–2 weeks after exposure. The major differential diagnosis involves *Toxicodendron* species, which produce more pruritus and a delayed response. The treatment for poison ivy and phytophotodermatitis are similar with immediate decontamination with soap and water being the first priority.

TABLE 105.4. Common Sources of Phytophotodermatitis

Family	Species	Vernacular Name
Apiaceae		
	Ammi majus L.	Bishop's weed, Artrillal
	Anethum graveolens L.	Dill
	Angelica archangelica L.	Angelica
	Apium graveolens L.	Celery
	Daucus carota L.	Carrot
	Foeniculum vulgare P. Mill.	Fennel
	Heracleum spp.	Giant hogweed, cow parsnip
	Pastinaca sativa L.	Parsnip
	Peucedanum spp.	Masterwort
	Pimpinella anisum L.	Anise
Clusiaceae		
	Hypericum spp.	St. John's wort
Brassicaceae		
	Brassica spp.	Mustard
Fabaceae		
	Psoralea corylifolia L.	Babchi
Chenopodiaceae		
	Chenopodium spp.	Goosefoot
Moraceae		
	Ficus carica L.	Fig tree
Ranunculaceae		
	Ranunculus spp.	Buttercup
Rosaceae		
	Agrimonia eupatoria L.	Agrimony
Rutaceae		
	Citrus aurantium subsp. *bergamia* (Risso & Poit.) Wight & Arn. ex Engler	Bergamot orange
	Citrus aurantifolia (Christm.) Swingle	Lime
	Cneoridium dumosum (Nutt.) Hook. f. ex Baill.	Coast spice bush, berryrue
	Dictamnus albus L.	Gas plant
	Pelea anisata Mann	Hawaiian lei
	Phebalium argenteum Smith	Blister bush
	Ruta graveolens L.	Common rue

Topical steroids are effective only for minor cases, whereas more severe cases require oral steroids. Wet compresses with cool water or Burrow's solution for 15–20 minutes several times daily may improve patient comfort. The use of hydroquinone compounds for persistent hyperpigmentation is an option for hyperpigmented lesions that do not fade with time. Avoidance of exposure to the sensitizing agent is the most important reason to use patch testing to differentiate phytophotodermatitis from allergic contact dermatitis.

II Bulbs, Rhizomes, and Tubers

Chapter 106

BUTTERCUP FAMILY

BOTANICAL DESCRIPTION

The family Ranunculaceae (buttercup) has various species in a number of genera that contain the skin irritant, protoanemonin, including species of the genera *Anemone*, *Caltha* (marsh marigold), *Clematis* (clematis, leather flower), *Pulsatilla*, *Helleborus* (hellebore), and *Ranunculus* (buttercup). There are at least 30 species of *Anemone* that are distributed in the United States, Europe, and Asia. *Anemone* species are distributed primarily in northern temperate and Arctic climates of the Old and New World with about 15–20 *Anemone* species in the United States.

Common Name: Cutleaf Anemone, Pacific Anemone, Red Windflower

Scientific Name: *Anemone multifida* Poir.

Botanical Family: Ranunculaceae (buttercup)

Physical Description: Basal leaves with petioles reach up to 15 cm (~10 in.) in length and 6.5 cm (~3 in.) in width. Typically, there are several flowering stems reaching up to 45 cm (~18 in.) in height that produce a single, white to reddish-pink flower about 2.5 cm (~1 in.) in diameter. Three small leaf lobes (2–3 mm/~0.1 in. in width) develop at the end of the erect, silky-haired stems. Seed heads are globose.

Distribution and Ecology: These plants inhabit prairie hillsides and moist meadows in North America.

Common Name: American pasqueflower, pasqueflower

Scientific Name: *Pulsatilla patens* (L.) P. Mill. (*Anemone patens*)

Botanical Family: Ranunculaceae (buttercup)

Physical Description: This perennial plant has a single flowering stalk with a whorl of three leaves that is covered with long, white silky hairs. The basal leaves are palmately divided with a few, coarse teeth along the margins. Each basal leaf develops from a long, hairy petiole. When fully open, the flower is 7–8 cm (~3 in.) in diameter with five to eight petal-like, purple sepals and a ring of yellow stamens. The root system consists of a woody taproot, which swells into a caudex on older plants that can produce flowering stalks. The flower appears for a few weeks during the early spring.

Distribution and Ecology: This plant is a native species to both North America and Eurasia that inhabits dry hill or gravel prairies and barren areas with scant, woody vegetation.

EXPOSURE

There are a variety of herbal uses in traditional medicine for protoanemonin-containing species including *Anemone* and *Pulsatilla* species. The most common use by Native American peoples for these plants was as a counter-irritant in the form of an external poultice for

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

abrasions, boils, cuts, and skin sores.[1] Other traditional uses for extracts from these plants included rheumatism, stomach troubles, and promoting childbirth. The Teton Sioux Indians also used extracts from *Clematis hirsutissima* Pursh (sugarbowls, hairy clematis) to stimulate horses by inserting the scraped root from *C. hirsutissima* into the nostril of the horse.[2]

PRINCIPAL TOXINS

Physiochemical Properties

Protoanemonin (CAS RN: 108-28-1, $C_5H_4O_2$) is an unstable, pale yellow oil with a water solubility of approximately 1 g/dL.[3] This simple lactone compound is volatile. Protoanemonin possess some antibacterial[4] and antifungal[5,6] properties *in vitro*. Anemonin (CAS RN:508-44-1, $C_{10}H_8O_4$) is an inactive crystalline solid with limited water solubility. Drying or boiling of protoanemonin-containing herbs destroys the irritant properties in *Anemone* and *Pulsatilla* species by accelerating the polymerization of protoanemonin.

Poisonous Parts

Protoanemonin occurs in varying concentrations in different species with the highest concentrations (0.5–0.8%) in bulbs from *Ranunculus bulbosus* L. and *Helleborus niger* L. as displayed in Table 106.1.[3,7] Species of *Anemone* and *Pulsatilla* species do not contain clinically significant concentration of photosensitizing furocoumarin compounds. The roots of *Pulsatilla* species contain a variety of oleanane-type glycosides and other triterpene saponins.[8]

Mechanism of Toxicity

Toxicity to this plant usually results from hypersensitivity responses.

DOSE RESPONSE

Allergic responses to this plant depend on individual sensitivity rather than a direct toxic effect.

TOXICOKINETICS

Ranunculin (CAS RN:644-69-9, $C_{11}H_{16}O_8$) is a nonirritating glycoside, which forms protoanemonin by enzymatic hydrolysis after maceration of plant tissue or alkaline hydrolysis. Spontaneous polymerization results in the formation of a nonirritating substance, anemonin. Figure 106.1 displays the structures of protoanemonin, the precursor (ranunculin), and metabolite (anemonin).

CLINICAL RESPONSE

Contact with plants containing protoanemonin causes an irritant contact dermatitis characterized by erythema, edema, vesicles, and postinflammatory hyperpigmentation.[9] A case report associated the development of local erythema and bullae with the application of a compress of pasque flower (*Pulsatilla patens*).[10] The skin eventually healed after sloughing. Ingestion of these plants can cause stomatitis and mucosal ulcerations.

DIAGNOSTIC TESTING

Analytical methods for the separation of protoanemonin include reversed-phase high pressure liquid chromatography.[7,11]

TABLE 106.1. Protoanemonin Content of Ten Species of the Ranuculaceae Family

Genus	Species	Protoanemonin Content (mg/g Wet Weight)
Anemone	*nemorosa* L.	0.33
	trifolia L.	0.17
Clematis	*flammula* L.	0.50
	recta L.	0.01
	vitalba L.	0.15
Helleborus	*foetidus* L.	0.67
	odorus Waldtst et Kit	0.004
	niger L.	5.82
Ranunculus	*bulbosus* L.	7.77
	repens L.	0.13

Source: Adapted from Ref 7.

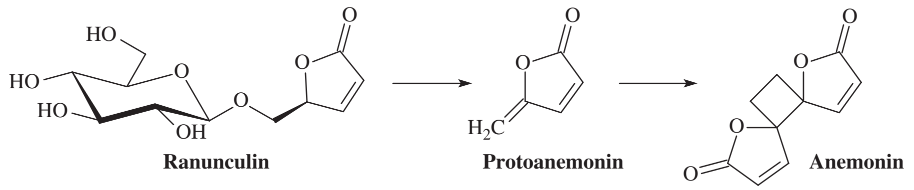

FIGURE 106.1. Protoanemonin formation and degradation.

TREATMENT

Treatment is supportive. The most common toxic effect associated with exposure to protoanemonin-containing plants is an irritant contact dermatitis that responds to wound cleansing and topical steroids (0.05% fluocinonide). Gut decontamination measures are unnecessary.

Chapter 107

COLCHICINE-CONTAINING PLANTS

HISTORY

The toxicity of *Colchicum autumnale* has been recognized for over 2,000 years. Theophrastus of Eresus, a Greek botanist, provided the first written account of the toxicity of extracts from this plant in 370 BC.[1] He described the toxic ingredient as Ephemeron. In 150 BC, Nicander named this substance after Colchis, a district near the Black Sea known for sorcery, and he called this extract "the destructive fire of Colchican Medea." Alexander of Trallis first recommended the use of extracts of *Colchicum autumnale* in 550 AD.[2] Known as Surugen to Arabian physicians and Herbstzeit-lose to European physicians during the Middle Ages, this extract was a common treatment for gout in many parts of the world. However, purified colchicine was not available until John Dorsey isolated colchicine from *Colchicum autumnale* tubers in 1820.

BOTANICAL DESCRIPTION

Misidentification of *colchicum autumnale* as alpine wild garlic (*Allium ursinum* L.) can result in colchicine poisoning. The ingestion of tubers from the glory lily is a common cause of admission to local hospitals for plant poisonings in Sri Lanka.[3]

Common Name: Autumn Crocus, Meadow Saffron, Wild Saffron, Naked Lady, Son-before-the-Father

Scientific Name: *Colchicum autumnale* L.

Family: Liliaceae (lily)

Physical Description: This bulb is cultivated in the United States for its clusters of white or light violet crocus-like flowers that appear in the autumn after the long, lanceolate leaves detach. They are often sold as a curiosity because they bloom without soil or water.

Distribution and Ecology: The autumn crocus is a native plant of Europe that was introduced into the United States. The habitat of this plant includes Oregon, Utah, Kentucky, North Carolina, and parts of the northeastern United States.

Common Name: Glory Lily, Gloriosa, Climbing Lily, Superb Lily, Flame Lily

Scientific Name: *Gloriosa superba* L.

Family: Liliaceae (lily)

Physical Description: This slender plant or vine has a large tuberous root, alternate leaves, and colorful flowers on a long stalk. Occasionally, the tubers of the glory lily have been mistakenly consumed because of their similarity to sweet potatoes (*Ipomoea batatas* (L.) Lam.) and wild garlic (*Allium ursinum* L.).

Distribution and Ecology: The flame or glory lily is a tropical plant native to Asia and Africa that grows outdoors in the southern United States including Florida. In colder regions, cultivation of the plant requires a greenhouse.

EXPOSURE

Colchicine is one of the drugs used for the relief of acute gouty arthritis and currently colchicine is administered for the prophylactic treatment of familial Mediterranean fever. The effectiveness of colchicine for amyloidosis, sarcoid arthritis, primary biliary cirrhosis, Behçet's disease, Paget's disease, pulmonary fibrosis, systemic scleroderma, vasculitis, and liver/biliary cirrhosis remains unproven. In experimental studies, the antimitotic properties of colchicine are useful to evaluate cell division and function. Product formulations of colchicine include 0.5- and 0.6-mg tablets and an injectable solution of 0.5 mg/mL.

PRINCIPAL TOXINS

Physiochemical Properties

Colchicine is a white, crystalline alkaloid extracted from the following two members of the Liliaceae family: autumn crocus (*Colchicum autumnale*) and glory lily (*Gloriosa superba*). Table 107.1 lists some physical properties of colchicine. This substance is soluble in water and alcohol. Figure 107.1 displays the chemical structure of colchicine (CAS RN: 64-86-8, $C_{22}H_{25}NO_6$).

TABLE 107.1. Some Physical Properties of Colchicine

Physical Property	Value
Melting Point	156 °C/~313 °F
pKa Dissociation Constant	1.85
log P (Octanol-Water)	1.3
Water Solubility	4.50E+04 mg/L (25 °C/77 °F)
Vapor Pressure	3.13E–12 mmHg (25 °C/77 °F)
Henry's Law Constant	1.79E–17 atm-m^3/mole (25 °C/77 °F)
Atmospheric OH Rate Constant	3.32E–10 cm^3/molecule-second (25 °C/77 °F)

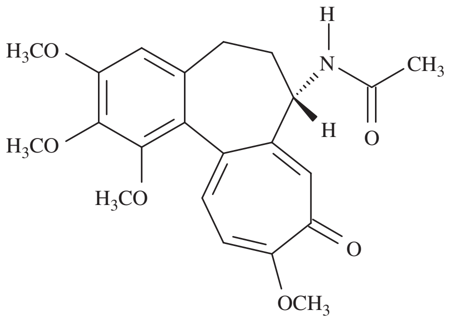

FIGURE 107.1. Chemical structure of colchicine.

Poisonous Parts

Autumn Crocus

Colchicine and related compounds are found throughout the plant, but the highest concentrations occur in the bulb (about 0.8% by weight). The pale purple flowers contain about 0.1–0.6% colchicine by weight.[4]

Glory Lily

All parts of the plant are poisonous. The tubers of the glory lily contain about 0.02–0.3% colchicine by dry weight, depending on season and location.[5] About 10 g fresh tubers contain approximately 6 mg colchicine depending on the variety. In addition to colchicine, the glory lily contains a structurally related toxin known as gloriosine. This compound possesses antimitotic properties similar to those of colchicine.

DOSE RESPONSE

Medicinal Dose

Recommended oral doses of colchicine begin in the range of 0.5–1 mg every 2–3 hours until the symptoms of gout resolve or gastrointestinal symptoms develop. Typically, the intravenous dose of colchicine is about half the oral dose. Single intravenous doses of colchicine should not exceed 2–3 mg with the cumulative intravenous dose over 7 days limited to 4–5 mg.[6] Gastrointestinal symptoms are much less common after intravenous than oral doses.

Toxic Dose

Colchicine

The ingestion of equivalent amounts of autumn crocus (*C. autumnale*) and colchicine tablets produces similar toxicity.[7] In clinical series on colchicine toxicity, survival with supportive care was associated with the ingestion of <0.5 mg colchicine/kg, whereas fatalities occurred when the colchicine dose exceeded 0.8 mg/kg.[8] This series did not include patients who vomited or received decontamination measures within the first 4 hours after ingestion. Case reports of colchicine intoxication associated the ingestion of 0.37 mg/kg and 1.72 mg/kg with survival and death, respectively, in pediatric patients presenting after decontamination measures would be expected to significantly reduce colchicine absorption.[9] Fatal oral doses in healthy adults typically exceed 30–40 mg.[10,11] The ingestion of 20 mg colchicine by a 47-year-old man with gout caused gastroenteritis, dehydration, leukopenia, thrombopenia, mild hepatocellular

injury, and renal dysfunction.[12] He survived without sequelae and all laboratory abnormalities resolved. The intravenous administration of 8–12 mg colchicine may cause death, particularly in patients with hepatorenal dysfunction.[13] A 70-year-old man developed a fatal marrow aplasia and pancytopenia after he received 10 mg of intravenous colchicine over 5 days.[14]

Colchicine-Containing Plants

Clinical features of colchicine toxicity following the ingestion of colchicine-containing plants depend on a variety of factors other than dose including season, plant part, and species. The ingestion of an estimated 40 flowers of *C. autumnale* by a 44-year-old man produced gastrointestinal symptoms without any significant systemic abnormalities.[4] However, the intentional ingestion of approximately 12 *Colchicum autumnale* flowers resulted in hypovolemia, renal failure, adult respiratory distress syndrome, and death in a 16-year-old girl.[15]

TOXICOKINETICS

Analysis of the toxicokinetics of colchicine following massive overdose indicates that the pharmacokinetic parameters of therapeutic and toxic doses are similar.[16]

Absorption

Colchicine undergoes extensive presystemic metabolism, resulting in a bioavailability below 50% of the administered oral dose. The absorption of colchicine from the gastrointestinal tract is rapid with peak plasma concentrations occurring about 1–1.5 hours after administration.[17] Analysis of toxicokinetics data during colchicine poisoning indicates that the ingestion of large amounts of colchicine does not delay gastrointestinal absorption.[16] Case reports of colchicine intoxication suggest that absorption of colchicine through nasal membranes is sufficient to produce serious toxicity.[18]

Distribution

The clearance of colchicine from the blood is rapid and extensive with complete distribution into the body occurring in 3–6 hours.[22] In a study of volunteers administered 0.5–1.5 g colchicine orally, the volume of distribution (V_d) ranged from about 11–15 L/kg.[19] Following the intravenous administration of 0.5 mg colchicine, the average volume of distribution in six healthy males and four elderly female volunteers was 6.7 L/kg and 6.3 L/kg, respectively.[20] The V_d is slightly larger during colchicine intoxication. In a study of 2 patients with colchicine poisoning, the V_d averaged approximately 21 L/kg.[16] Plasma protein binding of colchicine is about 50%.

Biotransformation

Metabolism of colchicine occurs primarily by deacetylation in the liver mediated by the cytochrome P450 isoenzyme, CYP3A4.

Elimination

Clearance of colchicine occurs primarily by hepatic metabolism with renal clearance accounting for about 10–20% of absorbed dose.[17] Renal clearance increases moderately in patients ingesting large doses of colchicine.[16] The enterohepatic circulation is a significant route of excretion with relatively large amounts of both parent drug and metabolites excreted in the bile and intestines. The presence of liver or renal failure reduces the clearance of colchicine. The terminal plasma elimination half-life of colchicine in a series of 5 patients ingesting 8–20 g colchicine ranged from approximately 20–32 hours.[16] The average plasma elimination half-life of colchicine following intravenous administration to six healthy adult males and four elderly females was 30 hours and 34 hours, respectively.[20]

Drug Interactions

Grapefruit juice, erythromycin, cimetidine, and ketoconazole inhibit the cytochrome P450 isoenzyme (CYP3A4) involved with the metabolism of colchicine.[21] The ingestion of large amounts of grapefruit juice by an 8-year-old child on chronic colchicine therapy for familial Mediterranean fever was associated with severe colchicine toxicity.[22]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

The disruption of microtubule function following the ingestion of colchicine results from the binding of colchicine to the protein subunit of microtubules. Colchicine prevents the polymerization of tubulin into microtubules by the reversible, noncovalent binding to tubulin.[23] This antimitotic property disrupts the spindle apparatus that separates chromosomes during metaphase. The most seriously affected organs involve tissues containing cells (e.g., intestinal epithelium, hair follicles, bone marrow) with high metabolic rates. However, the inhibition of cellular division does not account for the

appearance of multiorgan failure during severe colchicine overdoses.[13]

Colchicine produces gastrointestinal dysfunction leading to significant water loss and sequestration of fluid. The probable mechanism of toxicity is neurogenic rather than direct irritation. In experimental studies, colchicine has no direct stimulant action on isolated segments of the small bowel, and atropine abolishes the diarrhea associated with experimentally induced colchicine toxicity.[24] Although depressed myocardial function occurs in patients with normal right-sided filling pressures, hypotension probably results from hypovolemia.[25] Experimental studies indicate that colchicine produces muscle weakness and direct toxic effects on skeletal muscle.[26] Direct myocardial toxic effects are less well documented.

Postmortem Examination

Postmortem findings after fatal colchicine poisoning typically demonstrate multiorgan failure characterized by hemorrhagic pulmonary edema, cerebral edema, centrilobular fatty necrosis of the liver, blunting and shortening of the intestinal villi, petechial bleeding in the fatty tissues, hypocellular bone marrow, and necrosis of the proximal convoluted tubules of the kidney.[27–29] In a patient who died 33 hours after ingesting colchicine, the pathological examination demonstrated a bilateral bronchopneumonia with marked hypocellularity of the bone marrow and decreased megakaryocytes and myeloid cells.[30] Histological examination confirmed the presence of numerous mitotic figures in the metaphase of cells from the gastrointestinal epithelia. Typically, tissues with rapidly regenerating epithelium (e.g., gastrointestinal mucosa, testes, urinary tract) contain numerous blocked mitoses.[31] Other histological findings include diffuse sloughing of the surface epithelium of the colon, collapse of the crypt cells of Lieberkühn, extensive autolysis of the stomach and small intestine, and disruption of the sinusoidal architecture of the red pulp in the spleen. Tissue from the heart, skeletal muscle, and nervous system frequently are normal.[32] In some cases of acute colchicine intoxication involving multisystemic failure, focal areas of contraction band necrosis and pale, anuclear myocytes appear consistent with ischemia. Cardiac changes may occur in the absence of coronary artery disease.[33] Clumps of chromatin (i.e., "colchicine bodies") in nuclei of hepatocytes may occur in pathological specimens,[29] but these changes are not invariably present.

CLINICAL RESPONSE

Adverse effects associated with the therapeutic use of colchicine include gastrointestinal irritation, bone marrow depression with aplastic anemia, thrombocytopenia, alopecia, peripheral neuropathy, myopathy, and rhabdomyolysis, particularly in patients with renal dysfunction.[34] Colchicine is a potent gastrointestinal toxin that causes intractable multiorgan failure following the absorption of large doses.[35] The clinical features of colchicine toxicity appear in three stages depending on the severity of the ingestion.[13] Similar toxic effects also result from the consumption of parts from the autumn crocus and tubers from glory lily (*Gloriosa superba*); however, the severity of these reactions are usually less prominent than toxicity secondary to colchicine tablets because of the large volume of plant material needed to cause a serious toxic response. The ingestion of crude extract of tubers from *Gloriosa superba* with suicidal intent produced burning sensation in the GI tract, nausea, vomiting, diarrhea, abdominal pain, and sinus bradycardia.[36]

Gastrointestinal Phase (Phase I)

The presence of gastrointestinal symptoms is a sensitive, but not specific, sign of serious colchicine poisoning.[10] Almost all seriously poisoned patients develop signs of gastrointestinal distress (nausea, vomiting, anorexia, diarrhea, cramping abdominal pain), usually within 2–6 hours after ingestion. Occasionally, the emesis or diarrhea may be bloody. Volume depletion, electrolyte imbalance, and hypotension may occur during this period. During this stage, a peripheral leukocytosis frequently occurs characterized by numerous immature myeloid cells, damaged cells with karyorrhexis, and unsegmented granulocytes (Pelger-Huet cells).[8]

Multisystem Failure (Phase II)

Life-threatening complications often develop 24–72 hours after ingestion. Respiratory insufficiency may develop from multiorgan failure, liver dysfunction, pancreatitis, sepsis, hypovolemia, muscle weakness or adult respiratory distress syndrome (ARDS).[37,38] Muscle weakness may last several weeks and contribute to ventilatory depression. Sepsis is a well-recognized and common fatal complication of severe colchicine overdose. Intestinal ileus commonly develops during phase II of severe colchicine intoxication, and gastrointestinal dysfunction may persist for one week. Figure 107.2 demonstrates the time course in days of multiorgan failure developing after a patient ingested *Autumn crocus*.

Cardiovascular System

Sudden cardiac arrest resulting from asystole or ventricular dysrhythmias has occurred between 36 and 54

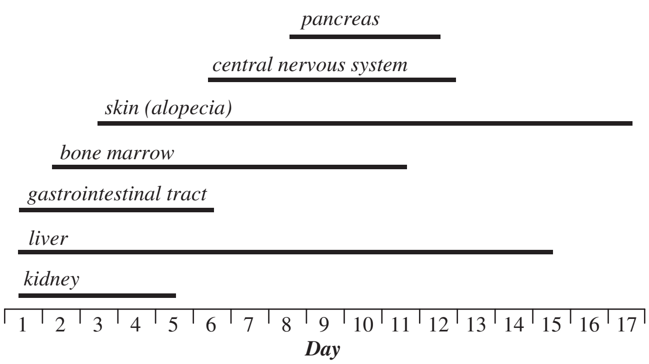

FIGURE 107.2. Time course of colchicine poisoning in a patient, who developed multiorgan failure after autumn crocus ingestion. From Gabrscek L, et al. Accidental poisoning with *Autumn crocus*. J Toxicol Clin Toxicol 2004;42:86. Copyright Taylor and Francis Ltd. Reproduced with permission.

hours after ingestion despite adequate oxygenation and fluid/electrolyte replacement.[13,39] Most deaths result from cardiogenic shock within the first 72 hours. Patients with hemodynamic features of cardiogenic shock (decreased cardiac index, increased systemic vascular resistance despite adequate filling pressures) have a poor prognosis.[25]

Central Nervous System

Confusion and delirium usually results from poor cerebral perfusion rather than direct central nervous system toxicity.[40] Papilledema, coma, seizures, and cerebral edema may occur during severe colchicine intoxication.[41] Case reports associate the development of peripheral neuropathy (i.e., loss of deep tendon reflexes and ascending paralysis) with severe colchicine toxicity.[42] The ingestion of *Gloriosa* tubers was associated with an ascending polyneuropathy characterized by stocking-glove anesthesia, weakness, and loss of deep tendon reflexes that resolved after 4 weeks.[43]

Kidney

Oliguric renal failure is a common complication of severe colchicine intoxication.[44] Dysuria, hematuria, and proteinuria are common; however, renal dysfunction is probably secondary to hypoxia, hypotension, and myoglobinuria. The contribution of direct colchicine toxicity to renal failure is unclear, but severe renal dysfunction is usually a terminal event rather than a prominent part of most fatal overdose cases.

Blood

Severe leukopenia and thrombocytopenia are common during the second phase of severe colchicine intoxication. The lack of bone marrow suppression suggests mild toxicity. Peak bone marrow suppression occurs between the fourth and seventh day after ingestion. Case reports document the development of a consumptive coagulopathy with elevated fibrin degradation products, decreased fibrinogen, and prolonged coagulation profiles.[45,46] Heinz body hemolytic anemias develop rarely after acute ingestions of colchicine.[47]

Recovery Phase (Phase III)

If the patient survives, most organ systems show definite signs of improvement by the 10th day. A rebound leukocytosis often occurs during this phase. Alopecia begins about the 12th day, reaching completion by 3 weeks after ingestion.[7,43] Replacement hair growth begins after the first month. Case reports suggest that complete recovery from acute complications of colchicine poisoning often occurs after a convalescent period of several months to a year, but a neuropathy, muscle weakness, and intermittent hair loss can persist a few years after ingestion.[37,48] Fever may be a persistent part of the clinical picture for the first several weeks, but the body temperature rarely exceeds 39 °C/~102 °F. Myopathy can occur about 3 months after ingestion along with elevation of serum creatine kinase concentrations.

DIAGNOSTIC TESTING

Analytical Methods

Sensitive and specific methods for the detection of colchicine in biological fluids include high performance liquid chromatography with diode array detector (HPLC/DAD),[49] HPLC coupled to ion spray mass spectrometry,[50] and HPLC combined with electrospray ionization/tandem mass spectrometry,[51,52] The limits of detection and quantitation for the latter method are approximately 0.1 ng/mL and 0.5 ng/mL, respectively, whereas the limit of quantitation for HPLC/DAD is about 4 ng/mL.

Biomarkers

Therapeutic

Following therapeutic doses of colchicine, the plasma colchicine concentrations are relatively low (<10 ng/mL), depending on the duration and time after ingestion.[20] Typical therapeutic concentrations of *plasma* colchicine are <2.4 ng/L and <13 ng/mL following the daily administration of 1 mg and 3 mg colchicine, respectively.[53] Fifteen minutes after the intravenous administration of 2 mg colchicine to 16 volunteers, the *plasma*

colchicine concentration averaged 11.4 µg/L with a range of 4.5–33 µg/L.[54]

Overdose

Serum colchicine concentrations document exposure to *Colchicum autumnale* or colchicine medication, but there are few clinical data on the prognostic value of these biomarkers. Concentrations of colchicine in the blood decline rapidly, and multiorgan failure during severe colchicine intoxication occurs after peak colchicine concentrations. In a *serum* sample drawn from a hypotensive, comatose patient 24 hours after the ingestion of a large amount of colchicine, the colchicine concentration was 4.5 ng/mL.[55] The patient died on the second day of hospitalization. Another patient died 2 days after mistakenly ingesting *Colchicum autumnale* following the development of hypotension, disseminated intravascular coagulation, and asystolic cardiac arrest. The serum colchicine concentration of the second day after ingestion was 9 ng/mL.[56] In a patient, who survived after developing multiorgan failure, the serum colchicine concentration 48 hours following the ingestion of *Autumn crocus* was 70 ng/mL.[48] Two days later colchicine was not detectable in the serum.

In a case report on the ingestion of flowers from *C. autumnale* that produced only gastrointestinal symptoms, the *plasma* colchicine concentration 6 hours after ingestion was 3.8 ng/mL as measured by HPLC coupled to ion spray mass spectrometry.[4] The peak *plasma* colchicine concentration was 4.34 ng/mL at 13 hours after ingestion, whereas the maximum colchicine concentration in erythrocytes was 5.43 ng/mL at 16 hours postingestion. After an intentional multiple-drug overdose that included 7.5 g of colchicine, the blood colchicine level 6 hours and 24 hours after ingestion was 21 ng/mL and <5 ng/mL, respectively.[57]

Postmortem

Postmortem colchicine blood concentrations do not correlate to the clinical severity or the amount ingested because of the rapid distribution of colchicine from the blood and the extended length of time between ingestion and death.[58] Frequently, the colchicine concentrations are nondetectable in postmortem samples from fatal colchicine intoxications depending on the time between absorption, the time of death, and medical interventions.[32] Two hours after ingesting an estimated 18–21 g colchicine, the colchicine concentration in blood samples from a 39-year-old woman was 250 µg/L. She died 40 hours after ingestion and her postmortem blood samples did not contain detectable concentrations of colchicine.[59] A 45-year-old man died in the hospital 3–4 days after ingesting colchicine.[30] Colchicine was detectable in blood as measured by HPLC with photodiode array detection, but not in postmortem samples from liver, stomach contents, or vitreous humor (limit of detection <5 µg/L). A postmortem bile sample contained 4,200 µg colchicine/L. An antemortem plasma sample collected 30 hours before death contained 60 µg colchicine/L, but subsequent antemortem samples did not contain detectable concentrations of colchicine. The postmortem peripheral and heart blood from a 57-year-old man found dead contained 21.9 ng colchicine/mL and 22.8 ng colchicine/mL, respectively, whereas similar samples from a 33-year-old nurse contained 17.4 ng colchicine/mL and 5.2 ng colchicine/mL, respectively.[52] The latter patient died after 61 hours of intensive care following the ingestion of 80 mg colchicine. Postmortem vitreous humor samples contained much lower (e.g., 0.5 ng/mL and 3 ng/mL, respectively) colchicine concentrations than postmortem blood.

The extensive distribution of colchicine into cells suggests that colchicine concentration may be higher in whole blood than in plasma. Compared with other tissue samples, bile may contain high concentrations of colchicine because of the extensive hepatobiliary recirculation of colchicine.[60] Analysis of postmortem blood samples from a 44-year-old man, who died of multiorgan failure 2 days after ingesting a meal containing leaves from *Colchicum autumnale*, did not detect colchicine as measured by HPLC with UV-detection.[27] Postmortem samples from the bile contained 7.5 µg colchicine/mL.

Abnormalities

Transient elevation of serum hepatic aminotransferase concentrations may occur, but fulminant hepatic failure is not a common occurrence.[36] Electrolyte abnormalities during the various stages of colchicine poisoning include hypocalcemia, hypophosphatemia, hyponatremia, hypomagnesemia, mild hyperamylasemia, hyperbilirubinemia, elevated hepatic aminotransferases, hypokalemia thrombocytopenia, and leukopenia.[42,45] Metabolic acidosis usually occurs as a result of lactate accumulation secondary to hypovolemia or shock. Rhabdomyolysis and myoglobinuria occur during acute colchicine poisoning as a result of direct muscle damage associated with dramatic increases in muscle enzymes and myoglobinuria.[42] The presence of rhabdomyolysis may contribute to the metabolic acidosis and electrolyte abnormalities. Rising serum cardiac troponin I concentrations indicate the myocardial injury and the potential to develop cardiogenic shock.[33] Urinary abnormalities include hematuria, proteinuria, myoglobinuria, and oliguria during severe toxicity.[61] The ECG may demonstrate signs of

myocardial injury (e.g., ST elevation in limb and precordial leads) with both creatine kinase and initial MB isoenzyme fractions increased.[45,61]

TREATMENT

Stabilization

Initially, hypotension represents the most serious risk. An intravenous line with fluid replacement (normal saline or Ringer's lactate) should be established, and then vasopressors given if the hypotension does not respond to fluid challenges. All patients should receive cardiac and pulse oximeter monitoring in an intensive care unit. Hemodynamic monitoring is often required in seriously ill patients. Respiratory dysfunction is usually secondary to the adult respiratory distress syndrome, which commonly presents between 24 and 36 hours after ingestion.

Decontamination

All symptomatic patients should be medically evaluated. The usual measures of decontamination (lavage, charcoal) are often unnecessary because of the severe gastrointestinal symptoms associated with colchicine intoxication and the delay in seeking medical care. Decontamination measures (e.g., activate charcoal) are a therapeutic option even beyond the usual 1–2 hours postingestion in colchicine plant ingestions, but there are no clinical data to confirm the efficacy of these measures. A postmortem examination 30 hours after a glory lily flower ingestion revealed 196 mg of colchicine in the victim's stomach.[15] Because colchicine is a potent poison, children who ingest more than one tablet (0.5 mg) and present < 2 hours often ingestion should receive decontamination measures. Plant toxicity is more difficult to predict, but decontamination measures should also be used in all patients except those who ingest small amounts during exploratory activity. Intravenous fluids and electrolytes must be given to maintain adequate peripheral perfusion. The use of cathartics is not necessary because of spontaneous diarrhea.

Elimination Enhancement

Serial activated charcoal (0.5 g/kg every 3–4 hours) is a therapeutic option because of the enterohepatic circulation of colchicine, but there are inadequate human data to evaluate the efficacy of serial-activated charcoal for colchicine intoxication. Paralytic ileus may complicate the use of serial-activated charcoal therapy. Duodenal drainage is also an alternative method of reducing the enterohepatic circulation of colchicine, but there are no data to document the efficacy of this method. There is no evidence that hemoperfusion or hemodialysis increases elimination of colchicine, especially in view of its large volume of distribution and limited renal excretion.

Antidotes

No effective antidotes are available. A case report suggests that the administration of experimental goat-derived, colchicine-specific Fab fragments may reverse serious colchicine poisoning,[62] but these antibodies are not commercially available. In this case report, the use of Fab fragments did not prevent transient bone marrow suppression.

Supplemental Care

Hemodynamic Status

Symptomatic patients (e.g., those with nausea, vomiting, diarrhea, dyspnea) require hospitalization for fluid replacement and medical observation in a monitored setting. Fluid administration often requires hemodynamic monitoring to replace losses accurately in the setting of cardiogenic shock. The hemodynamic response to fluid administration has prognostic value because intoxicated patients with cardiogenic shock (low cardiac index, high systemic vascular resistance) despite adequate filling pressures have a poor prognosis.[24] Close monitoring of oxygen saturation is important because the presence of increasing hypoxemia suggests the onset of adult respiratory distress syndrome. Most fatalities occur within the first 24–72 hours.

Laboratory Monitoring

Daily complete blood counts are important to detect either hemolytic anemia or upper gastrointestinal hemorrhages. Transfusions of both platelet packs and packed red blood cells may be needed. A consumptive coagulopathy may appear within the first several days. Treatment with fresh-frozen plasma is usually reserved for patients with active bleeding rather than prophylactic use because of the interference of activated factors with the prothrombin time and the lack of data on the effect of this treatment on clinical outcome. The use of vitamin K_1 is a therapeutic option, but the effect of prophylactic vitamin K_1 on outcome has not been defined. The prothrombin time, partial thromboplastin time, and platelet count should be monitored daily for the first several days and then as indicated. Fibrinogen and fibrin split product levels should also be obtained if a consumptive coagulopathy is suspected.

Frequent (twice daily) monitoring of electrolytes (e.g., sodium, potassium, calcium, phosphorus) is necessary during the first several days. Electrolyte abnormalities may persist for one week. Hypoglycemia, myoglobinuria, and creatine kinase levels also should be monitored. The presence of myoglobinuria indicates the need for generous fluid replacement to maintain good urine output (1–2 mL/kg/h) along with furosemide as need to maintain adequate urine flow. The use of urinary alkalinization is a therapeutic option, but the efficacy of this treatment is not well documented.

Sepsis

Sepsis may complicate the clinical course, especially during the nadir of bone marrow suppression between the fourth and seventh days. Patients who have fever and/or hemodynamic instability should have blood cultures and broad-spectrum antibiotic coverage if sepsis is suspected. Granulocyte transfusions are usually unnecessary because of the short period of leukocytopenia. Granulocyte colony-stimulating factor is an option to granulocyte transfusions during severe colchicine intoxications.[63,64] Fever is not a specific sign of infection because colchicine intoxication produces elevated temperatures. Hypothermia is a poor prognostic sign and should be treated with the usual passive rewarming measures.

Chapter 108

DAFFODILS and OTHER EMETIC BULBS

HISTORY

These bulbs are native species of Western Europe. The Romans brought daffodils to Britain for medicinal purposes. However, now the bulb is widely cultivated as an ornamental plant.

BOTANICAL DESCRIPTION

The Amaryllidaceae family contains approximately 725 species of perennial bulbs that are native to tropical and subtropical regions in Europe, South American Andes, and southern Africa.

Common Name: Daffodil, Wild Daffodil

Scientific Name: *Narcissus pseudonarcissus* L.

Botanical Family: Amaryllidaceae (amaryllis)

Physical Description: Narcissus plants are usually similar to lilies and onions with numerous narrow leaves and a single flowering stalk arising from a true bulb. The flowers appear in early spring with petals that form a prominent tubular "corona" in the center.

Distribution and Ecology: Daffodils are native plants of Western Europe, United Kingdom, Iraq, and Turkey. They grow in moist areas of lightly shaded woodlands.

EXPOSURE

Galanthamine occurs in several members of the Amaryllidaceae (*Leucojum* spp., *Narcissus* species, *Galanthus* spp.). In Eastern European countries (e.g., Bulgaria), this compound was used in the treatment of poliomyelitis; recently, galanthamine was introduced into Western markets as a treatment for Alzheimer's disease.[1]

PRINCIPAL TOXINS

Physiochemical Properties

The daffodil bulb contains the heat-stable, gastrointestinal irritant alkaloid lycoramine as well as lesser amounts of narcissamine and galanthamine.[2] Galanthamine (galantamine, CAS RN: 357-70-0) is a specific, competitive, and reversible acetylcholinesterase inhibitor that is approved for the treatment of Alzheimer's disease along with the synthetic drug, galantamine hydrobromide (CAS RN: 69353-21-5). Figure 108.1 displays the chemical structure of galanthamine. Lycorine-type alkaloids (e.g., 1-*O*-acetyllycorine) from the Amaryllidaceae family exhibit greater acetylcholinesterase inhibitor than galanthamine.[3] There are few data on the contribution of this alkaloid to the gastrointestinal toxicity associated with the ingestion of daffodil

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

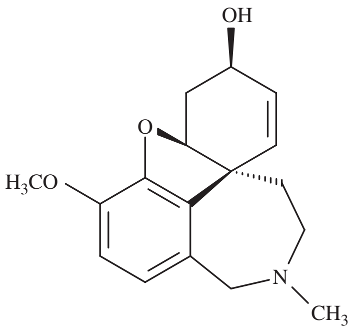

FIGURE 108.1. Chemical structure of galanthamine (galantamine).

bulbs. The sap from *Narcissus* bulbs and hollow stems contain large amounts of calcium oxalate crystals.[4] These crystals are water insoluble. California species of buttercup (*Ranunculus*) contain irritant oils (e.g., protoanemonine), which are mild gastrointestinal irritants. Hydrolysis of the glycoside ranunculin produces protoanemonin.

Poisonous Parts

Narcissus pseudonarcissus contains at least seven major alkaloids including hemanthamine, galanthamine, galanthine, narcissamine, masonin, homolycorine, lycoramine, pseudolycorine, and lycorine. Lesser amounts of lycoramine occur in the stems, leaves, and flowers of *Narcissus* cultivars. Galanthamine is widespread within species of the Amaryllidaceae family with galanthamine content typically averaging from trace to 0.5% dry weight. Some *Narcissus* species (e.g., *N. confusus* Pugsley) contain high concentrations of galanthamine exceeding 1.2% (dry weight) with the highest concentrations occurring in the emerging bulb.[5] The concentration of galanthamine varies with different *Narcissus* cultivars with the concentration typically <1–2.5%.[6] In an Egyptian species of *Ranunculus* (*R. sceleratus* L.), the protoanemonin and ranunculin content was approximately 0.25% and 0.67%, respectively, after steam distillation.[7] There are few data on the alkaloids responsible for the irritant and toxic effects of daffodil bulbs.[8]

DOSE RESPONSE

Galanthamine and the synthetic drug, galantamine hydrobromide are used to treat Alzheimer's disease with maximum daily doses of galantamine ranging up to 24–32 mg.[9] Galanthamine was first isolated from snow drop (*Galanthus* spp.), but today other sources for the production of galanthamine include *Narcissus* species, *Leucojum* species, and chemical synthesis.[1]

MECHANISM OF TOXICITY

In animal models, galanthamine is a powerful gastrointestinal irritant and central nervous system (CNS) stimulant that can cause death after large doses.[2] Galanthamine is a reversible, competitive inhibitor of acetylcholinesterase and an allosteric modulator of nicotinic receptors.[10] This compound increases the sensitivity of the nicotinic receptors, facilitating both excitatory and inhibitory transmissions in human brain tissue.[11]

TOXICOKINETICS

The gastrointestinal absorption of galanthamine is high with a bioavailability of about 90%. Galanthamine has a relatively large (i.e., about 2.5 L/kg) volume of distribution and low protein binding (i.e., 15–20%).[12] Biotransformation of galantamine occurs primarily via the cytochrome P450 isoenzymes (i.e., CYP2D6, CYP3A4) to inactive *O*-desmethyl galantamine and galantamine *N*-oxide metabolites.[13] Inhibitors of CYP2D6 (e.g., paroxetine) and CYP3A4 (ketoconazole, erythromycin) increase the bioavailability of galantamine.

CLINICAL RESPONSE

Daffodils

Ingestion of daffodil bulbs produces the rapid onset of gastroenteritis (nausea, vomiting, abdominal pain, diarrhea, lightheadedness) that usually resolves within several hours depending on the amount ingested.[14] Profuse vomiting and diarrhea developed in a family following the consumption of a soup prepared from jonquil (*Narcissus jonquilla* L.) leaves.[2] The gastrointestinal symptoms resolved after approximately 24 hours. In contrast to the cardiovascular and neurological effects present in experimental animals administered large quantities of *Narcissus* bulbs, cardiovascular and neurological toxicity are uncommon in these human case reports.

Occupational exposure of bulb handlers to daffodil bulbs is a common cause of a rash called "daffodil itch."[15] This rash is primarily an irritant contact dermatitis that affects areas of the skin (hands, wrists) in direct contact with the sap during picking.[16] Allergic responses to daffodils occur rarely. Typically, pruritus is localized to the tips of the fingers, first dorsal web space, and the periungual region (i.e., paronychia). Lesions also occur on the sides of the fingers, the hands, and the forearms. Occasionally, lesions involve the face, neck or genitals as a result of contact with contaminated gloves or hands. Erythema, edema, painful fissures, and a dry, hyperkeratotic dermatitis may develop. Skin lesions sometimes

appear on distant sites, such as the neck, abdominal wall, face, and genital region. Rarely, delayed asthmatic symptoms (cough, dyspnea) may occur within 48 hours after exposure to daffodil bulbs.[17]

Other Bulbs

The ingestion of other bulbs (amaryllis, hyacinth, buttercup) may produce a self-limited gastroenteritis, but there are limited data on the toxic effects of these bulbs in humans. Ingestion of plants from *Iris* species may cause mucosal irritation as well as gastrointestinal symptoms; the clinical course of these symptoms is also mild and self-limited. Illness resulted from the prolonged use of bulbs as food sources during World War II in Holland.[18] Native *Anemone* species also produce mild gastrointestinal irritation similar to the effects following consumption of bulbs from *Ranunculus* species. The South African bulb, *Boophane disticha* (L.f.) Herb. contains buphanine, which produces an anticholinergic syndrome similar to scopolamine characterized by hallucination, agitation, and altered mental status.[19]

DIAGNOSTIC TESTING

Methods to quantitate the concentration of galanthamine in plasma include high performance liquid chromatography with UV detection[20] and liquid chromatography/tandem mass spectrometry.[21] The blood to plasma ratio of galantamine averages about 1.2. Following administration of daily doses of 32 mg galantamine to healthy volunteers, the mean steady state galantamine concentration in plasma samples drawn with 10 hours of administration was approximately 115–125 μg/L.[13]

TREATMENT

Treatment of the gastrointestinal complications following the ingestion of daffodil bulbs is supportive. Fluid and electrolyte imbalance represents the most serious toxic effect in those patients experiencing protracted vomiting or diarrhea. Decontamination measures are not usually necessary because of the protracted vomiting associated with substantial ingestions.

Chapter 109

DEATH CAMAS

HISTORY

Early settlers, Native Americans, and explorers of the western United States and Canada were familiar with the toxicity of death camas. Diaries from the Lewis and Clark Expedition documented the presence of a poisonous bulb growing on hillsides of the upper Missouri River plains that probably was from the Melanthiaceae family.[1] Consequently, members of the Expedition were required to buy roots from local Indians rather than dig roots by themselves when adequate food was unavailable. Indians of Northern California recognized the toxicity of death camas bulbs, and several fatalities were associated with the use of this bulb by these Indians during the late 19th century.[1] Similar edible species (e.g., common camas, sego lily) were important staples for Pacific Northwest Indians and early settlers.

BOTANICAL DESCRIPTION

There are approximately 15 species of death camas in the United States; however, the taxonomy of death camas remains unsettled. These bulbs are listed in several genera including *Zigadenus, Toxicoscordion, Stenanthium*, and *Anticlea*. Most authorities list these genera under the Melanthiaceae family and sometimes under the Liliaceae family. Table 109.1 lists common species of death camas and associated synonyms.

These perennial herbs have tall, narrow leaves that are clustered mostly at the base of a thick horizontal rootstock. Yellow or whitish green flowers form during the spring along the top of a central stalk depending on the species. These bulbs are distinguished from wild onion by the lack of the characteristic onion odor. Most species are found in moist grassy meadows in the western United States, but these species also occur in foothills, mountains, and deserts. Toxicity usually occurs when these bulbs are misidentified as edible wild onion or Sego lily.

Common Name: Foothill death camas, Sand-corn, Deadly Zigadenus, Meadow death camas

Scientific Name: *Toxicoscordion paniculatum* (Nutt.) Rydb.

Botanical Family: Melanthiaceae

Physical Description: This glabrous perennial herb arises from an onion-like bulb with a simple stem reaching 30–50 cm (~12–20 in.) in height. The mostly basal, linear leaves are tapered at the ends. Clusters of white to cream-colored flowers develop on a panicle up to 10–30 cm (~4–12 in.) long. The fruits are capsules about 1.4–1.8 cm (~0.5–0.8 in.) long.

Distribution and Ecology: This species inhabits moist grassy meadows in the western United States including Utah, New Mexico, Colorado, Nevada, and California.

EXPOSURE

There are no commercial uses for death camas because of the toxicity associated with ingestion of plant parts.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

Zigadenus glaberrimus Michx.		Sandbog death camas,
Toxicoscordion gramineum (Rydb.) Rydb.	*Zigadenus acutus* Rydb., *Zigadenus falcatus* Rydb., *Zigadenus gramineus* Rydb, *Zigadenus intermedius* Rydb.	Grassy death camas, death camas
Toxicoscordion micranthum (Eastw.) A. Heller	*Zigadenus micranthus* Eastw.	Smallflower death camas
Zigadenus mogollonensis W.J. Hess & R.C. Sivinski		Mogoll death camas
Toxicoscordion nuttallii (A. Gray) Rydb.	*Zigadenus nuttallii* (A. Gray) S. Watson	Nuttall death camas, poison camas, poison sego, death camas
Toxicoscordion paniculatum (Nutt.) Rydb.	*Zigadenus paniculatus* (Nutt.) S. Watson	Foothill death camas, sand-corn, deadly zigadenus, meadow death camas
Zigadenus vaginatus (Rydb.) J.F. Macbr.		Sheathed death camas
Toxicoscordion venenosum (S. Watson)	*Zigadenus venenosus* S. Watson	Elegant death camas, grassy death camas, meadow death camas, Watson's death camas
Zigadenus virescens (Kunth) J.F. Macbr.	*Anticlea virescens* (Kunth) Rydb.	Green death camas
Zigadenus volcanicus Benth.	*Anticlea virescens* (Kunth) Rydb.	Lava death camas

Intoxication usually results from misidentification of these plants as similar edible plants, such as common camas [*Camassia quamash* (Pursh) Greene] or the sego lily (*Calochortus nuttallii* Torr. & Gray).

PRINCIPAL TOXINS

Physiochemical Properties

Death camas contain veratrum-like steroidal alkaloids that produce hypotension, bradycardia, and respiratory depression in experimental animals.[2] Major ester alkaloids include veratroyl zygadenine, and vanilloyl zygadenine, and neogermitrine.[3] The bitter taste of these bulbs discourages consumption.

Poisonous Parts

Although all parts of the plant contain veratrum-like alkaloids, toxicity usually results from ingestion of the bulb and, less often the flowers.[4]

Mechanism of Toxicity

The primary effects of these veratrum-like alkaloids are hypotension, bradycardia, gastrointestinal distress, and central nervous system (CNS) depression. Hypotension results from peripheral vasodilation from reduced α-adrenergic activity rather than bradycardia, and changes in blood pressure are not related to the heart rate.[2,5]

DOSE RESPONSE

The typical bulb weighs approximately 10–15 g.[1] The ingestion of 1–2 bulbs by adults produces gastrointestinal distress and bradycardia.[4] Although the ingestion of death camas bulbs is potentially lethal, there are no well-documented fatalities in the modern medical literature. The ingestion of large numbers of bulbs (e.g., four to five) by a young child and of much larger doses by adults probably is necessary to cause serious intoxication.[1]

TOXICOKINETICS

There are few data on the toxicokinetics of the veratrum-like alkaloids present in the these species. The rapid onset of symptoms suggests that these alkaloids are easily absorbed from the gastrointestinal tract.[4]

CLINICAL RESPONSE

The classical presentation following the ingestion of bulbs or other parts of these plants includes profound gastrointestinal distress (nausea, vomiting, diarrhea, abdominal pain), bradycardia, and hypotension.[6,7] Other symptoms include paresthesias, ataxia, gait disturbances, muscle fasciculations, mydriasis, and obtundation.[8] Gastrointestinal symptoms typically begin within 1 hour of ingestion, and resolve within 4–24 hours. Although sinus bradycardia is common, serious dysrhythmias do not usually occur. Fatalities following the ingestion of death camas are not well documented in the medical literature.

DIAGNOSTIC TESTING

Laboratory abnormalities are usually absent during intoxication from these plants.

TREATMENT

Treatment is supportive. Decontamination measures are usually unnecessary because of the early onset of severe gastrointestinal symptoms. There are no clinical data to document the efficacy of the administration of activated charcoal within 1 hour after ingestion. Hypotension usually responds to intravenous fluids. If hypotension persists despite fluid therapy and signs of inadequate perfusion appear, vasoconstrictive agents (dopamine, norepinephrine) may be necessary. The administration of atropine usually improves the heart rate, but often the increased heart rate is not associated with increases in blood pressure.[6] Patients with vital sign abnormalities or CNS depression should be observed for at least 12 to 24 hours.

Chapter 110

KAFFIR LILY
[*Clivia miniata* (Lindley) Bosse]

HISTORY

The Kaffir lily is a native species of South Africa that was imported into England from Kwazulu-Natal during the 1800s. During Victorian times, this beautiful plant was a popular indoor plant in England and Europe.

BOTANICAL DESCRIPTION

Common Name: Kaffir lily, Bush Lily, Umayime (Zulu), Boslelie (Afrikaans)

Scientific Name: *Clivia miniata* (Lindley) Bosse

Botanical Family: Amaryllidaceae

Physical Description: This perennial plant forms clumps of dark green, shiny elongated leaves that originate from a fleshy underground stem. Brilliant orange, trumpet-shaped flowers appear in spring and occasionally at other times of the year with a sweet smell. The fruit is a red berry. The plant reaches up to 45 cm (~18 in.) in height.

Distribution and Ecology: The Kaffir lily is an indigenous plant of South Africa. This plant prefers partial shade or deep shade in rich soil of the forest floor or between boulders on slopes.

EXPOSURE

In South Africa, traditional herbal uses of this plant include initiation of parturition, fever, and treatment of snake bites. Additionally, extracts of the Kaffir lily are used as oxytocic agents in South African traditional herbal medicine.

PRINCIPAL TOXINS

Physiochemical Properties

5-Hydroxymethyl-2-furancarboxaldehyde is a component of this extract that has cholinergic agonist properties.[1] *In vitro* studies indicate that the extract of the Kaffir lily has uterotonic activity.[2] Table 110.1 lists some physical properties of lycorine, which is the major alkaloid in this plant.

Poisonous Parts

Alkaloids isolated from the Kaffir lily are primarily derivatives of the 2-benzopyrano(3,4-g) indole nucleus. The major alkaloid in the Kaffir lily is lycorine (CAS RN: 476-28-8, $C_{16}H_{17}NO_4$). Figure 110.1 displays the chemical structure of lycorine. Following ethanol extraction and ion exchange chromatography, leave samples of *Clivia miniata* contained lycorine concentrations of approximately 0.043% by wet weight.[3] Other components in extracts of the Kaffir lily include clivonine (CAS RN: 477-16-7, C_{17}-H_{19}-N-O_5,), clivatine (CAS RN: 1355-66-4, C_{21}-H_{25}-N-O_7), linoleic acid and 5-hydroxymethyl-2-furancarboxaldehyde.

Mechanism of Toxicity

The mechanism of action of lycorine has not been determined.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

TABLE 110.1. Some Physical Properties of Lycorine

Physical Property	Value
Melting Point	280 °C/535 °F
log P (Octanol-Water)	0.930
Atmospheric OH Rate Constant	2.03E-10 cm^3/molecule-second (25 °C/77 °F)

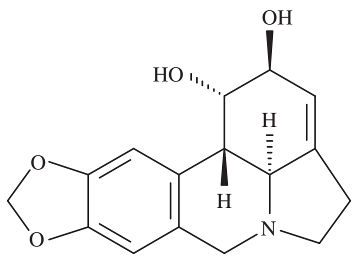

FIGURE 110.1. Chemical structure of lycorine.

DOSE RESPONSE

There are few data on the mechanism of toxicity associated with the gastrointestinal distress that occurs following the ingestion of this plant.

TOXICOKINETICS

There are inadequate data on the toxicokinetics of lycorine to determine the absorption, distribution, or elimination of this compound in humans.

CLINICAL RESPONSE

There are few clinical data on the effects of ingesting parts of the Kaffir lily. Based on the presence of lycorine in the bulbs, the most likely clinical effects following ingestion are minor gastrointestinal symptoms (e.g., nausea, vomiting, diarrhea).

DIAGNOSTIC TESTING

Previously published methods to identify active components of extracts of the Kaffir lily include spectrophotometry and ion exchange chromatography.[1]

TREATMENT

Treatment is supportive. Because gastrointestinal irritation is the major effect of ingestion of these bulbs, the patient should be evaluated for fluid and electrolyte balance as indicated by the clinical presentation. However, the clinical effects of exposure to the Kaffir lily are usually minimal, and only observation frequently is required. Decontamination measures are unnecessary because of the vomiting associated with more severe cases of poisoning by these bulbs.

Chapter 111

SNOWDROP
(*Galanthus nivalis* L.)

HISTORY

Snowdrop (*Galanthus nivalis* L.) has been used as a treatment for pain and neurological disorders since ancient Greek times.[1] In the epic poem, the Odyssey, Homer describes the plant, "moly," which was given to Odysseus by the god Hermes as an antidote to the potions of the enchantress, Circe. Plaitakis and Duvoisin hypothesized that Circe's potion contained a belladonna alkaloid-containing Solanaceae plant (*Atropa belladonna* L. or *Datura stramonium* L.) and the antidote was the acetylcholinesterase-containing snowdrop plant.[2] Hence, Homer's Odyssey may be the first recorded use of an anticholinesterase to reverse the muscarinic symptoms associated with belladonna alkaloids. This small perennial bulbous herb most likely originated in Turkey, Iran, and the Caucasus, and the plant was probably introduced into Great Britain during the early medieval period by religious communities. Saint Francis of Assisi called the snowdrop an emblem of hope as a result of the appearance of the flower at the end of winter. Because the snowdrop flowers near the feast of the Purification of the Blessed Virgin Mary, the flower was used in churches on Candlemas as a symbol of virginity and purity. The flower was also considered a symbol of death because a single bloom resembled a shrouded corpse. In the early 1950s, Russian pharmacologists isolated galantamine from a species of *Galanthus* after investigating the use of snowdrop in local Caucasian villagers for the treatment of poliomyelitis in children.[3] By the late 1950s, preclinical studies documented the antagonist effects of galantamine on nondepolarizing neuromuscular blocking agents, and galantamine hydrobromide was registered in Bulgaria under the trade name Nivalin® (Sopharma Pharmaceuticals, Sofia, Bulgaria). By the 1990s, clinical investigations indicated that galantamine was an effective treatment for early Alzheimer's disease.

BOTANICAL DESCRIPTION

Common Name: Snowdrop, Candlemas Bell, Mary's Taper, Snow-Piercer, Dingle-Dangle, February Fairmaids, Purification Flower

Scientific Name: *Galanthus nivalis* L.

Botanical Family: Liliaceae (lily)

Physical Description: Narrow linear leaves protrude from the bulb with three long, outer tepals surrounding three green inner tepals. The snowdrop flowers in early February near Candlemas (February 2nd), which is feast of the Purification of the Blessed Virgin Mary and the source of several common names for this plant. Many cultivars exist.

Distribution and Ecology: The common snowdrop probably originated in the Caucasus region of eastern Europe or western Asia. This plant now inhabits the United Kingdom, the northeastern United States, and Washington. Snowdrops grow in damp, deciduous woodlands, particularly in shady areas near rivers, pastures, woods, and streams.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Common Name: Giant Snowdrop

Scientific Name: *Galanthus elwesii* Hook.f.

Botanical Family: Liliaceae (lily)

Physical Description: Slender, oblong leaves about 6 in. (~15 cm) long arise from a small bulb. The flower stalks produce solitary, white flowers with three spreading outer petals surrounding three smaller, less convex inner pedals that contain distinctive green markings. The flower is milky-white (in Greek, *galanthus* means milk flower—*gala* is milk, *anthos* is flower).

Distribution and Ecology: The plant inhabits areas of Bulgaria, Greece, Turkey, and Romania, and the giant snowdrop is an introduced species in Ohio, Pennsylvania, and New York.

EXPOSURE

The snowdrop has a long tradition of use as a folk medicine for pain and neurological conditions. Galantamine is a tertiary alkaloid present in snowdrop and other members of the Liliaceae family. This acetylcholinesterase inhibitor has been used during anesthesia to reverse the neuromuscular paralysis induced by tubocurarine and other paralytic agents.[4] The use of galantamine (Reminyl®, Shire Pharmaceuticals, UK) is approved in many European countries and the United States for the treatment of Alzheimer's disease, but improvement in measures of cognition and global assessment of dementia is usually clinically marginal.[5] A meta-analysis of studies on the use of drugs including galantamine on the outcome of Alzheimer's disease indicated that the standardized estimates of effect size across diverse functional outcome measures for drug treatment in patients with Alzheimer's disease were small.[6] The current lack of alternative treatments for Alzheimer's disease and the good safety profile of galantamine suggest a role for this drug in the treatment of Alzheimer's disease and possible other dementias.[7,8] Although galantamine was first isolated from *Galanthus* species, the principal sources are now synthetic production as well as species of *Narcissus* and *Leucojum*. Galantamine is an experimental treatment for alcoholism.[9]

PRINCIPAL TOXINS

Physiochemical Properties

Galantamine (galanthamine, galanthine, lycoremine) is one of several Liliaceae alkaloids with anticholinesterase inhibitor activity that reverses the central actions of tropane alkaloids (hyoscine, atropine). This compound

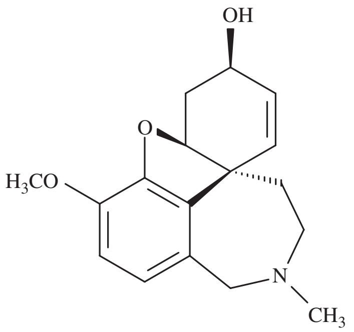

FIGURE 111.1. Chemical structure of galantamine.

(CAS RN: 357-70-0, $C_{17}H_{21}NO_3$) is a phenanthrene alkaloid that has a chemical structure similar to codeine as displayed in Figure 111.1. The pK_a of galantamine is 8.32. This compound has substantially greater affinity for human erythrocyte acetyl cholinesterase than plasma acetyl cholinesterase, and the affinity of galantamine is about 10 times greater for human brain acetyl cholinesterase than human erythrocyte acetyl cholinesterase.[10] Lycorine-type Liliaceae alkaloids also exhibit acetylcholinesterase activity with 1-*O*-acetyllycorine being about 2-fold more potent than galantamine.[11,12]

Poisonous Parts

Galantamine occurs in a variety of plant genera besides *Galanthus* including *Narcissus*, *Crinum*, *Hippeastrum*, *Leucojum*, *Lycoris*, and *Hemerocallis*.[1] This compound is one of several Liliaceae alkaloids present in *Galanthus* species that include hamayne, ismine, lycorenine, lycorine, tazettine, and ungeremine as well as crinane and phenanthridine type alkaloids.[13] The concentrations of these alkaloids vary substantially between *Galanthus* species with haemanthamine, galantamine, and crinine being the principal alkaloids in the giant snowdrop (*Galanthus elwesii*).[14,15] The common snowdrop (*G. nivalis*) contains a unique lectin that possesses a carbohydrate-binding specificity for nonreducing terminal α-D-mannosyl groups.[16]

Mechanism of Toxicity

Galantamine is a long-acting, selective, reversible, and competitive inhibitor of acetylcholinesterase. This compound potentiates nicotinic neurotransmission by allosteric modulation on nicotinic acetyl cholinergic receptors as well as inhibiting acetylcholinesterase.[17] Galantamine can penetrate the blood—brain barrier and augment cholinergic transmission.

DOSE RESPONSE

Intravenous doses of 5 mg to 20 mg galantamine reverse therapeutic doses of pancuronium, gallamine, and tubocurarine, although the recovery of muscle is slower compared with similar doses of neostigmine. In a study of 10 medical students administered 2 mg scopolamine IV, the subsequent IV administration of galantamine hydrobromide 0.5 mg/kg reversed the central effects (drowsiness, disorientation, visual hallucination, delirium) of scopolamine within 5–10 minutes.[18] In placebo-controlled trials of Alzheimer's patients, the dose of galantamine hydrobromide ranged up to 100 mg daily with adverse effects including gastrointestinal distress, agitation, and insomia.[4]

TOXICOKINETICS

The gastrointestinal absorption of therapeutic doses of galantamine is excellent, and the volume of distribution is relatively large with little protein binding based on volunteer studies.[19] Renal clearance accounted for about 25% of the elimination of galantamine. The mean terminal elimination half-life was approximately 5–6 hours. Biotransformation of galantamine involves chiral conversion to epigalantamine and oxidative metabolism with cytochrome P450 isoenzymes (CYP2D6, CYP3A4) to *O*-desmethyl-galantamine, *N*-desmethyl-galantamine, and galantamine-*N*-oxide.[20]

CLINICAL RESPONSE

Side effects of the therapeutic use of galantamine include parasympathetic effects, such as nausea, vomiting, salivation, and blurred vision.[21] The ingestion of lycorine is associated with profuse vomiting.

DIAGNOSTIC TESTING

Analytical methods for the detection and quantitation of galantamine in plasma and tissues include liquid chromatography/tandem mass spectrometry[22] and high performance liquid chromatographic method with UV photodiode array, fluorescence, and mass spectrometric detection.[23] The lower limit of quantitation of the former method was 0.5 ng/mL. There are inadequate data in the medical literature to associate the ingestion of snowdrop bulbs with laboratory abnormalities, such as abnormalities in plasma or red blood cell (RBC) cholinesterases.

TREATMENT

Treatment is supportive. Because gastrointestinal irritation is the major effect of ingestion of these bulbs, the patient should be evaluated for fluid and electrolyte balance as indicated by the clinical presentation. Decontamination measures are unnecessary because of the vomiting associated with poisoning by these bulbs. Although snowdrop bulbs contain anticholinesterase inhibitors, there are few data in the medical literature to suggest that cholinergic crisis results from the ingestion of snowdrop bulbs.

Chapter 112

ZEPHYR LILY
(*Zephyranthes* Species)

BOTANICAL DESCRIPTION

There are at least 11 species of the genus *Zephyranthes* in the United States. Zephyr lily refers generally to most species in this genus including *Zephyranthes grandiflora* Lindl. (rosepink zephyr lily) and *Zephyranthes simpsonii* Chapman (redmargin zephyr lily); whereas atamasco lily refers to *Zephyranthes atamasco* (L.) Herbert.

Common Name: Rosepink Zephyr Lily, Rain Lily
Scientific Name: *Zephyranthes grandiflora* Lindl.
Botanical Family: Liliaceae (lily)
Physical Description: Narrow, pointed green leaves arise from bulb along with a length of about 25–30 cm (10–12 in.). Funnel-shaped pink flower appear on the end of the stem that reach up to about 10–18 cm (~2–7 in.) in length. This perennial plant blooms several times during the summer and autumn, usually after a heavy rain; hence, the common name rain lily.
Distribution and Ecology: This plant is a native species of Mexico and Central America that inhabits moist, open areas near woodlands.

Common Name: Atamasco Lily, Fairy Lily
Scientific Name: *Zephyranthes atamasco* (L.) Herbert
Botanical Family: Liliaceae (lily)
Physical Description: This plant arises from an ovoid to oblong bulb with a short neck. The light green, glossy leaves are shaped like a blade. Funnel-shaped white or purple-tinged flowers appear on a long stem. In contrast to the rain lily, the atamasco lily blooms once in the early spring.
Distribution and Ecology: This bulb is a native species of North America ranging from Missouri and Virginia to Florida. These plants prefer moist meadows and woods.

EXPOSURE

Zephyr lilies are popular cultivated plants. Traditional uses of *Zephyranthes* extract in herbal medicine included the treatment of cancer and diabetes mellitus. Pancratistatin (CAS RN: 96281-31-1) is a biosynthetic product of *Zephyranthes grandiflora* and some other Liliaceae plants.[1] Derivatives of this compound have been investigated for antineoplastic activity.[2]

PRINCIPAL TOXINS

Lycorine is a glucosidic alkaloid common to many species in the Liliaceae family including the zephyr lily (*Zephyranthes* species). Other alkaloids include tazettine (CAS RN: 507-79-9, $C_{18}H_{21}NO_5$) as displayed in Figure 112.1.[3]

DOSE RESPONSE

Most human exposures to the zephyr lily produce no symptoms or minor gastrointestinal distress.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

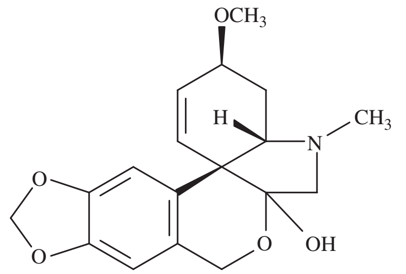

FIGURE 112.1. Chemical structure of tazettine.

TOXICOKINETICS

There are few data on the toxicokinetics of lycorine or tazettine.

CLINICAL RESPONSE

There are few clinical data on the clinical effects of the ingestion of parts from *Zephyranthes* species. Based on the presence of lycorine and similar alkaloids, the predominant effect probably would be gastrointestinal irritation including nausea, vomiting, and diarrhea. The veterinary literature suggests the grazing animals can develop bloody diarrhea, ataxia, and death following the ingestion of *Zephyranthes* bulbs.[4]

DIAGNOSTIC TESTING

Analytical methods for the identification of alkaloids in the *Zephyranthes* species include solid-phase extraction and reversed-phase high performance liquid chromatography.[5]

TREATMENT

Treatment is supportive. Because gastrointestinal irritation is the major effect of the ingestion of these bulbs, the patient should be evaluated for fluid and electrolyte balance as indicated by the clinical presentation. Decontamination measures are unnecessary because of the vomiting associated with poisoning by these bulbs. Although some *Zephyranthes* bulbs (*Z. simpsonii*) contain anticholinesterase inhibitors (galanthamine), there are few data in the medical literature to suggest that cholinergic crisis results from the ingestion of snowdrop bulbs.

III Beans

Chapter 113

CASTOR BEAN and RICIN
(*Ricinus communis* L.)

HISTORY

Castor bean extract was a constituent of classical Greek medicine, and the early Egyptians used castor bean extract as a salve, purgative, and oil.[1] The medicinal use of castor bean was described in the Susruta Ayurveda, which is a Sanskrit work on medicine dating back to the 6th century BC.[2] Raw or roasted castor beans were chewed by indigenous peoples of Africa, China, India, Jamaica, and Mexico for medical purposes (leprosy, syphilis, laxative). In 1978, a 49-year-old Bulgarian journalist, Georgi Markov died 3 days after the injection of a 1.52-mm platinum sphere into his thigh at a London bus stop. The West London coroner ruled that his death was a homicide, most likely the result of ricin poisoning based on circumstantial evidence (i.e., no tissue confirmation of ricin).[3] Within 1 month of the death of Georgi Markov, another Bulgarian exile, Vladimir Kostov survived a febrile illness that began after sustaining a small wound at a Paris metro station.[2] Examination of the wound revealed a platinum pellet similar to the one associated with the death of Georgi Markov.

The US Chemical Warfare Service studied ricin as a potential chemical weapon during World War I, and the British military developed a ricin bomb called the W-bomb.[2] In 1952, the US Army filed a patent on the preparation of ricin for use as an inhalational weapon (i.e., purified, respiratory particles stored in artillery shells for aerosolization during a mass attack). Ricin was also developed as a biological weapon by the former Soviet Union, and ricin was found in Al-Qaeda caves in Afghanistan. During the late 1980s, Iraq manufactured and tested weapons-grade ricin.[4] The US Centers for Disease Control (CDC) lists ricin as a category B agent (i.e., modestly easy to disseminate, causes moderate morbidity and low mortality, requires specific surveillance, and special diagnostic techniques for detection) along with Q fever, brucellosis, epsilon toxin of *Clostridium perfringens, Staphylococcus* enterotoxin B, and waterborne pathogens (*Salmonella* spp. *Shigella dysenteriae, Escherichia coli* 0157:H7, *Vibrio cholerae, Cryptosporidium parvum*). Ricin is the only protein listed under the Chemical Weapons Convention (CWC). Under the CWC, ricin is listed as a schedule I agent (toxic chemical developed primarily for military purposes with few or no legitimate uses). There are no documented uses of ricin as a biological warfare agent against large populations, although there have been instances where ricin was developed for use against specific individuals. On October 15, 2003, a mail processing and distribution facility in Greenville, South Carolina received a sealed container together with a letter threatening to poison water supplies. Although laboratory testing confirmed the presence of ricin in the container, investigation of the postal facility did not detect any ricin in the building or any ricin-related illness among the postal workers.[5]

BOTANICAL DESCRIPTION

Common Name: Castor Bean, Palma Christi, Mole Bean

Scientific Name: *Ricinus communis* L.

Botanical Family: Euphorbiaceae (spurge)

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

FIGURE 113.1. Castor bean (*Ricinus communis* L.). Photograph courtesy of Kimberly Ann Barceloux, MFCC. See color insert.

Physical Description: A large shrub that grows on woody stalks to 4–5 ft (~1.2–1.5 m) in height with wide palmate green-red leaves. Three of the mottled brown and gray-white, oblong seeds are found in a soft-spine brown capsule clustered together on a central stalk. Figure 113.1 displays a specimen of the castor bean plant with seed pods, which contain three seeds.

Distribution and Ecology: In California, castor bean plants grow abundantly in disturbed soils (e.g., along roadsides). This species is native to tropical Africa, but castor bean has been naturalized in most subtropical and temperate climates.

EXPOSURE

An estimated one million tons of *Ricinus* seeds are processed annually in the world with India being a major exporter of castor oil. This country accounts for about one-quarter of the world production of *Ricinus* seeds.[6] Other major exporters include Brazil and China. Cold mechanical pressing or solvent extraction of the castor beans produces components used in a variety of products including high-temperature lubricants [Castrol-R (BP Lubricants, Wayne, NJ), racing motor oil], coatings, antifungal additives, paints, and plastics. The chemical composition of castor oil including the presence of glycerine results in castor oil being an excellent emollient and pigment carrier. Oxidation of the extracted oil from the castor bean plant is an important commercial process for the production of sebacic acid, which is an important component of a variety of products including corrosion inhibitors, plasticizers, lubricants, polymers (nylon), and personal care products.[7] The oil extraction process destroys the ricin in the oil portion. Castor oil is a purgative that increases peristalsis of the small intestine by the action of ricinoleic acid on the small intestine. Following oil extraction, the resultant meal or pomace is used as an additive to fertilizer.[8]

PRINCIPAL TOXINS

Physiochemical Properties

Purified ricin is a water soluble, white powder that is stable over a wide range of pH. In aqueous solution, ricin degrades after heating to 80 °C (176 °F) for 1 hour, whereas higher temperatures are necessary to destroy ricin in powder form.[9] Although ricin is relatively stable after extraction, heat or any method that breaks the disulfide bond inactivates ricin. Because of the low volatility of ricin, delivery of ricin via inhalation requires aerosolization of the ricin.[10] The technical difficulty aerosolizing of ricin limits the use of ricin as a large-scale terrorist agent. Ricin is unlikely to persist in the environment after aerosolization, but low micron-sized particles of ricin can remain in undisturbed areas or become resuspended after many hours. Although dermal absorption occurs, massive quantities of ricin necessary to produce toxicity via the dermal route limits the use of this route of exposure for terrorist acts.

After the separation of oil from the castor bean, ricin concentrates in the fibrous residue (bean pulp, mash) rather than the oil because ricin is water soluble. Consequently, the oil extract of castor bean (castor seed oil or castor oil, CAS RN: 8001-79-4) does not contain significant amounts of ricin. Ricinoleic acid composes about 85–90% of castor oil resulting from the organic solvent extraction of the mash from the castor bean plant.[11] In addition to ricinoleic acid, castor oil contains smaller amounts of glycerides of ricinoleic acid, isoricinoleic acid, and other fatty acids. Estimated concentrations of the fatty acids include oleic acid (2–7%), linoleic acid (3–5%), palmitic acid (1–2%), stearic acid (1%), and dihydroxystearic acid (1%).[12]

Ricin is a highly toxic, heterodimeric type II ribosome-inactivating protein.[13,14] This toxin (CAS RN: 9009-86-3) is a 66 kDa glycoprotein composed of a cell-binding, galactose-specific lectin subunit (Chain B) linked by a disulfide bridge to a rRNA N-glycosidase-subunit (Chain A) that inhibits protein synthesis.[15] The A-chain contains 267 amino acid residues with eight alpha helices and eight beta sheets, whereas the B-chain consists of 262 amino acid residues with a barbell-like tertiary structure.[16]

The pulp of the castor bean contains a variety of allergenic glycoproteins, which account for the allergic responses that occur in workers exposed to the pulp.[17] The major allergen of castor bean is probably a 2S albumin storage protein consisting of two heterodimeric

proteins, Ric c 1 (11,212 Da) and Ric c 3 (12,032 Da).[18,19] The castor bean plant contains a glycoprotein lectin, ricin communis agglutinin; this lectin causes hemolysis following intravenous administration, but not following ingestion or inhalation.[20]

Poisonous Parts

Although ricin is present throughout the plant, seeds contain the highest concentration of ricin. In addition to ricin, the leaves, stems, and seeds of the castor bean plant contain potassium nitrate and hydrocyanic acid. Toxicity occurs after the ingestion of well-masticated seeds, whereas whole seeds are relatively nontoxic. The castor seed contains about 40% oil, 1–5% ricin, and 0.3–0.8% ricinine. Analysis of freshly dried leaves of *Ricinus communis* demonstrated the presence of ricinine (0.7%), *N*-demethylricinine (0.008%), and at least six flavonol glycosides (kaempferol-3-*O*-β-D-xylopyranoside, quercetin-3-*O*-β-D-xylopyranoside, kaempferol-3-*O*-β-D-glucopyranoside, quercetin-3-*O*-β-D-glucopyranoside, kaempferol-3-*O*-β-rutinoside, quercetin-3-*O*-β-rutinoside).[21]

Mechanism of Toxicity

The ingestion of castor oil produces diarrhea. Animal studies suggest that the major component of castor oil, ricinoleic acid, increases both intraluminal secretions and peristalsis.[22] Parenteral administration of ricin causes widespread disruption of cell processes as a result of the action of ricin, a type 2 ribosome-inactivating protein.[23] The target of ricin is the eukaryotic ribosome; hence, ricin is called a ribosome inactivating protein (RIP) or ribotoxin. Ricin is a large (66 kDa) glycoprotein composed of an enzymatically active A-protein chain and a receptor-binding B-protein chain bound together by a single disulfide bridge.[24] Chain B binds reversibly to cell surface galactose-terminated oligosaccharides (i.e., β-D-galactopyranoside) via lectin-binding sites, and the bound glycoprotein facilitates the entry of Chain A into the cell and the endoplasmic reticulum through endocytosis.[25] Chain A is an *N*-glycosidase, which catalytically inactivates protein synthesis by hydrolysis of a specific adenosine residue at position 4324 in the 28 s ribosomal RNA in the cytosol.[26] This action halts the binding of elongation factors and ultimately protein synthesis. The larger rRNA 60s subunit is responsible for protein synthesis, and this larger subunit contains the 28s rRNA. Inactivation of the smaller 28s rRNA inhibits protein synthesis by the larger 60s rRNA subunit, and the inhibition of protein synthesis ultimately causes cell death by necrosis or apoptosis.[27] Isotoxins of ricin (e.g., ricin D, ricin E) occur in cultivars of the castor bean plant.[28]

Entry of ricin into the cell involves the following steps: 1) binding to a range of cell surface glycolipids or glycoproteins, which contain beta-1,4-linked galactose residues, via the ricin B chain; 2) uptake of ricin into the cell by endocytosis; 3) entry of the toxin into early endosomes; 4) transfer of ricin from early endosomes to the trans-Golgi network by vesicular transport; 5) retrograde vesicular transport through the Golgi complex to reach the endoplasmic reticulum; 6) reduction of the disulfide bond connecting the ricin A and B chains; 7) partial unfolding of ricin A chain to cross the endoplasmic reticulum membrane via the Sec61p translocon; 8) avoidance of rapid degradation by cytosolic proteasomes after membrane translocation; 9) refolding into its protease-resistant, biologically active conformation; and 10) interaction with the ribosome to catalyze the depurination reaction.[29] Brefeldin A protects cells from the toxic effects of ricin by disrupting the structure of the Golgi apparatus, but research indicates that brefeldin A is not an effective treatment for ricin intoxication.[16]

The red cell agglutinating properties are independent of the diffuse, systemic effects of ricin, and these properties probably do not contribute significantly to the toxic effects of ricin.[30] The pulp of the seed contains allergenic glycoproteins, which cause allergic dermatitis, rhinitis, and asthma in sensitized industrial workers. The 2-S albumin storage protein of *Ricinus communis* is the major allergen of castor bean, and this protein resides in the CB-1A fraction of the castor bean extract.[18]

The pathology associated with inhalation of ricin is limited to the lungs with little evidence of significant systemic toxicity. The target cell for inhaled ricin is the type I pneumocyte. Animal studies indicate that *Ricinus communis* agglutinin I binds to cell surface receptors on type I pneumocytes and initiates acute alveolitis and necrosis of the lower respiratory tract epithelium.[31] A rapidly progressive pulmonary edema develops that causes severe hypoxia and death. Proliferation of type II pneumocytes occurs in response to the injury during the resolution phase of the pulmonary damage.

DOSE RESPONSE

Predicting toxicity based on the number of seeds ingested is difficult because a variety of factors affect the toxicity of castor beans including growing conditions, season, species, host susceptibility (i.e., immunity), cooking techniques, degree of mastication, bioavailability of ricin, and route of exposure (e.g., parenteral >> oral).[32] Anaphylaxis may occur following exposure to a single bean.

Parenteral

Ricin is several hundred times more toxic when administered parenterally than by ingestion. In animal models, ricin is one of the three most toxic *parenteral* substances by weight with an LD_{50} in the range of 0.1–1 µg/kg. Botulinum neurotoxin is about 1,000 times more toxic than ricin based on the LD_{50} in animals.[13] The estimated lethal dose of ricin in humans is about 1–10 mg/kg.[32] The injection of an estimated 2 mg ricin/kg body weight caused fever, nausea, anorexia, mild elevation of hepatic aminotransferases, and leucocytosis that resolved over 10 days.[33] The sphere found during the autopsy of the Bulgarian journalist, who died 3 days after the injection of the sphere, had a 0.28-mm^3 hole that contained an estimated 500 µg ricin.[34] During phase I cancer clinical trials, the intravenous injection of 23 µg ricin/m^2 every 2 weeks was tolerated by the participants with mild complaints that included fatigue, myalgias, nausea, and vomiting.[35,36] The dose-limiting side effect of ricin A-chain-containing immunotoxins in these clinical trials was a vascular leak syndrome, characterized by hypoalbuminemia and edema.[37]

Oral

Historical accounts of the number of beans ingested do not necessarily estimate the actual dose of ricin ingested because of a number of factors including the maturity of the bean, the degree of mastication, seasonal variation in moisture and ricin, age of patient, and associated diseases. However, most case reports denote the number of beans ingested rather than ricin content. These case reports suggest that the ingestion of 2–30 seeds produces gastrointestinal symptoms in a dose-dependent manner with the ingestion of 10–15 seeds by an adult causing a moderate gastroenteritis that resolves in 2–3 days.[38] Clinical features of the sepsis-like illness associated with parenteral injection of ricin are unlikely following ingestion of castor beans. In an Italian report, ingestion of two seeds by a 12-year-old boy caused protracted nausea and vomiting, but the child recovered without complications.[39] His father ingested three seeds, and he displayed similar symptoms as well as subclinical hyperbilirubinemia. Ingestion of eight seeds by the mother caused a hemorrhagic gastritis, and ingestion of 10 seeds by the 8-year-old sister caused dehydration. An Indian series of 57 children revealed that 22 children displayed evidence of hypovolemic shock, but there were no fatalities.[40] The average ingestion was four to five seeds up to a maximum of 15. A 38-year-old woman intentionally ingested 24 chopped seeds, but she remained asymptomatic after gut decontamination.[32] Ingestion of 30 partially masticated seeds by a 21-year-old resulted in severe hemorrhagic gastritis and dehydration, which responded to supportive care.[41]

Inhalation

In animal studies, large doses (20.95–41.8 µg/kg) of aerosolized ricin produce necrotizing tracheitis, bronchitis, bronchiolitis, interstitial pneumonia, and alveolar edema.[42] The toxicity of aerosolized ricin is highly dependent on particle-size. In a study of mice exposed to aerosolized ricin, all mice died within 72 hours of exposure to 1-µm aerosols (mass median aerodynamic diameter) at 55 µg ricin/kg (i.e., approximately 4.5 times LD_{50}) with about 60% of the total ricin dose being deposited in the lungs.[43] In the comparison group, none of the mice died after exposure to aerosols containing three times the LD_{50} when delivered by a device that produced particles in the range of 1–50 µm. With this device, about 20% of the total ricin dose was deposited in the lungs of the experimental animals. In contrast to humans, mice are obligate nose-breathers and the turbinates of rodents trap more large particulates than humans. However, the inhalation LD_{50} of rodents and humans are the same order of magnitude.[44]

TOXICOKINETICS

There are few clinical data on the toxicokinetics of ricin in humans. The usual route of exposure is gastrointestinal, and, rarely, parenteral. Animal studies indicate that the oral absorption of ricin is low, and the gastrointestinal tract absorbs only small amounts of ricin. Absorption of ricin through the skin is negligible. Inhalation is a potential route of a toxic exposure during a bioterrorism attack, but clinical effects from the absorption of ricin following inhalation are not well documented.[5] The effects of ricin following inhalation depend primarily on particle size with low micron-sized particles producing the most serious effects. Although larger-sized particles can be transported to the gastrointestinal tract via the mucociliary system, clinically significant systemic absorption of ricin does not usually occur in animal models following pulmonary exposures.[31]

A relatively large portion (i.e., approximately 20–45%) of the oral dose of ricin is excreted in the feces over 72 hours.[45] A case report suggested that urinary excretion of ricin was slow with a calculated urinary elimination half-life of 8 days.[41] However, experimental data in rats indicate that the elimination of ^{125}I-labelled ricin following intravenous administration is rapid with only 11% remaining after 24 hours.[46] Renal elimination accounted for 70% of the parenteral dose during the first 24 hours. Following nose-only aerosol inhalation

exposure of ^{125}I-ricin in mice, the lungs sequester most of the ricin until degradation.[47] In the small intestine of humans following ingestion of castor oil, pancreatic enzymes hydrolyze components in castor oil primarily to glycerol and ricinoleic acid.[48]

CLINICAL RESPONSE

Oral

The latent period for toxic effects following ingestion of castor beans varies between 1–24 hours depending on the absorbed dose of ricin. In the large series from India, the mean onset of gastrointestinal symptoms was 1–3 hours with 10 patients admitted within 1 hour.[40] The most common initial symptoms result from a severe gastroenteritis that includes burning in the alimentary tract, nausea, vomiting, diarrhea, and colicky abdominal pain.[38,49] In severe oral poisoning, these symptoms progress to hemorrhagic gastritis, hypovolemia, and hypotension. The primary target organs are the kidney, liver, and pancreas, although the inhibition of protein synthesis by ricin may affect any organ. Death usually results from prolonged dehydration, hypotension, and electrolyte imbalance.[50] Hematuria and elevated free serum hemoglobin level were reported in a 4-year-old girl who ingested four seeds.[51] However, hemolysis is a rare complication of castor bean ingestion.[50] Ricin poisoning is not contagious and person-to-person transmission does not occur.

Parenteral

Compared with oral ricin, parenteral administration of ricin causes more serious toxicity as a result of clinical effects similar to septic shock (fever, multisystem failure, cardiovascular collapse). In the famous case report of the Bulgarian journalist, he developed fever, leukocytosis, tachycardia, and lymphadenopathy, followed by progressive hypotension and a septic shock-like condition.[3] All these effects developed within 36 hours of the injection of a sphere reputedly containing ricin. A necrotizing fascitis containing *Enterococcus faecalis* developed after a 53-year-old man, who masticated 13 castor bean seeds and injected the pulverized material into his left thigh.[52] No evidence of multisystem failure developed, and there were no specific symptoms that could be directly attributed to the injected material other than an infectious process. The differential diagnosis of ricin poisoning includes biological toxins (*Staphylococcus aureus, Salmonella* spp., *Shigella* spp., Norwalk virus, adenovirus, influenza), heavy metal poisoning (arsenic, inorganic mercury, thallium, iron), acute radiation sickness, sepsis, capillary leak syndromes, overdose with chemotherapeutic agents, paraquat poisoning, and phosgene intoxication.

Inhalation

There are few human data on the effects of pulmonary exposure to ricin, but experimental studies indicate that large doses of inhaled ricin can cause irreversible pathological pulmonary changes that result in epithelial necrosis of type I and II pneumocytes, pulmonary edema, and death.[53] In laboratory animals, anorexia and progressive weakness develop within 8–24 hours after inhalation of ricin followed by death about 36–48 hours after exposure. Mortality following pulmonary exposure to ricin usually results from respiratory failure rather than the multisystem failure associated with parenteral ricin. In a study of five monkeys administered approximately 21–42 μg/kg of aerosolized ricin, all monkeys developed fibrinopurulent tracheitis and pneumonia, diffuse necrosis, and acute inflammation of airways, diffuse peribronchiolar edema, alveolar exudates, and purulent mediastinal lymphadenitis.[42] Sensitized individuals may develop allergic responses to inhaled ricin ranging from urticaria and wheezing to anaphylaxis.

Hypersensitivity

Castor bean dust is highly allergenic as a result of potent allergens in the seed, seed coat, and pollen.[54] Inhalation of this dust in facilities using castor beans can cause rhinitis, conjunctival irritation, nasal and throat congestion, urticaria, cough and wheezing.[55] Although gastrointestinal toxicity from ingesting masticated ricin occurs within several hours, allergic responses in sensitized individuals may occur immediately after exposure. Allergic reactions in workers handling these products include rhinitis, urticaria,[56] conjunctivitis, dermatitis,[57] facial edema, wheezing, and anaphylaxis.[58] Case reports document the development of severe orbital edema and urticaria after contact with a castor bean necklace.[59]

DIAGNOSTIC TESTING

Analytical Methods

Methods to detect ricin include radioimmunoassay, ELISA, polymerase chain reaction (PCR),[60] immunoaffinity and liquid chromatography/tandem mass spectrometry (IAC/LC/MS/MS),[61] time-resolved fluorescence immunoassay (TRF), and liquid chromatography/mass spectrometry (LC/MS) for the analysis of ricinine. The lower limit of detection was 0.1 ng ricin/mL using IAC/LC/MS/MS. The analysis of ricin in biological samples is complicated because ricin is a large

heterogeneous protein with glycosylation. The most common screening methods for detection of ricin exposure include radioimmunoassay and ELISA. The limits of detection for radioimmunoassays of ricin in blood samples range from about 0.05–0.1 ng/mL with little cross-reactivity between ricin and abrin.[62] Colorimetric and chemiluminescence ELISA assays for ricin are available from specialized laboratories with limits of detection in the range of 1 and 0.1 ng/mL, respectively, along with limits of quantitation of approximately 10 ng/mL.[63] A colloidal gold-based immunochromatography assay uses a pair of high-affinity anti-ricin monoclonal antibodies to detect ricin at concentrations of 50 ng/mL.[64] Presumptive identification of ricin involves determination of the molecular weight and trypsin-digested peptide mapping from LC/MS with matrix assisted laser desorption/ionization time-of-flight analysis.[65] The detection of ricinine by LC/MS provides additional evidence of exposure to ricin.[66] However, interference with similar compounds (e.g., *R. communis* agglutinin, biological variants of ricin–ricin D, ricin E) during the purification process limits the identification of ricin during these procedures. Protein sequencing with high performance liquid chromatography/electrospray/mass spectrometry (HPLC/ES/MS) provides core structural information on the peptide backbone of ricin, and this method provides definitive determination of ricin.[67] Confirmatory tests for detection of suspected cases of ricin poisoning as a result of bioterrorist acts include nasal or throat swabs within 24 hours postexposure (aerosol exposure) and serum tests for toxin assay and antibody response within 36–48 hours. Other proposed rapid methods for the detection of exposure to ricin include immunochromatography with a reported limit of detection in the range of 1 ng/mL buffer.[68] Methods for the detection of fatty acids in castor oil include thin-layer chromatography,[69] reverse-phase high performance liquid chromatography/mass spectrometry,[70] and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry.[71]

Biomarkers

There are no commercial biomarkers for exposure to ricin, although ricinine is a potential confirmatory biomarker as determined by isocratic HPLC/MS/MS.[72] The advantage of ricinine is that it is a low-molecular-weight component (i.e., $C_8H_8N_2O_2$, MW 164.1) of the castor bean that requires only simple extraction compared with the complicated extraction of the large ricin molecule. In a blood sample from a patient who survived ricin poisoning, the ricin concentration was approximately 0.3 ng/mL 14 hours after the ingestion of ricin seeds as measured by radioimmunoassay.[62]

Abnormalities

Mild, transient elevation of serum hepatic transaminases may occur 1–3 days after ricin ingestion, but these changes are not usually associated with liver dysfunction.[73] Rhabdomyolysis with elevation of serum creatine kinase may also occur.

TREATMENT

Decontamination

Exposure to ricin does not require any unique decontamination techniques.[74] There are limited data on the use of decontamination measures following castor bean ingestion. Vomiting and diarrhea are early symptoms of castor bean ingestion, and these patients usually require no decontamination measures. If the patient presents less than 1 hour after the ingestion of several masticated beans and the patient has not vomited, the use of one dose of activated charcoal is a therapeutic option, but there are inadequate data to confirm the efficacy of this decontamination measure. For aerosol exposure, treatment involves standard measure for the detection and the treatment of noncardiogenic pulmonary edema with respiratory support (oxygen, bronchodilators, endotracheal intubation, positive end-expiratory pressure, continuous positive expiratory pressure) as needed. Patients with substantial airborne exposure to ricin should have a chest x-ray and pulse oximetry to detect the early development of alveolar edema and hypoxemia. Gut decontamination is unnecessary for exposure to airborne toxins. Standard methods for the decontamination of the skin of patients directly contaminated with ricin include removal of contaminated clothes, washing exposed skin with soap and copious amounts of water, and double-bagging contaminated clothes. The risk to health care workers is minimal.[9]

Antidotes

There are no antidotes to ricin. Rabbit antibodies directed against ricin have been described by Houston[75] and tested parenterally in mice models. The antiserum provided protection at five times the LD_{50} dose of ricin only if given within 1 hour; however, at this dose, only 30% of the antiserum-treated group survived. Although there are no specific ricin antidotes at the present time, research continues into the use of pterins (e.g., pteroic acid), which bind in the specificity pocket of ricin and inhibit the action of ricin.[76] Several antiricin vaccines currently are being investigated. Potential vaccine candidates include the vascular leak syndrome site (V76M) and the recombinant ribotoxic A chain

with amino acid substitutions that disrupt the ribotoxic site (Y80A).[77,78]

Supplemental Care

The treatment of ricin poisoning is supportive, primarily directed at the presenting symptoms. Following ingestion or inhalation, the clinical course typically progresses over 4–36 hours. The maintenance of fluid and electrolyte balance is the most important aspect of supportive care. Useful laboratory tests for the treatment of ricin toxicity include a complete blood count, blood urea nitrogen, prothrombin time, urinalysis, and measurement of serum electrolytes, creatinine, glucose, amylase, creatine phosphokinase, and hepatic amino transaminases. Symptomatic patients should be hospitalized and monitored for dehydration, liver dysfunction, pancreatic inflammation, and rhabdomyolysis. Asymptomatic patients who have ingested more than several beans should be observed for at least 4–6 hours after ingestion. If a patient remains asymptomatic during this period, discharge is appropriate with instructions to return immediately should symptoms develop. Initial daily outpatient follow-up for several days is important to identify target organ toxicity (e.g., liver, kidney). Ricin is not dialyzable as a result of its large molecular weight; therefore, measures to enhance elimination of ricin are probably not effective.[17] Patients with aerosol exposure to ricin should be observed for 24 hours if abnormalities appear on the pulse oximetry or chest x-ray. Otherwise, asymptomatic patients can be discharged after 6–12 hours with the provision to return if pulmonary symptoms develop. Although there are few human data, animal experiments suggest that the onset of respiratory symptoms can occur up to 24 hours after exposure.[42]

Chapter 114

COWITCH and HORSE EYE BEAN
(*Mucuna* Species)

HISTORY

The ancient Ayurveda Indian and Chinese systems of traditional medicine used *Mucuna pruriens* for the treatment of stress, male sexual disorders, aging, and general susceptibility to infections.[1] In 1937, Damodaran and Ramaswamy isolated L-dopa from the seeds of *Mucuna pruriens*.[2] In the late 1970s, preliminary clinical trials evaluated the administration of seeds from *Mucuna pruriens* as an inexpensive substitute for medicinal doses of L-dopa for the treatment of Parkinson's disease. However, no subsequent clinical trials were conducted.[3]

BOTANICAL DESCRIPTION

Common Name: Cowitch, Cowhage, Kewanch, Pic-Pica, Feijão Macaco, Velvet Bean

Scientific Name: *Mucuna pruriens* (L.) DC.

Botanical Family: Fabaceae (pea)

Physical Description: This hardy annual vine has trifoliate leaves and purple flowers that produce 10–13 cm (~4–5 in.) fruiting pods with many barbed spicules.

Distribution and Ecology: *M. pruriens* is an annual vine indigenous to North and South Carolina, Florida, Puerto Rice, and the Virgin Islands. This plant grows well in tropical areas, such as India and the Caribbean Islands.

Common Name: Horse Eye Bean, Ojo de Venado (eye of the deer)

Scientific Name: *Mucuna sloanei* Fawcett & Rendle

Botanical Family: Fabaceae (pea)

Physical Description: This perennial climbing vine produces yellow flowers and a nondescript brown bean about 2 × 1 cm (~0.8 × 0.4 in.).

Distribution and Ecology: *M. sloanei* is a native plant in Florida, Hawaii, and Puerto Rico. This plant is now distributed worldwide in temperate and tropical areas of South American, Central America, the Caribbean, and Africa.

EXPOSURE

Previously, components of the seeds from *M. pruriens* were constituents of itching powder and anthelmintic agents. Other traditional herbal uses of *M. pruriens* include uterine stimulation, treatment of dysentery, diuretic, hypoglycemic agent, aphrodisiac, and nerve tonic.[4,5] The seeds from *M. pruriens* are also traditional remedies for developing resistance to snake venom (e.g., *Echis carinatus*)[6,7] and the treatment of Parkinson's disease.[3] During famines in India, the pods of *M. pruriens* are a food source after repeated boiling and thorough rinsing with water.[8]

PRINCIPAL TOXINS

Physiochemical Properties

The pods, seed, leaves, and roots of *M. pruriens* contain indole alkylamine compounds (*N,N*-

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

dimethyltryptamine, bufotenine, 5-methoxy-*N,N*-dimethyltryptamine, β-carboline compounds)[4] and 1,2,3,4-tetrahydroisoquinoline alkaloids.[8] Seeds of *M. pruriens* are well-know sources of L-dopa (L-3,4-dihydroxyphenylalanine).[3,9]

Poisonous Parts

Each fruiting pod from *M. pruriens* contains approximately 5,000 barbed spicules that easily detach and produce an inflammatory response. These spicules measure about 20 µm × 2 mm, and they contain a protease, mucunain, that is the suspected cause of pruritus.[10] The average L-dopa content is somewhat greater in samples of unripe seeds than mature seeds, and the average L-dopa content ranges up to approximately 3–4% dry weight depending on the extraction technique.[11] The L-dopa yield of *Mucuna pruriens* seeds using an ethanol extraction with ascorbic acid was 1.78% compared with 0.98% for water extraction with sulfur dioxide.[12] Seed powder from *M. pruriens* contains up to approximately 350 mg L-dopa.

DOSE RESPONSE

Other than local skin reactions, the ingestion of *M. pruriens* seeds produces clinical effects similar to the ingestion of L-dopa. The administration of doses of *M. pruriens* seed powder up to 60 g (3 g L-dopa) produced minimal side effects that included giddiness, diaphoresis, dry mouth, and diarrhea.[3]

CLINICAL RESPONSE

Dermal contact with hairs from the dried seed pods of *M. pruriens* causes an immediate inflammatory response characterized by erythematous, pruritic macular lesions.[13] Symptoms usually resolve within 1–2 hours of decontamination. There are few data on the human toxicity of *M. sloanei*. Because of the high concentration of L-dopa in the seeds from *Mucuna* species, the clinical features of intoxication from *Mucuna* seeds may resemble L- dopa toxicity. However, there are few data in the medical literature regarding *Mucuna* intoxication in humans.

DIAGNOSTIC TESTING

There are few data on the analytical methods or biomarkers for toxicity associated with the cowitch bean.

TREATMENT

All skin exposed to the pods of *M. pruriens* should be washed with soap and water; all pods and contaminated material should be handled with caution. Treatment is supportive. Decontamination measures are unnecessary.

Chapter 115

JEQUIRITY BEAN and ABRIN
(*Abrus precatorius* L.)

HISTORY

In India, there is a long history of the use of abrin from the jequirity bean plant to poison animals and humans.[1] Administration of small doses of seeds (beans) from *Abrus precatorius* to protect animals from abrin poisoning is one of the earliest examples of active immunization.[2] The seeds from *Abrus precatorius* are called gumchi in Hindustani and gunja in Sanskrit. The physical properties (e.g., uniformity, durability) of these seeds were used in Southeast Asia for weighing jewels and gold. An old system of weights called the Ganda system was based on multiples of the weight of four *A. precatorius* seeds.[2] In addition, jequirity beans were used by some African and Madagascar tribes as an ordeal poison, but the delayed toxicity and the development of immunity limited the effectiveness of the these seeds as an ordeal poison. In Arab countries, jequirity beans (coq's eye) were an aphrodisiac. Extracts of these seeds were used to treat chronic eye diseases during the 19th century, particularly trachoma.[3] In India and Sri Lanka during the early 20th century, abrin was used as a homicidal agent by stabbing the victim with a hardened, needle-shaped abrin paste.[21]

BOTANICAL DESCRIPTION

Common Name: Jequirity Bean, Rosary Pea, Buddhist Rosary Bead, Indian Bead, Corral Peas, Paternoster Beans, Lucky Beans, Minnie-Minnies, Seminole Bead, Prayer Bead, Crab's Eye, Weather Plant, Ojo de Pajaro, Pois Rouge, Tento Muido

Scientific Name: *Abrus precatorius* L.

Botanical Family: Fabaceae (pea)

Physical Description: Small (1 cm/~0.4 in.) alternate compound leaflets develop on a twisting vine that grows up to 20 ft (6 m) in length. The bright scarlet seeds are 3–8 mm (0.1–0.3 in.) long and ovoid with a jet black end. The three color variations of these seeds include a red seed with a black eye (Indian native), a black seed with a white eye, and a white seed with a black eye.

Distribution and Ecology: *Abrus precatorius* is a vine used as an ornamental plant in tropical regions, such as southern Florida and the Florida Keys. *Abrus precatorius* also inhabits tropical and subtropical climates in Southeast Asia, India, Hawaii, Virgin Islands, and Puerto Rico.

EXPOSURE

Traditional herbal uses of *Abrus precatorius* include an anticonvulsant, insecticide, and the treatment of corneal opacities and trachoma by oculists.[4,5] In the Andaman Islands of India, aborigines eat boiled jequirity beans during extreme famines.[6] The jequirity bean is also a decorative bead in jewelry (e.g., necklace), shoes, and rosaries. Potential uses of abrin as a chemical weapon include aerosolization as a dry powder or liquid droplets and/or the contamination of food and water sources.[9] However, to date there is no documentation of the use of abrin as an aerosolized weapon.

PRINCIPAL TOXINS

Physiochemical Properties

Constituents of the jequirity bean include *N*-methyl tryptophan, abric acid, glycyrrhizin (the active principle of licorice), a lipolytic enzyme, a heterodimeric glycoprotein (abrin), and a heterotetrameric glycoprotein (*Abrus* agglutinin-I). The latter two structurally similar substances are class II ribosome-inactivating proteins (ribotoxin). However, *Abrus* agglutinin-I is significantly less toxic than abrin, probably as a result of a difference in the secondary structural elements in chain A.[7] Like ricin, abrin has two dissimilar, disulfide-linked polypeptide chains composed of a lectin with two D-galactose moiety-binding sites (B chain) and an RNA-specific *N*-glycosidase that inhibits protein synthesis (A chain).[8] The A chain contains 251 residues divided into three folding domains with a molecular weight of approximately 30 kDa.[9] The B chains share the same 256 residues in addition to 12 other amino acids. There are at least three variants of abrin within *Abrus precatorius* species that differ in toxicity, binding ability, and lag period.[10] The toxic constituents of the jequirity bean are heat-labile and water soluble.[11] A thorough boiling removes these toxic ingredients.[6] The abrin compounds consist of four isolectins (A to D), which are monovalent compounds with molecular weights ranging from 63,000 to 67,000 Da. However, ricin and abrin are not identical disulfide-linked polypeptide chains. Based on minimal lethal intravenous doses to mice, abrin (0.7 μg/kg) is approximately four times more potent than ricin (2.7 μg/kg).[12]

Poisonous Parts

The seeds of the jequirity bean plant (*Abrus precatorius*) contain four toxic lectins (i.e., abrin compounds) that bind to carbohydrates containing terminal nonreducing galactose residues.[13]

DOSE RESPONSE

There is a marked variation between animal species and abrin toxicity with an intravenous minimal lethal dose (MLD) in mice and rabbits of 0.7 μg/kg and 0.06 μg/kg, respectively.[14] Predicting the fatal oral dose of jequirity beans is difficult because of the lack of data on the bioavailability of abrin in jequirity beans. A 20-year-old male died about 4 days after the ingestion of part of a mixture containing 20 pulverized jequirity beans.[15] The patient did not seek medical treatment until one day before his death, and the case report did not include a detailed case history or results of any laboratory analyses (e.g., drug screens) except the hematocrit.

Mechanism of Toxicity

Most cases of human poisoning after the ingestion of jequirity beans involve gastrointestinal toxicity. These clinical features are consistent with abrin-induced damage to vascular endothelial cells, interstitial edema, and extravasation of fluids and proteins similar to the vascular leak syndrome associated with ricin toxicity.[16] The general structure of abrin compounds is similar to ricin with two polypeptide chains (A chain and B chain). At the cellular level, abrin inhibits protein synthesis and causes cell death. Like ricin, the A chain inactivates the 60 S ribosomal subunits enzymatically after the B chain attaches the A chain to cell surface receptors. *In vitro* studies indicate that the B chain of each abrin molecule rapidly binds to nonreducing β-galactosyl residues of cell surface glycoproteins, particularly to mannose receptors on cells of the reticuloendothelial system.[17] Following the entry of the A chain into the cell, this *N*-glycosidase cleaves adenine from positions 4 and 324 from a loop on the 28S rRNA.[18] The result is the inhibition of protein synthesis after a 30-minute delay and subsequent cell death.[19] The roots of *Abrus precatorius* also contain glycyrrhizin, the active ingredient in licorice; therefore, the clinical syndrome of hyperaldosteronism characterized by sodium retention and hypertension potentially may develop following large doses of roots. However, there are no data to confirm this adverse affect in humans.

Like ricin, the pathology associated with inhalation of abrin is limited to the lungs with little evidence of significant systemic toxicity. The target cell for inhaled abrin and ricin is the type I pneumocyte. Animal studies indicate that abrin binds to cell surface receptors on type I pneumocytes and initiates acute alveolitis and necrosis of the lower respiratory tract epithelium.[8] A rapidly progressive pulmonary edema develops that produces severe hypoxia and death in exposed animals. Proliferation of type II pneumocytes occurs in response to the injury during the resolution phase of the pulmonary damage.

TOXICOKINETICS

There are few data on the toxicokinetics of abrin. The hard coat surrounding the jequirity bean limits the gastrointestinal absorption of abrin. Release of abrin from jequirity beans requires chewing or grinding of the bean prior to ingestion, and nonmasticated seeds pass through the gastrointestinal tract without causing toxicity. The high molecular weight (i.e., about 65 kDa) of abrin also limits the gastrointestinal absorption of this toxin. Based on animal studies, elimination of abrin probably occurs by the renal excretion of metabolites.[20]

CLINICAL RESPONSE

The ingestion of jequirity beans frequently involves children, who are attracted to the bright colors of the seeds. These ingestions are usually asymptomatic because the whole bean passes through the gastrointestinal tract without absorption of abrin from the bean.[21] Serious abrin ingestion produces a severe gastroenteritis several hours after consumption, followed by the development of bloody diarrhea. Delayed symptoms do not usually occur during abrin intoxication; however, rare case reports associated the development of cerebral edema, altered sensorium, and seizures 4–6 days after ingesting 7–10 crushed jequirity beans.[22] One of these patients died, but the cause of death was unclear because of the lack of imaging studies or an autopsy. The latter case is typical of fatalities associated with exposure to jequirity beans. These case reports lack sufficient clinical details to determine the cause and mechanism of death. Jequirity beans are highly antigenic and exposure to material in these beans may produce allergic or anaphylactic responses, particularly in atopic patients.

DIAGNOSTIC TESTING

Older analytical techniques include the detection of aqueous extracts of *A. precatorius* by characteristic ultraviolet absorption on spectrophotometry.[23] Radioimmunoassays have limits of detection near 50–100 pg abrin/mL, and there is little cross-reactivity of abrin with ricin on radioimmunoassay.[24] In animal experiments, sublethal parenteral doses of abrin cause a leukocytosis and mild to moderate elevation of serum hepatic aminotransferases.[25] There are few data on the laboratory abnormalities in humans following the ingestion of jequirity beans.

TREATMENT

The treatment of jequirity bean poisoning is supportive.[26] Decontamination measures are usually unnecessary after the ingestion of whole seeds. The administration of activated charcoal is a therapeutic option for patients, who present to a health care facility within one hour of the ingestion of well-masticated seed, but there are no clinical data to determine the efficacy of decontamination measures including activated charcoal in this clinical setting. There are no commercial antidotes or efficacious methods to enhance the elimination of abrin. Merck and Company (Whitehouse Station, NJ) developed an antiserum in large animals (Antiabrin® or Jequiritol®) to control abrin-induced ocular inflammations (i.e., secondary to trachoma treatment), but no clinical trials have ever been conducted in humans. Consequently, there is no commercial source of the antiserum. Careful fluid and electrolyte replacement is the most important aspect of management. In general, supportive care is similar to treatment for ricin (castor bean) poisoning. Asymptomatic children may be observed at home; symptomatic patients should be hospitalized. Gram-negative sepsis from the passage of intestinal bacteria across damaged intestinal mucosa should be considered when a patient with serious abrin ingestion develops fever and hypotension.

Chapter 116

MESCAL BEAN
[*Sophora secundiflora* (Ortega) Lagasca ex DC.]

HISTORY

Anthropomorphs during prehistoric times depict shamans of the Great Plains Indians engaged in mescal bean cult activities.[1] Consistent with the same archaic tradition that produced these rock paintings, caves in Texas contained the same materials (mescal beans, red pigments).[2] Prior to the discovery of peyote, many southwestern American Indian tribes used mescal beans to induce visions during ceremonies. Native Americans continue to use the mescal bean as part of the ceremonial dress for the leaders of the peyote ceremony.[3] There is no modern experimental evidence that mescal beans contain hallucinogens.

BOTANICAL DESCRIPTION

Common names for the seeds include mescal bean, red bean, coral bean, red-hot, frijolillo, burn bean, and dry whiskey.

Common Name: Texas mountain laurel, Mescal Bean Plant

Scientific Name: *Sophora secundiflora* (Ortega) Lagasca ex DC.

Botanical Family: Fabaceae (pea)

Physical Description: This large woody, evergreen shrub or small tree grows up to 15–25 ft (~5–8 m) in height with a 10 ft (3 m) spread. The thick, dark green leaves are alternate and pinnate. Pendulous clusters of blue to purple flowers form hairy seedpods that contain yellow to scarlet seeds about 1 cm (~0.4 in.) long.

Distribution and Ecology: This shrub is indigenous to the southwestern United States and northern Mexico along the lower Pecos River region.

EXPOSURE

American and Mexican Indians used the seeds from this plant in religious ceremonies for many centuries, reportedly for hallucinogenic purposes. However, there is no clear clinical evidence to support the association of mescal bean ingestion with hallucinations.[4] Today, the seeds are most commonly used as a good luck charm.[5]

PRINCIPAL TOXINS

Physiochemical Properties

Of the seven quinolizidine alkaloids found in mescal beans, the major alkaloids are cytisine (0.25%), methylcytisine, and sparteine.[4] Figure 116.1 displays the chemical structure of cytisine (CAS RN: 485-35-8, $C_{11}H_{14}N_2O$). By contrast, golden chain seeds (*Laburnum anagyroides* Medikus) contain cytisine concentrations of approximately 1%. Minor alkaloids found in *Sophora secundiflora* include lupinine and Δ_5-dehydrolupanine. Pharmacologically, cytisine resembles nicotine. Analysis of the alkaloids in *S. secundiflora* did not reveal any

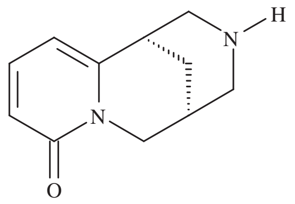

FIGURE 116.1. Chemical structure of cytisine.

TABLE 116.1. Some Physical Properties of Cytisine

Physical Property	Value
Melting Point	152.5 °C/306.5 °F
log P (Octanol-Water)	0.600
Water Solubility	4.39E + 05 mg/L (16 °C/60.8 °F)
Vapor Pressure	1.57E-05 mmHg (25 °C/77 °F)
Henry's Law Constant	4.01E-12 atm-m^3/mole (25 °C/77 °F)
Atmospheric OH Rate Constant	8.59E-11 m^3/molecule-second (25 °C/77 °F)

known hallucinogenic compounds.[6] Table 116.1 lists some physical properties of cytisine.

Poisonous Parts

The mescal bean contains about 0.25% cytisine, whereas seeds from the golden chain tree contain cytisine concentrations about 4 times higher.[4]

Mechanism of Toxicity

In animal studies, the administration of alkaloids (cytisine, sparteine, methylcytisine) produces neurological effects similar to mescaline, *N*,*N*-dimethyltryptamine, and psilocybin.[7] However, there are no well-documented human studies that demonstrate hallucinogenic effects following the ingestion of these alkaloids at concentrations found in the mescal bean.

DOSE RESPONSE

Cytisine has an oral LD_{50} dose in mice of 50–100 mg/kg.[4] The subcutaneous injection of 0.5 mL of a 50% ethanolic extract of 250 mg of *S. secundiflora* seeds was rapidly fatal to 150- to 200-g rats.[8] The lethal human dose is not known. Most children who ingest the more toxic laburnum seeds do not develop symptoms. In those children who are symptomatic, the most common presentation is vomiting and abdominal pain with delirium, drowsiness, diarrhea, and sore mouth occurring occasionally.

TOXICOKINETICS

There are few toxicokinetic data on cytisine in humans. Based on animal studies, the peak concentration of cytisine occurs about 2 hours after ingestion with bioavailability being about 40%.[9] The plasma elimination half-life of cytisine in these animal studies is about 3–4 hours. Following intravenous administration, the concentration of cytisine in the bile is high compared with the blood.

CLINICAL RESPONSE

Mescal bean intoxication is primarily an affliction of range sheep, which is manifest by stiff gait, trembling with exercise, and somnolence. Mescal bean poisoning may occur in domestic animals.[10] The clinical course of this illness is rarely fatal. Human poisoning is not well documented in the modern medical literature. A case report from the late 19th century associated the ingestion of powder from the crushing of one-quarter of a seed from *Sophora speciosa* Benth. with headache, paresthesias, lightheadedness, and difficulty in walking within 2 hours of ingestion.[11] Subsequently diarrhea developed. A "peculiar numbness in the spinal column" lasted over 24 hours. Because of the issue of plant identification during the 19th century, the relevance of this case report to mescal bean toxicity remains unclear.

DIAGNOSTIC TESTING

Cytisine is the major toxic constituent of the mescal bean, and confirmation of mescal bean poisoning requires analysis of this compound in blood samples. Methods for the quantitation of cytisine in plasma samples include liquid chromatography/atmospheric pressure chemical ionization/mass spectrometry and liquid chromatography/electrospray ionization/tandem mass spectrometry.[12] There are few data on the laboratory abnormalities following mescal bean intoxication because of the lack of clinical case reports in the modern medical literature associating the ingestion of mescal beans with toxicity.

TREATMENT

Management is primarily supportive. Decontamination measures are usually unnecessary, and there are no clinical data to support the efficacy of decontamination measures in the treatment of mescal bean ingestions. Serious poisoning is unlikely unless mescal teas or large quantities (probably over 20 beans) are ingested.

IV Nonwoody Plants (Herbs)

Chapter 117

ACONITE POISONING and MONKSHOOD

HISTORY

Aconite is a crude extract of dried leaves and roots from various species of *Aconitum* (e.g., *A. japonicum* Thunb., *A. carmichaelii* Debeaux) that contain aconitine and other diterpenoid ester alkaloids. During ancient times, aconite was a common poison in Europe and in Asia. Aconite was a medicinal drug as well as a homicidal agent and arrow poison in Asia. The use of aconite may account for some deaths in antiquity attributed to stroke, even though substantial physical pain accompanies fatal aconite poisoning. The death of the Jewish High Priest Alkimos in 159 BC was regarded as stroke-related (collapse and loss of speech followed shortly by death). However, the description of severe pain suggests another cause, such as aconite poisoning.[1] The manner of death of the Roman Emperor Claudius in 54 AD was consistent with some of the clinical effects of acute aconite poisoning; his spouse, Agrippina, was the suspected assassin. The Ainu inhabitants from the Japanese island of Hokkaido concocted an arrow poison called *surku* from *Aconitum japonicum* and other local plant species, such as the marsh marigold (*Caltha palustris* L.) and mugwort (*Artemisia vulgaris* L.).[2] The crude extract of the aconite root (*A. Japonicum*), called *bushi*, has long been a traditional treatment for debilitated patients to improve metabolism and to cure dysuria, cardiac weakness, gout, neuralgias, and rheumatism.

BOTANICAL DESCRIPTION

The genus *Aconitum* contains over 350 species. North American species of *Aconitum* include *A. columbianum* Nutt. (Columbia monkshood), *A. reclinatum* Gray (trailing white monkshood), and *A. uncinatum* L. (southern blue monkshood). *Aconitum napellus* L. (Venus' chariot) is a naturalized species from Europe. Figure 117.1 displays the flowers and branches of *A. napellus*. The Asian varieties of *Aconitum* include *A. carmichaeli* Debeaux, *A. japonicum* Thunb., *A. kusnezoffii* Reichb. (bei wu tou), and *A. vulparia* Reichb. ex Sprengel (yellow-flowered wolfsbane). The misidentification of *Aconitum* root as horseradish (*Armoracia rusticana* P.G. Gaertn., B. Mey. & Scherb.) or the leaves as parsley [*Petroselinum crispum* (Mill.) Nym.] can cause poisonings.

At least half of *Aconitum* species grow in northern latitudes including North America, Europe, and China.[3] *Aconitum columbianum* (Western or Columbia monkshood) is a native of moist woodlands in the Rocky Mountains and Sierra Nevada Mountains from southwestern Canada to New Mexico. *Aconitum reclinatum* (blue flowers) and *Aconitum uncinatum* (white flowers) are natives of mountains in the eastern United States.

Common Name: Cultivated Aconite, Friar's Cap, Monkshood, Wolfsbane, Venus' Chariot

Scientific Name: *Aconitum napellus* L.

Botanical Family: Ranunculaceae (buttercup)

Physical Description: This perennial herb grows 2–6 ft (0.6–1.8 m) in height with palmate leaves and a tuberous root. The blue or white trumpet-shaped flowers are bilaterally symmetrical with a prominent upper hood and grow in a raceme on a long stem.

Distribution and Ecology: *A. napellus* is a cultivated European species present in many US and Canadian gardens.

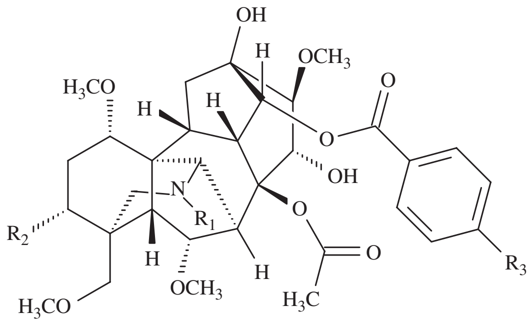
EXPOSURE

Aconitum tubers are a common component of traditional Chinese medicines including fu zi or fuzi (lateral root or tuber of *A. carmichaelii* Debeaux), caowu (*A. kusnezoffii* Reichb.), chuanwu (*A. carmichaelii* Debeaux.), futxu, wu tao, and zue shang yi zhi gao.[4] In Hong Kong, chuanwu (*A. carmichaelii*), fuzi (*A. carmichaelii*), and caowu (the root of *A. kusnezoffii*) are prescribed by traditional health care providers for musculoskeletal disorders (rheumatism, arthritis, fractures, bruises, trauma) based on potential anti-inflammatory, analgesic, and cardiotonic effects. A retrospective review of admissions to a Hong Kong hospital suggested that these two traditional Chinese remedies accounted for about 70% of the admissions for severe poisonings from Chinese herbal remedies.[4] In China and Hong Kong, traditional uses for herbal medicines derived from *Aconitum* species beside musculoskeletal disorders (e.g., gout) include hypertension, malaise, generalized weakness, and epigastric pain.[5] Aconite is also an abortifacient and suicidal agent. Experimental studies in rats suggest that a hetisane-type diterpenoid alkaloid in *Aconitum* root, called ignavine (CAS RN: 1357-76-2), has anti-inflammatory properties.[6]

PRINCIPAL TOXINS

Physiochemical Properties

There are over 170 *Aconitum* alkaloids that have been isolated from 20 *Aconitum* species in China alone.[7] Figure 117.2 and Figure 117.3 displays the structures of



Alkaloid	R_1	R_2	R_3	MW
Aconitine	Ethyl	Hydroxyl	Hydrogen	645
Mesaconitine	Methyl	Hydroxyl	Hydrogen	631
Jesaconitine	Ethyl	Hydroxyl	*O*-Methyl	675
Hypaconitine	Methyl	Hydrogen	Hydrogen	615
Deoxyaconitine	Ethyl	Hydrogen	Hydrogen	629

FIGURE 117.3. Structures of hydrolysis products of aconitum alkaloids.

common *Aconitum* alkaloids and hydrolysis productions of *Aconitum* alkaloids, respectively. Aconite is a crude extract of dried leaves and roots from various *Aconitum* species that contains aconitine and other diterpenoid ester alkaloids (aconitine, mesaconitine, jesaconitine, hypaconitine).[8] Aconitine (CAS RN: 302-27-2) is a methylated and benzoylated ester of the

hexacyclic norditerpenic amino alcohol, aconine (CAS RN: 509-20-6). Hydrolysis of these alkaloids forms less toxic substances.[3] Soaking and boiling during the preparation of herbal decoctions of dried aconite roots reduces the toxicity of the compound by hydrolyzing aconitine and related alkaloids to less toxic benzylaconine and aconine derivatives. However, these preparations may still cause toxicity.[4] In animal studies, the direct application of aconitine to the myocardium produced atrial and ventricular dysrhythmias.[9]

In addition to the cardioactive alkaloids, *Aconitum* roots contain physiologically active catecholamine analogs.[10] *A. carmichaelii* contains small amounts of the quaternary ammonium compound coryneine chloride (dopamine methochloride); *A. japonicum* possesses the triphenolic 1-benzyl-tetrahydroisoquinoline base, higenanine.[3] In animal studies, ignavine produces substantially less sedation and loss of motor coordination than aconitine, mesaconitine, or jesaconitine.[6] Other aconite alkaloids with low toxicity include ignavine, hypognavine, isohypognavine, kobusine, and pseudokobusine.[6] *Aconitum* alkaloids, which lack a benzoylester side chain (e.g., heteratisine, lappaconitine, napelline), produce lower toxicity compared with other *Aconitum* alkaloids.[11]

Poisonous Parts

Aconitine (CAS RN: 8063-12-5), yunaconitine (guayewuanine B, CAS RN: 70578-24-4), and jesaconitine (CAS RN: 16298-90-1) are the main toxic alkaloids in *Aconitum* species.[12] Other less cardiotoxic alkaloids include *N*-desacetyllappaconitine, 6-benzoylheteratisine, heteratisine, lappaconitine, and napelline. All parts of the plant contain toxic alkaloids including seeds,[13] but the alkaloid content and composition depends on the species, plant part, environmental conditions, and season. Generally, the relative alkaloid content is distributed as follows: roots > flowers > leaves > stems. Fresh *Aconitum* plants typically contain 0.4–2% alkaloids, depending on season, species, and environmental conditions.

Mechanism of Toxicity

The voltage-gated sodium channels generate the action potentials in nerve and in muscle tissue. Aconitine binds with high affinity to site 2 of the α-subunit of the Na^+ channel protein. This binding of aconitine to the open Na^+ channels shifts the voltage dependence of activation to more hyperpolarized potentials and reduces channel inactivation from the open state. As a consequence of prolonged sodium channel activation, sustained Na^+ influx causes a lack of excitability. Thus, aconitine initially stimulates and then inactivates the voltage-gated sodium channels in the heart and nervous system, resulting in interference with the propagation of the action potential.[14] Veratridine, grayanotoxin, and batrachotoxin also cause inactivation of the sodium channel by sustained activation at this transmembrane receptor.[15] The arrhythmogenic effects of these alkaloids result from the initiation of premature or triggered excitations secondary to a delay in the final repolarization phase of the action potential.

Histopathology

Postmortem examinations of fatalities following *Aconitum* toxicity demonstrate nonspecific finding (e.g., congestion of main organs) often without evidence of coronary artery disease.[16,17]

DOSE RESPONSE

The recommended dose of aconite decoctions of processed Chinese herbs is 1–3 grams. The exact composition and type of *Aconitum* alkaloids necessary to produce toxicity are not well defined. Inadequate curing of these decoctions increases toxicity. Most of the toxic effects of aconite result from the accidental, suicidal, or homicidal ingestion of aconite powder, especially in India and Asia where the paste is used to relieve neuralgias and dental pain. The estimated lethal dose of aconite is about 1–2 mg, but there are limited clinical data on the dose response of crude aconite and *Aconitum* alkaloids. Serious toxicity may result from the ingestion of a decoction from *Aconitum* species containing more than 6 g cured *Aconitum* alkaloids or consumption of more than 0.2–0.6 mg aconitine.[18] The estimated ingestion of 3–10 mg of aconite was associated with paresthesias, nausea, vomiting, weakness, and cardiac dysrhythmias.[19,20] The ingestion of an estimated dose of 11 mg *Aconitum* alkaloids caused ventricular tachycardia and cardiac arrest, but the patient survived with intensive supportive care.[21] A case report associated the reported ingestion of 3 capsules of dried *Aconitum napellus* root (i.e., about 57 µg aconite) with the development of paresthesias, nausea, diarrhea, vertigo, bradycardia, and ventricular ectopy.[22] Symptoms resolved within 12 hours. The concentrations of other terpenoid compounds (e.g., mesaconitine, jesaconitine) were not reported.

TOXICOKINETICS

Metabolic pathways for *Aconitum* alkaloids include de-esterification at the C8 and C14 groups by esterase and the *N*- and/or *O*-dealkylation by cytochrome P450 oxidases. Urinary metabolites of aconitine in humans

include 16-*O*-demethylaconitine and benzoylaconine, whereas benzoylhypaconine and 16-*O*-demethylhypaconitine are metabolites of hypaconitine. Benzoylmesaconitine is a metabolite of mesaconitine.[23] Elimination of *Aconitum* alkaloids from the blood is rapid with most of the absorbed dose of aconitine, mesaconitine, and hypaconitine appearing unchanged or hydrolyzed in the urine within 24 hours after ingestion. In a 21-year-old man with moderate aconitine poisoning (i.e., bradycardia without hypotension), the plasma elimination half-life of aconitine was about 3 hours.[22] In a case series of 5 patients admitted to an intensive care unit with aconite poisoning, the serum half-life of aconitine ranged from 3.7 hours to 17.8 hours.[24] The serum half-life of jesaconitine in these patients ranged from 5.8 hours to 15.4 hours.

Peak concentrations of these *Aconitum* alkaloids and their metabolites in the urine occurred about 24 hours after the ingestion of an estimated 11 mg of *Aconitum* alkaloids with small concentrations (<0.03 ng/mL) present 6 days after ingestion.[21] Analysis of urine samples 6 days after ingestion demonstrated trace amounts of the *Aconitum* alkaloids in the urine with aconine having the highest concentration (0.5 ng/mL). There are inadequate data to characterize the percentage of these *Aconitum* alkaloids excreted unchanged in the urine.

CLINICAL RESPONSE

The clinical presentation of aconite poisoning involves the gastrointestinal, cardiac, and nervous systems. Ingestion of aconite produces intoxication similar to veratrum alkaloids (veratrine), except that paresthesias are more prominent and persistent during aconite intoxication. Numbness and paresthesias of tongue, throat, and mouth begin soon after ingestion followed within several hours by nausea, salivation, and generalized weakness.[25] During serious intoxication, convulsions, quadriplegia, loss of deep tendon reflexes, and coma may develop within 6 hours after ingestion.[26,27] Changes in sensorium result from secondary causes rather than direct central nervous system (CNS) depression. Other neurological symptoms include blurred vision, mydriasis, and yellow-green vision. Most symptoms usually resolve within 24–30 hours.[28]

Cardiotoxicity usually occurs during serious aconite poisoning, characterized by hypotension, shock, conduction delays, and dysrhythmias beginning within 6 hours of ingestion.[29,30] Reported cardiac dysrhythmias include sinus bradycardia with first-degree atrioventricular block,[31] supraventricular tachycardia and hypotension,[32] multiple premature ventricular contractions,[20] bundle branch block, junctional escape rhythms,[26] ventricular tachycardia, and *torsade de pointes*.[33] Serious ventricular dysrhythmias typically resolve within 12–24 hours of ingestion,[34] but ST-T wave abnormalities and conduction delays may persist for several days. Death usually results from cardiovascular collapse and persistent ventricular fibrillation unresponsive to both defibrillation and the usual pharmacological agents.[18] The differential diagnosis of aconite poisoning includes poisoning by cardiac glycosides, andromedotoxin, or veratrine, ciguatera intoxication, and paralytic shellfish poisoning.[35]

DIAGNOSTIC TESTING

Analytical Methods

High performance liquid chromatography (HPLC) with UV detection and mass spectrometry detects aconitine, hypaconitine, jesaconitine, and mesaconitine in blood and urine samples at limits of detection approaching 50 ng/mL.[36] The limit of detection and limit of quantitation for aconitine in blood samples after solid-phase extraction using mixed-mode C8 cation exchange columns followed by liquid chromatography/tandem mass spectrometry (LC/MS/MS) were 0.1 ng/g and 0.5 ng/g, respectively.[37] The use of capillary liquid chromatographic-frit fast atom bombardment mass spectrometric analysis allows the detection of 1 pg aconitine.[38] Urinary metabolites of aconitine and hypaconitine are detectable by liquid chromatography/electrospray ionization/multistage tandem mass spectrometry.[23] After solid-phase extraction and analysis by LC/MS/MS, the limits of quantitation for urinary metabolites were as follows: yunaconitine, 0.15 ng/mL; crassicauline A, 0.20 ng/mL; and foresaconitine, 0.20 ng/mL.[39] The limits of detection for these urinary metabolites were 0.03 ng/mL, 0.05 ng/mL, and 0.05 ng/mL, respectively.

Biomarkers

There are little clinical data on the interpretation of serum *Aconitum* alkaloid concentrations. The clearance of aconitine, mesaconitine, and hypaconitine from the blood is relatively rapid. A 45-year-old man developed ventricular tachycardia and cardiovascular collapse after ingesting approximately 11 mg *Aconitum* alkaloids.[21] Analyses of blood samples obtained 2 hours after the ingestion demonstrated the following concentrations: aconitine, 1.72 ng/mL; mesaconitine, 4.04 ng/mL; and hypaconitine, 0.60 ng/mL. Analysis of blood samples from samples drawn the following day did not detect these alkaloids, although aconite alkaloids and metabolites remained in the urine for several more days. A 61-year-old man ingested boiled and seasoned *Aconitum* stems and leaves.[40] Within 6 hours, he developed

refractory ventricular fibrillation and anoxic brain damage leading to death on the sixth day as a result of cerebral edema and probable brain herniation. Approximately 24 hours after ingestion, the serum jesaconitine concentration was 0.6 ng/mL, whereas the aconitine, mesaconitine, and hypaconitine concentrations were not detectable. Mesaconine remained detectable at least 4 days after ingestion. Postmortem blood samples drawn from a 40-year-old woman, who died 4 hours after ingesting *Aconitum* tubers, demonstrated serum jesaconitine and aconitine concentrations of 69.1 ng/mL and 1.1 ng/mL, respectively.[41] Hypaconitine and mesaconitine were not detectable. A 60-year-old man developed a fatal cardiac arrest 2 hours after ingesting liquified tissue from *Aconitum napellus*.[42] The aconitine concentration in a sample of postmortem femoral blood was 10.8 ng/mL, as measured by HPLC. Aconitine was detectable in urine and liver samples 5 years after initial analysis of postmortem samples as measured by LC/MS/MS.[43]

Abnormalities

Occasional hypokalemia, hyperglycemia, and metabolic acidosis occur during aconite toxicity.

TREATMENT

Stabilization

Symptomatic patients (e.g., those with protracted vomiting, weakness) should receive an intravenous line, oxygen, and monitoring of the cardiac rhythm and oxygen saturation. Cardiovascular collapse and ventricular dysrhythmias represent the greatest risk to life, and prolonged cardiopulmonary resuscitation may be necessary for survival of severely intoxicated patients.[44] There are few clinical data on the most effective antiarrhythmic agent for ventricular dysrhythmias during aconite poisoning. Consequently, there is no universally accepted, first-line antiarrhythmic agent for the treatment of dysrhythmias associated with aconite toxicity.[29] Standard treatment includes amiodarone, magnesium, and lidocaine for ventricular dysrhythmias and atropine for sinus bradycardia.[45] Typically, agents that worsen QT prolongation (e.g., procainamide, disopyramide, quinidine, flecainide, encainide, sotalol) are avoided during intoxication by aconite because of concern that these drugs may prolong the QT interval and cause *torsade de pointes*. However, a case report of aconite poisoning documented the resolution of bidirectional tachycardia after the intravenous administration of 40 mg flecainide.[46] In this patient, analysis of serum, urine, and gastric samples did not detect digoxin, salicylates, or tricyclic antidepressants. A case series of 17 patients with aconitine poisoning suggested that amiodarone and flecainide were first line antiarrhythmic drugs, whereas lidocaine was a second-line antiarrhythmic drug.[35] Procainamide and phenytoin have been clinically and experimentally successful in suppression of ventricular dysrhythmias resulting from some cases of aconite poisoning,[9] whereas other cases of aconite-induce ventricular dysrhythmias have not responded to intravenous lidocaine.[47] A 32-year-old man survived aconite intoxication associated with bidirectional ventricular tachycardia and persistent ventricular fibrillation following cardiopulmonary bypass.[48] The presence of respiratory or CNS depression is unusual during aconite poisoning unless there is poor cerebral perfusion, and the presence of these clinical features suggests the ingestion of a CNS depressant.

Decontamination

Because all parts of the *Aconitum* plant contain aconitine, decontamination with activated charcoal is a therapeutic option for alert patients ingesting more than a taste of the plant and presenting for treatment within one hour of ingestion. However, there are no clinical data to confirm the efficacy of decontamination measures to improve outcome during aconite poisoning, and decontamination measures are usually unnecessary.

Supplemental Care

Laboratory assessment includes electrolytes, creatine phosphokinase, arterial blood gases, and an electrocardiogram. The severity of toxicity following aconite ingestion is difficult to predict based on history, and asymptomatic patients should be observed for at least 4–6 hours. Symptomatic patients should be hospitalized for 24 hours with cardiac monitoring.

Chapter 118

AFRICAN BLUE LILY
(*Agapanthus* Species)

BOTANICAL DESCRIPTION

Common Name: African Blue Lily

Scientific Name: *Agapanthus orientalis* F.M. Leight

Botanical Family: Liliaceae (lily)

Physical Description: This erect perennial herb forms large clumps of leaves and smooth, flowering stems up to about 1 m (~3 ft) arise from underground rhizomes. The leaves are long, elongated, glossy, and dark green. The tubular flowers are blue or white in large spherical clusters at the top of the flowering stems. Leathery, green capsules form from the flowers that contain black, winged seeds. As the capsule dries, the color changes to pale brown.

Distribution and Ecology: This plant was introduced into the United States, and now is cultivated in Florida, Arizona, and coastal California.

Common Name: Lily of the Nile

Scientific Name: *Agapanthus africanus* (L.) Hoffmanns.

Botanical Family: Liliaceae (lily)

Physical Description: This evergreen plant reaches 50 cm (~20 in.) in height with clumps of 8–18 linear-lanceolate leaves about 1–1.5 cm (0.4–0.6 in.) wide. The flowering stalks are umbel (nearly equal in length, arising from a common point) with funnelform, deep violet-blue flowers up to 4 cm (~2 in.) in length.

Distribution and Ecology: The plant is native to South Africa.

EXPOSURE

Agapanthus africanus is a traditional medicine (Isihlambezo) for Zulu women in South Africa as a health tonic during pregnancy and as a means to induce or augment contractions during labor.[1] The herbal remedy is prepared by boiling the herb in water (decoction). In the Transkei region of South Africa, women consume a decoction of the root of *Agapanthus africanus* beginning in the sixth month of pregnancy as means of ensuring an easy childbirth.[2]

PRINCIPAL TOXINS

The sap of these plants contains a direct mucosal and skin irritant rather than a potent allergen. The chemical structure of the irritant is not known. *In vitro* studies of isolated rat uterus preparations indicate that aqueous extracts of *A. africanus* produce some agonist activity on uterine muscarinic receptors and increase synthesis of prostaglandins in estrogenized rat uterus.[3]

DOSE RESPONSE

There are insufficient data on the toxic constituents of *Agapanthus* species to determine dose-response data.

TOXICOKINETICS

The toxic constituents of *Agapanthus* species have not been identified.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

CLINICAL RESPONSE

Contact of the oral mucosa or skin with parts of the plant can cause local irritation, but systemic symptoms are unlikely. Potentially irritation of the eyes, mouth, throat, or skin can develop following exposure to sap from the leaves or roots of *Agapanthus* species.

DIAGNOSTIC TESTING

There are few data on the use of diagnostic methods to detect biomarkers in *Agapanthus* species.

TREATMENT

Treatment is supportive. All plant material should be removed from the mouth and demulcents (milk, antacids, cool water) used as needed. Symptomatic irritation of the eye requires saline irrigation and examination for corneal abrasions. Contact with plant material does not usually cause substantial edema (i.e., intraoral edema, drooling), and treatment with topical analgesics [e.g., Cepacol® (Bayer Consumer Care, Morristown, NJ), Orabase Plain® (Colgate-Palmolive Company, New York, NY)] is usually sufficient.

Chapter 119

RED BANEBERRY
[*Actaea rubra* (Aiton) Willd.]

BOTANICAL DESCRIPTION

The European variety (Eurasian baneberry, Herb Christopher) is a separate species (*Actaea spicata* L.). Black cohosh (*Actaea racemosa* L.) and *Actaea rubra* are closely related species.

Common Name: Red Baneberry, Snakeberry, White Cohosh, Doll's Eyes, Coral Berry

Scientific Name: *Actaea rubra* (Aiton) Willd.

Botanical Family: Ranunculaceae (buttercup)

Physical Description: This tall perennial herb reaches up to about 50 cm (~20 in.). The roots are thick and the large leaves are compound with toothed edges. The white flowers appear in June to July and produce attractive red berries, which ripen from July to August.

Distribution and Ecology: The western baneberry (red fruit) inhabits areas from Alaska to central California and Arizona and east to Montana. The eastern baneberry (*Actaea pachypoda* Ell.) produces white fruit in rich woodlands from Canada to Georgia and west to the northern Rocky Mountains.

EXPOSURE

This North American native plant was used by Native Americans as an analgesic and rubefacient, particularly the root. An infusion of the root was a treatment for upper respiratory tract infections, intestinal pain, postpartum pain, and constipation.

PRINCIPAL TOXINS

The rootstock, sap, and berries of baneberry contain glycosides or essential oils that produce a severe gastroenteritis. White baneberry contains a variety of unique 9,10-seco-9,19-cyclolanostane arabinosides compounds (podocarpasides A-J).[1,2] The contribution of these novel triterpenoid compounds to the gastrointestinal toxicity of the baneberry plant has not been determined.

DOSE RESPONSE

There are insufficient data on the toxic constituents of the baneberry plant to determine dose-response data.

TOXICOKINETICS

The toxic constituents of the baneberry plant have not been identified.

CLINICAL RESPONSE

A case report from the older medical literature associated the development of gastroenteritis with the ingestion of six baneberries.[3] Gastrointestinal symptoms began within 1/2 hour after ingestion. Confusion, headache, and distorted visual perception developed within 1 hour followed by tachycardia, abdominal pain, lethargy, dry mouth, and indigestion. Symptoms resolved within 3 hours after ingestion. The toxicity of baneberry in not well documented in the modern medical literature.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

DIAGNOSTIC TESTING

Analytical methods for the detection of polyphenol compounds in the roots and rhizomes of baneberry include reversed-phase high performance liquid chromatography with diode array detection.[4]

TREATMENT

Treatment is supportive. Decontamination measures are usually unnecessary.

Chapter 120

BEGONIAS

HISTORY

The begonias are a large group of cultivated ornamental plants with many beautiful hybrids and variations. These plants are indigenous to Mexico, Central and South America, Asia, and South Africa; begonias were introduced into England during the late 18th century as an ornamental plant.

BOTANICAL DESCRIPTION

Common Name: Wax Begonia

Scientific Name: *Begonia semperflorens* Link & Otto

Botanical Family: Begoniaceae (begonia)

Physical Description: Begonias have fibrous or tuberous tubers and simple, alternate, broad leaves with lobed margins. The color and texture of the leaves are highly variable. The stems are thick and the leaves shiny. Small white, pink, or red flowers appear as two small and two large petal-like parts in axillary clusters. There are many stamens. The inconspicuous fruit is a winged capsule.

Distribution and Ecology: This native of tropical parts of Central and South America is widely cultivated throughout temperate zones.

Common Name: Tuberous or Non-stop Begonia

Scientific Name: *Begonia* x. *tuberhybrida*

Botanical Family: Begoniaceae (begonia)

Physical Description: This hybrid appears similar to *B. semperflorens* with flowers displaying a variety of colors (white, pink, salmon, yellow, orange)

Distribution and Ecology: This tuber is cultivated as an ornamental plant in a wide variety of temperate climates.

EXPOSURE

This plant is a common ornamental plant in temperate climates. Cucurbitacin compounds from begonias have been tested in *in vitro* antitumor assays because of the ability of these compounds to depolymerize F-actin in proliferating endothelial cells and thereby disrupt the cytoskeleton.[1] However, the relatively low therapeutic index of these compounds limits the medical use of cucurbitacins.

PRINCIPAL TOXINS

The tuber of the begonia contains calcium oxalate crystals, which are potential mucosal irritants when ingested. The alcoholic extract of the *Begonia* x *tuberhybrida* contains cucurbitacin B along with minor amounts of cucurbitacin D and dihydrocucurbitacin.[2] Rhizomes of the starleaf begonia (*Begonia heracleifolia* Cham. & Schlecht.) from Southern Mexico contain at least six cucurbitacin compounds including cucurbitacin B, cucurbitacin D, 23,24-dihydrocucurbitacin D, 23,24-dihydrocucurbitacin F, 2-*O*-β-glucopyranosylcucurbitacin B, and 2-*O*-β-glucopyranosylcucurbitacin F.[3]

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Cucurbitacin compounds are cytotoxic sesquiterpenoid sterols that inhibit the steroid hormones (ecdysteroids) in insects responsible for the regulation of many developmental, biochemical, and physiological processes.[4,5] These compounds occur primarily in the families Cucurbitaceae (gourd) and Brassicaceae (mustard). Cucurbitacin compounds are very bitter.

DOSE RESPONSE

Most adverse reactions to begonias result from individual hypersensitivity responses rather than direct toxicity with the exception of irritant contact dermatitis.

TOXICOKINETICS

There are few data on the toxicokinetics of cucurbitacin compounds in begonias.

CLINICAL RESPONSE

Begonias are relatively safe houseplants with little serious toxicity following exposure. Most oral exposures to begonia plants result in no symptoms. The tuber contains calcium oxalate crystals that potentially cause mucosal erythema, pain, and edema when ingested. Systemic symptoms do not usually develop after exposure to begonias. Contact with begonia plants is a rare cause of allergic dermatitis, and most contact dermatitis from exposure to begonia plants results from an irritant contact dermatitis.[6] Rarely, exposures to begonias are a source of occupational dermatitis.[7]

DIAGNOSTIC TESTING

Liquid chromatographic/mass spectrometric methods are available for the quantitation of the chemotherapeutic drug, cucurbitacin I, in plasma with a limit of quantitation of about 10 ng/mL.[8]

TREATMENT

Treatment is supportive. Most exposures to this plant cause no symptoms. Irritation of the mucosa can be treated with topical anesthetics [Chloraseptic® (Proctor & Gamble Pharmaceuticals, Cincinnati, OH), Cepacol lozenges® (Bayer Consumer Care, Morristown, NJ), Orabase® (Colgate-Palmolive Company, New York, NY)]. Decontamination measures are unnecessary.

Chapter 121

YELLOW BIRD-OF-PARADISE
[*Caesalpinia gilliesii* (Hook.) Wallich ex D. Dietr.]

BOTANICAL DESCRIPTION

Worldwide, there are over 150 species in the genus *Caesalpinia*. *Caesalpinia pulcherrima* L. Sw. (pride-of-Barbados, dwarf poinciana) is a smaller *Caesalpinia* species. *Caesalpinia* is primarily a tropical genus found in lowland rain forests or open, dry scrub areas.

Common Name: Bird-of-Paradise, Paradise Poinciana, Yellow Bird-of-Paradise, Desert Bird-of-Paradise

Scientific Name: *Caesalpinia gilliesii* (Hook.) Wallich ex D. Dietr.

Botanical Family: Fabaceae (pea)

Physical Description: This large, irregular shrub reaches 5–10 ft (~2–3 m) in height and spreads to 4–6 ft (~1– 2 m). The sparsely branched, alternate leaves are pinnate with numerous small leaflets resembling a fern. The long, showy, glandular flowers have bright red stamens that produce a tan, fuzzy pod.

Distribution and Ecology: *C. gilliesii* is a native of South America introduced into the warmer areas of the southern portions of the United States as an ornamental plant.

EXPOSURE

C. gilliesii and *C. pulcherrima* are cultivated as ornamental plants for their showy yellow, orange or red blossoms with brilliant red stamens. Aqueous extracts of *C. gilliesii* have been investigated for antitumor activity as part of routine screening programs,[1] but there are no current clinical applications for extracts of this plant. In India and the Philippines, *C. pulcherrima* is a common ornamental shrub. This plant has a variety of medicinal uses in India including anthelminthic, antispasmodic, antipyretic, hemostatic agent, abortifacient, and treatment for liver disease and mental disorders.

PRINCIPAL TOXINS

The main toxic constituents in *Caesalpinia* species are probably tannins. Analyses of *C. pulcherrima* indicate that this plant contains a variety of flavanoid and diterpene compounds including pulcherralpin, bonducellin, isobonducellin, caesaldekarin A, spathulenol, caryophyllene oxide, phytol, and sitosterol.[2–4] The pulcherralpin, tannins, and irritant diterpenoids in this plant cause dermatitis and gastrointestinal (GI) irritation.

DOSE RESPONSE

There are insufficient data on the toxic constituents of *Caesalpinia* species to determine a dose response between parts of this plant and clinical effects.

TOXICOKINETICS

There are few toxicokinetic data on the tannins, flavanoid, or diterpenoid compounds in these plants.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

CLINICAL RESPONSE

There limited human data on the ingestion of seeds or parts of *Caesalpinia* species. Based on the presence of tannins, the primary adverse effects of exposure to these plants are probably GI irritation including nausea, vomiting, and diarrhea. Severe systemic symptoms are unusual, and the persistence of symptoms beyond 24 hours suggests another etiology.

DIAGNOSTIC TESTING

Biomarkers of GI toxicity associated with the ingestion of parts of these plants have not been identified.

TREATMENT

Treatment is supportive with efforts directed toward the assessment and correction of fluid and electrolyte balance. Gastrointestinal decontamination is unnecessary because of the irritant effects of this plant on the GI tract.

Chapter 122

CENTURY PLANT
(*Agave americana* L.)

HISTORY

The fermented beverage, pulque, was depicted in Native American stone carvings from 200 AD.[1] This native plant of Mexico and the southwestern United States was introduced into Europe during the 16th century as an ornamental plant, and now this plant occurs throughout the Mediterranean region. *Agave* species were an important food source and commodity for both prehistoric and historic Native American peoples across the Southwest and Mexico. *Agave tequilana* A. Weber (i.e., an *Agave* species other than the century plant) is an important distillation stock for tequila liquors.

BOTANICAL DESCRIPTION

The Agavaceae family contains about 20 genera and 300 species with about 200 species inhabiting Mexico.

Common Name: Century Plant, American Agave, American Century Plant, Maguey Americano

Scientific Name: *Agave americana* L.

Botanical Family: Agavaceae

Physical Description: This large plant has a low basal rosette composed of thick succulent leaves up to 6 ft (~2 m) in length that contain hooked spines along the margins. The flowering stalk appears after 10 or more years, and this stalk may reach 15–20 ft (~5–6 m) in height. Some varieties have yellow or white stripes. The plant dies shortly after flowering. The plant is nearly stemless.

Distribution and Ecology: *Agave americana* is a native of Mexico that has been naturalized into open, arid areas in a variety of soils of the southwestern United States and California.

EXPOSURE

This plant is a popular ornamental in warm areas. The stems of the century plant are also consumed by native peoples after cooking. The stems are then chewed for the sweet juice before expectorating the residue. *Agave* species are sources of popular food (quiote), fermented beverages (pulque), and distilled products (tequila). Tequila is produced by the distillation of fermented juice from the heads (i.e., leafless stem) of *Agave tequilana* A. Weber and up to 49% additional sugars (sugar cane, molasses, hydrolyzed maize syrup). Tequilas differ as a result of variation in the proportion of agave material (i.e., 51–100%), strain of fermenting bacteria, production processes, distillation equipment, aging times, and growing conditions. The ethanol content ranges from about 40% to 55%. The production process involves cooking to hydrolyze inulin to fructose in stone ovens or autoclaves, extraction of sugars from the cooked agave by milling, bacterial fermenting to convert the sugars to ethanol and organoleptic compounds, and a two-step distillation of the fermented wort using pot stills or rectification columns.[2] The head of an 8- to 9-year-old *Agave tequilana* contains high concentrations of the linear fructose polymer, inulin, compared with other *Agave* species. Mezcal is a rudimentary

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

fermentation and distillation product of *Agave potatorum* Zucc. or *Agave angustifolia* Haw. from the Mexican state of Oaxaca. During the production process some brands of mezcal add a worm to the bottle, primarily as a commercial ploy.

Pulque is a viscous fermentation product of several *Agave* species (*A. atrovirens* Karw. ex Salm-Dyck, *A. salmiana* Salm-Dyck) that results from the actions of a complex series of yeasts and bacteria. Because the product is not distilled or pasteurized, pulque deteriorates relatively quickly. The ethanol content of this fermentation product ranges from approximately 4–6%.[3] Fibers from *Agave fourcroydes* Lemaire and *Agave sisalana* Perrine are used to form rope and carpets. Folk uses for *Agave* species include diuresis, purgative, treatment of rheumatism, and birth control.[1]

PRINCIPAL TOXINS

The agave plant contains calcium oxalate crystals that produce local irritation upon contact with mucosal or dermal surfaces along with oxalic acid, saponins, and acrid volatile oil. *Agave* species including *A. americana* contain hecogenin and tigogenin, which previously was used as a natural precursor for the synthesis of corticosteroids.[4] Other compounds include steroidal saponins (agamenosides) and cholestane steroids (agavegenin).[5] The sap contains saponins and needle-like raphides composed of calcium oxalate crystals that probably contribute to the development of the irritant contact dermatitis (agave worker's disease).[6] Histological examination of skin lesions demonstrate spongiotic dermatitis with superficial and deep perivascular lymphohistiocytic infiltrates with occasional eosinophils.[7]

CLINICAL RESPONSE

Dermal contact with the sap of the century plant produces an acute irritant contact dermatitis.[8] Case reports indicate that the direct application of the sap from the century plant produces the immediate onset of a burning sensation followed by the development of a confluent vesiculopapular rash and an exudative dermatitis of the area in contact with the sap.[9] Rarely, the vesiculopapular rash progresses to purpura suggestive of a leukocytoclastic or purpuric vasculitis.[10,11] Biopsies of the affected skin demonstrate superficial perivascular infiltrates, superficial crusts, spongiosis, extravasated erythrocytes, and mild suppurative folliculitis.[12]

Systemic symptoms following contact with the sap are unusual, but mild fever and nonspecific constitutional symptoms can occur.[7,13] Direct contact with the oral mucosa causes inflammatory lesions. Symptoms following the chewing of unprocessed leaves from the century plant include intraoral erythema and edema. Mechanical trauma following contact with agave spines usually heals without infections, although rarely infections develop involving common plant organisms (e.g., *Enterobacter agglomerans*). Because of the high fiber content of *Agave* species, phytobezoars may develop following the chronic ingestion of material from *Agave* species.[14] Typically, the cooked stems are masticated to extract the sweet juice and the remainder is expectorated.

DIAGNOSTIC TESTING

Agave spines appear as elongated low-signal-intensity lesions during magnetic resonance imaging (MRI).[15]

TREATMENT

Treatment is supportive. The irritant contact dermatitis usually responds to topical steroids (0.05% fluocinonide) and oral antibiotics are not usually necessary. Gastrointestinal decontamination measures are unnecessary.

Chapter 123

CLEISTANTHIN, DITERPENE ESTERS, and the SPURGE FAMILY
(Euphorbiaceae)

HISTORY

Many species in the spurge family (Euphorbiaceae) contain a milky sap that is mildly toxic and irritating to the skin. The name derives from Euphorbus, the physician to King Juba II of Mauritania (50 BC–23 AD), who discovered the therapeutic properties of Euphorbiaceae plants grown in nearby mountains. Passages from the Greek herbalist, Dioscorides, and by the Roman writer, Pliny the Elder, suggest that the sap from *Euphorbia* species has long been used to treat skin diseases.[1] During the Medieval Ages, the acrid yellow-brown resin from several *Euphorbia* species (euphorbium) was an irritant remedy brought to Europe by Arab traders from Morocco. *Euphorbium* was used as a vesicant plaster and a sneezing powder during the Renaissance. Some species of the spurge family contain potent systemic toxins including *Ricinus communis* L. (ricin) and *Cleistanthus collinus* (Roxb.) Hook. f. (cleistanthin A and B, diphyllin, collinusin). The extracts of these two species are ancient homicidal agents in India. The poinsettia is a member of the *Euphorbia* genus that was introduced into the United States in the 1800s by the American Ambassador to Mexico, Joel R. Poinsett, and this plant has been a popular ornamental since the early 1900s.

BOTANICAL DESCRIPTION

Euphorbiaceae is a highly diversified family with substantial differences in morphologically, chemical, and ecological characteristics. This family is widely distributed throughout both hemispheres with approximately 8,000 species ranging from large desert succulents to small herbaceous plants and trees in grasslands and forests. The presence of latex (milky sap) is characteristic of plants from the spurge family. This milky sap is mildly irritating to the skin. In general, the leaves are small and the flowers are inconspicuous. African milkbush (*Synadenium grantii* Hook. f.) plants are closely related to *Euphorbia* species.

Common Name: Poinsettia
Scientific Name: *Euphorbia pulcherrima* Willd. ex Klotzsch
Botanical Family: Euphorbiaceae (spurge)
Physical Description: This popular indoor Christmas ornamental plant has large (3–6 in./~8–15 cm) alternating leaves and prominent red, pink, yellow, or cream bracts clustered at the tops of the stems.
Distribution and Ecology: Poinsettia is native to the tropical areas of Central America and Mexico, but now this plant is cultivated worldwide in temperate climates or indoors.

Common Name: Candelabra Cactus, Mottled Spurge
Scientific Name: *Euphorbia lactea* Haw.
Botanical Family: Euphorbiaceae (spurge)
Physical Description: This plant is a multibranched succulent with serrated edges.
Distribution and Ecology: This ornamental plant from tropical areas is often grown as a houseplant.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Common Name: Pencil Tree, Milk Bush, Malabar Tree, Indiantree Spurge

Scientific Name: *Euphorbia tirucalli* L.

Botanical Family: Euphorbiaceae (spurge)

Physical Description: This spineless, succulent shrub has green branching stems and a few, small, linear leaves confined to the branch tips. The finely striated branches form dense, tangled masses.

Distribution and Ecology: This ornamental plant is found in tropical habitats and is often grown as a houseplant.

Common Name: Crown of Thorns

Scientific Name: *Euphorbia milii* Des Moulins

Botanical Family: Euphorbiaceae (spurge)

Physical Description: This spiny, woody plant grows as a shrub up to 4 ft (~1 m) high with attractive small floral bracts one centimeter across.

Distribution and Ecology: This ornamental plant is found in tropical areas, and is often grown as a houseplant.

Common Name: African Milkbush

Scientific Name: *Synadenium grantii* Hook. f.

Botanical Family: Euphorbiaceae (spurge)

Physical Description: This succulent shrub has obovate, red-tinged leaves, short stalks, and dark red clusters of flowers. The shrub may reach 12 ft (~4 m) in height.

Distribution and Ecology: The African milkbush is a succulent shrub that is indigenous to East Africa, Madagascar, and the Mascarene Islands.

Common Name: Oduvan, Garari, Karada, Pasu, Karlajuri

Scientific Name: *Cleistanthus collinus* (Roxb.) Hook. f.

Botanical Family: Euphorbiaceae (spurge)

Physical Description: This bushy, thorny shrub has dark brown bark and long spines.

Distribution and Ecology: *Cleistanthus collinus* is a native plant of India, Malaysia, and Africa.

Common Name: Dog's Mercury

Scientific Name: *Mercurialis perennis* L.

Botanical Family: Euphorbiaceae (spurge)

Physical Description: This plant has serrated, opposite leaves and clusters of flowers on a central stalk.

Distribution and Ecology: Dog's mercury is a woodland plant indigenous to Britain.

Common Name: Annual Mercury

Scientific Name: *Mercurialis annua* L.

Botanical Family: Euphorbiaceae (spurge)

Physical Description: This slender, erect annual reaches up to 60cm (~2 ft) in height. The leaves are ovate to oblong leaves within serrated margins. Flowers appear in the spring. The male flowers are long, terminal inflorescences, whereas female flowers occur in the upper leaves.

Distribution and Ecology: Annual mercury is a common weed found in uncultivated areas of California, northeastern United States, Alabama, and South Carolina. This annual herb was introduced into the United States.

EXPOSURE

Many species of the spurge family are houseplants and ornamental plants in temperate climates including *Synadenium grantii, Euphorbia lactea, and Euphorbia tirucalli*. In India, the extract of crushed oduvan leaves (*Cleistanthus collinus*) has been used as an abortifacient, animal poison, suicidal agent, and homicidal agent. Plants from the Euphorbiaceae family have been used for many centuries in Indian and Brazilian traditional medicine for the treatment of tumors, metastatic cancer, and a depilatory for the removal of skin blemishes and warts.[2] Resiniferatoxin is a potent capsaicin analog isolated from the sap of *Euphorbia resinifera* O. Berg that interacts with vanilloid receptors and reduces neurogenic inflammation. Recently, the administration of resiniferatoxin has been investigated as an alternative therapy for neurogenic and nonneurogenic forms of detrusor overactivity in the bladder.[3]

PRINCIPAL TOXINS

Physiochemical Properties

Toxins from the Euphorbiaceae family belong to a group of diterpene hydrocarbons that include tigliane, daphnane, and ingenane groups that demonstrate irritant and tumor-promoting activities.[4] Oxygenated derivatives of macrocyclic diterpenes with effects similar to toxins in these groups include the following diterpene types: casbane, jatrophane, lathyrane, jatropholane, and crotofolane.[5] Potential irritants in the sap of plants from the spurge family include a variety of diterpene esters (e.g., phorbols, ingenols, daphnanes). The poinsettia plant (*E. pulcherrima*) contains small amounts of triterpenes compounds (e.g., 9,19-cycloart-25-ene-3β, 24-diol; 9,19-cycloart-23-ene-3β, 25-diol) that possess cytotoxic properties as demonstrated in tumor cell cultures.[6] The

concentration of skin and gastrointestinal irritants in the milky sap varies between *Euphorbia* species.[7] The latex of *Euphorbia tirucalli* originating from Madagascar contains irritant constituents (e.g., ingenane- and tigliane-type diterpene esters) derived from the parent alcohols, ingenol and phorbol.[8] The main irritant constituents are isomeric 12,13-acetates, acylates of phorbol and 3-acylates of ingenol, whereas other *Euphorbia* species contain higher concentrations of 4-deoxyphorbol esters in their latex.[9] The latex of *Synadenium grantii* contains an unusual irritant ester of 4-deoxyphorbol, 12-*O*-tigloyl-4-deoxyphorbol-13-isobutyrate.[10] The active principle in Dog's mercury is thought to be the volatile basic oil mercurialine. Latex from several species in the spurge family including the sandbox tree (*Hura Crepitans* L.)[11] and the Mediterranean spurge (*Euphorbia characias* L.)[12] contains ribosome-inactivating proteins (ribotoxins), but the role of these chemicals in causing toxicity is unclear. These lectins share a similar mechanism of action to ricin, but the lectins from the *Euphorbia* species are less potent. *In vitro* studies suggest that some members of the spurge family contain variable amounts of tumor-promoting (nongenotoxic) phorbol esters, but the clinical relevance of these substances is unclear.[13,14]

The major toxic compounds in *Cleistanthus collinus* are the lignan lactone glycosides, cleistanthin A and B. The genin, diphyllin, is the major metabolite of these lignan lactone glycosides. The leaves of *C. collinus* also contain another lignan lactone glycoside (collinusin). Cleistanthin A (CAS RN: 25047-48-7) is a $C_{28}H_{28}O_{11}$ compound that is also known as sheng bai xin in traditional Chinese medicine. Cleistanthin B (CAS RN: 30021-77-3) is a $C_{27}H_{26}O_{12}$ compound that is structurally similar to Cleistanthin A. Figure 123.1 demonstrates the chemical structure of the major lignan lactone glycosides (Cleistanthin A and B), the major metabolite (diphyllin), and another lignan lactone glycoside (collinusin) present in the leaves of *C. collinus*.

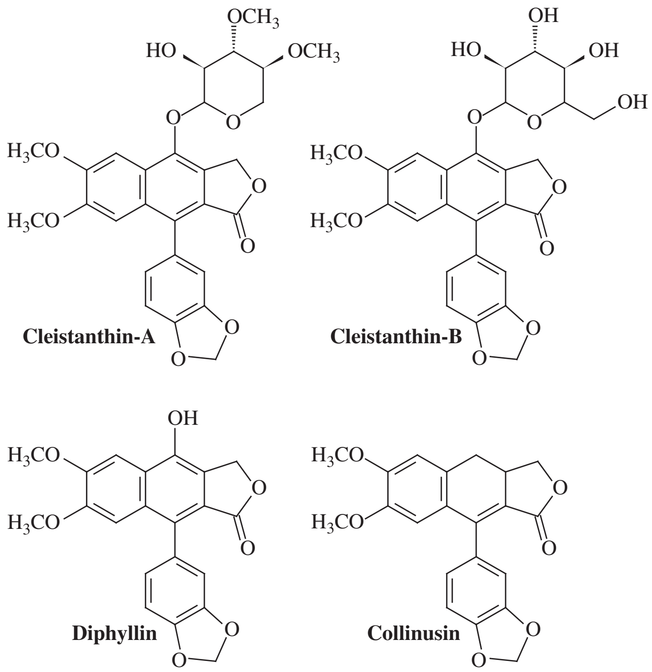

FIGURE 123.1. Chemical structures of *Cleistanthus collinus* toxins.

Poisonous Parts

Unicellular or multicellular tubes (laticifers) in the stems, leaves, and fruits of species from the spurge family produce the milky latex seen following damage to these plant parts. Within the sap are esters of polycyclic diterpene alcohols, but the identity of the exact irritant compound remains unclear. Ingenol and ingenol esters are common compounds in members of the spurge family, and ability of these diterpenes to activate protein kinase C may contribute to the toxicity of these plants.[15] Although most parts of the oduvan plant (*Cleistanthus collinus*) contain toxic arylnaphthalene lignan lactones (cleistanthin A and B, collinusin), the most serious poisonings occur following ingestion of the extract of the leaves.[16]

Mechanism of Toxicity

The primary mechanism for the development of vesiculopapular lesions following contact with the sap from the spurge family commonly involves an irritant contact dermatitis rather than an allergic response.[17] Mechanical irritation may occur following contact with stiff hairs, but the clinical consequences of this exposure is usually minimal.

The toxicity of *Cleistanthus collinus* results from the cytotoxic effects of lactones on a number of cellular, tissue, and organ systems. In experimental studies, cleistanthin A inhibits DNA synthesis, induces DNA damage, and causes apoptosis.[18] These genotoxic properties have been evaluated as potential chemotherapeutic agents.[19] The severe hypokalemia results from the renal tubular loss of potassium rather than intracellular translocation of the potassium.[20]

DOSE RESPONSE

Parts of the poinsettia plant are relatively nontoxic based on animal studies and human case series. The feeding of fresh leaves and bracts of poinsettia plants in doses up to 125 mg/kg over 5 days did not produce any alterations of behavior, pathological changes in the gas-

trointestinal tract, or decrease in weight when compared with controls.[21,22] Repeated exposure of albino rats to poinsettia plant materials resulted in mild skin irritation and skin photosensitivity, but there was minimal mucosal irritation.[23]

CLINICAL RESPONSE

Local

Exposure to the sap from the *Euphorbia* plants (e.g., poinsettia) produce primarily an irritant contact dermatitis manifest by erythema, edema, and urticaria.[24,25] The ability of species from the spurge family to cause erythematous papulovesicular skin lesions varies with individual species. Other spurge species capable of causing an irritant contact dermatitis following exposure to the sap include the croton [*Codiaeum variegatum* (L.) Blume],[26] African milk bush (*Synadenium grantii*),[10,27] *Euphorbia milii* (crown-of-thorns), *E. trigona* Mill. (African Milk Tree),[28] *E. lactea* (candelabra cactus), *E. tirucalli* (pencil tree), *E. marginata* Pursh (snow on the mountain),[29] and *Euphorbia myrsinites* L. (cushion spurge).[30,31] During the chronic phase of healing, hyperpigmentation can develop in the areas of vesiculobullous eruptions.[32] Rarely, mucosal ulceration may occur after prolonged contact with the sap of *Euphorbia* species including the poinsettia plant.[33] Contact of the eye with sap from *E. lactea* (candelabra cactus),[34] *E. cyparissias* L. (cypress spurge), *E. helioscopia* L. (madwoman's milk), *E. lathyris* L. (moleplant), *E. peplus* L. (petty spurge), or *E. tirucalli* (pencil tree) can produce mild to moderately severe keratoconjunctivitis and uveitis.[35,36] Symptoms of irritation include immediate conjunctival burning, tearing, and photophobia. Chemosis of the conjunctiva may develop within 8–12 hours after exposure along with increased pain and blurred vision as epithelial sloughing occurs. The healing of corneal ulcerations may require up to 9 days.[37] Rarely, uveitis occurs that usually responds to steroid therapy without the development of permanent corneal damage.[38]

Systemic

Most exposures to plants from the spurge family do not produce systemic symptoms other than mild gastrointestinal irritation. Self-limited, spontaneous vomiting may occur following ingestion of the poinsettia plant, but systemic symptoms of toxicity do not usually occur[39] contrary to the older medical literature.[40,41] Exposure to plant parts from a few species of the Euphorbiaceae family causes systemic toxicity. In addition to the castor bean plant (*Ricinus communis* L.), ingestion of extracts of *Cleistanthus collinus* produces serious cardiotoxicity.[42] Clinical manifestations of severe intoxication from *C. collinus* include gastrointestinal distress, neuromuscular weakness with respiratory failure, renal dysfunction, metabolic acidosis, severe hypokalemia, serious ventricular dysrhythmias, and sudden death.[16] The onset of clinically significant organ dysfunction usually occurs several days after ingestion, and serious cardiac abnormalities are usually associated with severe hypokalemia (i.e., <2 meq/L).[43]

Ingestion of boiled stems and leaves from *Mercurialis perennis* (Dog's mercury) produced severe gastroenteritis, bilateral flank pain, anisocytosis, and trace hemoglobinuria without anemia or hepatorenal dysfunction.[44] In grazing animals, (e.g., cattle) excessive consumption of *M. perennis* causes methemoglobinemia and hemolytic anemia,[45] but these effects have not been reported in humans. Allergic responses may occur following exposure to pollens from *Mercurialis* species, including the development of respiratory allergies.[46] A case series of 18 Chinese patients associated the ingestion of a soup containing parts of *Breynia officinalis* Hemsley (Chi R Yun) from the Euphorbiaceae family with gastroenteritis (nausea, vomiting, diarrhea), mild hyperbilirubinemia, and elevated serum hepatic aminotransferases.[47] Progression to marked jaundice, ascites, and hepatic failure did not develop, and these patients recovered within 6 months. The latex from some Euphorbiaceae species are strongly sensitizing including the castor bean (*Ricinus communis* L.), the annual mercury (*Mercurialis annua*), and the rubber tree [*Hevea brasiliensis* (Willd. ex A.Juss.) Müll.Arg.]. There is substantial cross-reactivity with these allergenic species.[48]

DIAGNOSTIC TESTING

In experimental studies, an enzyme-linked immunosorbent assay (ELISA) has been developed in rabbits for the detection of the toxic lignan glycosides, cleistanthin A and cleistanthin B, present in serum after the ingestion of plant parts from *Cleistanthus collinus*.[49,50] This assay cross-reacts with other phytotoxins (e.g., diphyllin, collinusin) in this plant, but not with other plant toxins (e.g., digitoxin, digoxin, gitoxin, neriifolin, oleandrigenin, oleandrin, thevetin). The limit of detection is approximately 2 ng/mL.

Electrocardiographic abnormalities during severe intoxication by *C. collinus* reflect severe hypokalemia, including QT_c prolongation, ST wave depression, inverted T waves, and malignant cardiac rhythms (pulseless electrical activity, ventricular fibrillation, asystole). AV conduction block does not usually occur during *Cleistanthus collinus* leaf poisoning.[20] Case reports of *C. collinus* intoxication document clinically

significant laboratory abnormalities in addition to severe hypokalemia including coagulopathy, hyperchloremic anion gap metabolic acidosis, and alkaline urinary pH.[16]

TREATMENT

Treatment of local irritation secondary to the sap from species of the spurge family is supportive (e.g., removal of all plant material as soon as possible), particularly from the mouth. Skin irrigation and cleansing reduces the risk of minor irritation associated with exposure to irritant sap from species in Euphorbiaceae family. The use of demulcents (milk, antacids, cool water) may reduce the effects of the sap on the oral mucosa. Although healing may be delayed up to approximately 1 week, corneal erosions following contact with the sap of Euphorbiaceae species usually respond to topical antibiotics and pressure patching.[37]

Exposure to *Cleistanthus collinus* extract can produce severe cardiotoxicity and hypokalemia. These patients require intravenous access and cardiorespiratory monitoring for the development of malignant ventricular dysrhythmias, respiratory failure, and sudden cardiac arrest. Additionally, these patients should be monitored frequently for the development of fluid and electrolyte imbalance including hypokalemia. Decontamination measures are usually unnecessary because of the typical delay between ingestion and the onset of symptoms. The administration of activated charcoal to alert patients, who present to the emergency department less than 1 hour prior after ingestion, is a therapeutic option, but there are no clinical data to confirm the clinical efficacy of activated charcoal on outcome.

Substantial amounts of potassium may be excreted during intoxication, and these patients often require large doses of intravenous potassium as well as continuous monitoring of serum potassium and creatinine concentrations. Potassium replacement may be complicated by the development of renal failure. There are no clinical data on antidotes for *C. collinus* poisoning, although changes in glutathione stores during intoxication suggest a potential role for *N*-acetylcysteine.[51]

Chapter 124

CYANOGENIC PLANTS and LAETRILE®

HISTORY

From a toxicological perspective, amygdalin and the commercial extract, Laetrile®, are some of the most important natural cyanogenic substances. The ancient Egyptians probably used amygdalin extracted from peach pits as a means of capital punishment known as "penalty of the peach." In 1830, French chemists isolated the diglucoside of mandelonitrile, called amygdalin, from bitter almonds. Emulsin was the crude extract of bitter almond that contained the plant enzymes necessary to hydrolyze amygdalin and release hydrogen cyanide.

Laetrile® is a cyanide-containing substance allegedly synthesized by Ernst T. Krebs, Jr. that was registered with the US Patent Office for the treatment of certain intestinal disorders. Subsequently, this compound was marketed illicitly as an intravenous cancer chemotherapeutic agent.[1] Although Laetrile® was patented as mandelonitrile-β-glucuronide, analysis of samples of Laetrile® demonstrated mostly *d*-amygdalin, similar to the compound isolated by French chemists.[2] Laetrile® itself does not contain the hydrolytic enzymes present in emulsin necessary to release cyanide from amygdalin; therefore, the intravenous administration of laetrile does not usually produce hydrogen cyanide poisoning. The US Food and Drug Administration banned the sale of Laetrile® to consumers because this compound lacks efficacy as a chemotherapeutic agent. Additionally, the ingestion of laetrile is associated with a risk of cyanide toxicity in patients receiving this therapy.[3] Despite the legal ban on the use of Laetrile®, proponents of this compound continued to advocate the use of Laetrile® for cancer including labeling this compound, "vitamin B-17," and promoting of the use of Laetrile®, vitamins, and special diets as a natural cure for cancer. Interest in the "Laetrile Movement" peaked during the late 1970s following an adverse Supreme Court decision, the lack of efficacy in the National Cancer Institute (NCI) study on Laetrile®, and the cancer-related death of Steve McQueen despite his use of Laetrile® in a Mexican facility. However, illicit marketing of this compound continues.

BOTANICAL DESCRIPTION

The distribution of cyanogenic glycosides is widespread throughout the plant kingdom, occurring in at least 2,500 plants species. These plants reside primarily in the families Compositae, Fabaceae, Linaceae, and Rosaceae.[4] Amygdalin occurs primarily in Rosaceae species (peach, apricot, apple seeds), whereas the closely related compound, prunasin occurs in at least six plant families (Myoporaceae, Myrtaceae, Polypodiaceae, Rosaceae, Saxifragaceae, Scrophulariaceae).

Prunus Species

Common Name: Black Cherry

Scientific Name: *Prunus serotina* Ehrh.

Botanical Family: Rosaceae (rose)

Physical Description: Black cherry is an oval-shaped tree that reaches 60–90 ft (~18–27 m) in height. The drooping branches reach the ground. The fine-toothed, waxy, dark green leaves turn yellow, orange, and red before dropping in the fall. The

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

glabrous leaves are alternate, simple, and oval to oblong-lanceolate, being 5–15 cm (~2–6 in.) long and 2.5–5 cm (~1–2 in.) wide. Small, white blossoms appear in March to June, and produce a fleshy, round, purple fruit that attracts many birds from June to October.

Distribution and Ecology: This native North American species inhabits valleys and floodplains of the southwestern, midwestern, and eastern United States. This ornamental tree is an invasive species in European forests.

Common Name: Chokecherry, Common Chokecherry, Virginia Chokecherry

Scientific Name: *Prunus virginiana* L.

Botanical Family: Rosaceae (rose)

Physical Description: Mature plants reach up to 1–6 m (~3–18 ft) in height with smooth, reddish brown bark that turns gray with age. The bright green, hairless leaves are alternate and oblong with a pointed tip. Small white flowers appear in drooping clusters from May to June, and each flower produces a single-seeded red cherry that becomes red-purple upon maturity in August or September.

Distribution and Ecology: This native species occurs over most of Canada and the United States with the exception of the southern United States. This large shrub inhabits streams, river banks, wood edges, and open woods, particularly in the central and northern United States.

Common Name: Bitter Almond

Scientific Name: *Prunus amygdalus* Batch var. amara (DC.) Focke

Botanical Family: Rosaceae (rose)

Physical Description: The physical characteristics of the bitter almond and sweet almond are similar. The presence of substantial concentrations of amygdalin distinguishes the bitter almond from the edible sweet almond [*Prunus dulcis* (P. Mill.) D.A. Webb], which is grown commercially in California.

Distribution and Ecology: The bitter almond tree is a native of the temperate desert parts of Western Asia that spread westward to warm, dry areas in the Mediterranean region.

Elderberry

Common Name: European Black Elderberry

Scientific Name: *Sambucus nigra* L.

There are several subspecies of the European black elderberry including the blue elder (*Sambucus nigra* L. ssp. *caerulea* (Raf.) R. Bolli), the common elderberry (*Sambucus nigra* L. ssp. *canadensis* (L.) R. *Bolli*), and the European black elderberry (*Sambucus nigra* L. ssp. *nigra*).

Botanical Family: Caprifoliaceae (honeysuckle)

Physical Description: The common elderberry is a perennial shrub that grows up to about 4 m (~13 ft) in height. The large, compound leaves have 5–11, toothed, elliptical leaflets. Small white flowers appear in flat-topped clusters that produce purple-black berries. The twigs are hollow. The European elderberry is a small tree that produces larger fruit than the common elderberry.

Distribution and Ecology: The common elderberry is a native species of Canada and the eastern United States.

Hydrangea

This family contains 17 genera, and the genus, *Hydrangea*, contains about 23 species worldwide.

Common Name: Hydrangea

Scientific Name: *Hydrangea macrophylla* Ser. (cultivar)

Botanical Family: Hydrangeaceae (hydrangea)

Physical Description: This cultivated species is a deciduous shrub that reaches up to 2 m in height. The color of the flowers range from white, pink, mauve, and blue depending on soil conditions (e.g., pH). These flowers form beautiful, round clusters. The broad, deeply lobed leaves are alternate and relatively large (i.e., 10–25 cm/~4–10 in. in length). The underside of the leaf is pale green and lighter than the top. The capsular fruit contains many small, brown seeds.

Distribution and Ecology: *H. macrophylla* is a popular garden and ornamental plant in temperate climates. The wild varieties of hydrangea grow in shady, moist habitat in the eastern United States.

EXPOSURE

The almond is a drupe that is closely related to the peach, apricot, and cherry. Unlike these other fruits, the edible portion of the sweet almond is the seed rather than the outer layer. The bitter almond is not edible, but this tree is cultivated for the extraction of bitter almond oil, which is used in cosmetics and flavorings. The bitter almond seed is banned for consumption in the United States. A flavoring extract of the fragrant, bitter bark of the black cherry is a constituent of wild cherry cough

syrup. Black cherry wood has been used since colonial times in the United States for the construction of quality furniture. *Hydrangea chinensis* Maxim. is a Chinese medicinal plant used for the treatment of malaria and cardiovascular disease.

Laetrile® is a semisynthetic derivative of amygdalin. The US patent for Laetrile® defines this compound as D-mandelonitrile-β-glucuronide. The Mexican version of this product is D-mandelonitrile-β-gentiobioside, which is derived from crushed apricot pits.[5] Both parenteral and oral products may contain a variety of contaminates. Although there are inadequate data to support the use of Laetrile® as a chemotherapeutic agent,[6] illicit use of this substance in the United States continues from illicit sources.[7]

PRINCIPAL TOXINS

Physiochemical Properties

The cyanogenic glycosides, sambunigrin (*Sambucus* spp.), vicianin (*Vicia* spp.), and amygdalin (*Prunus* spp.) are structurally similar to prunasin (*Prunus* spp.) with the exception of the sugar moiety.

Bitter Almond

Amygdalin is the cyanogenic diglucoside, D-mandelonitrile-β-D-gentiobioside. The active form of amygdalin is the dextrorotatory (*R*) configuration, whereas the *S*-isomer (neo-amygdalin) is inactive. Only the former isomer occurs naturally. Amygdalin hydrolase and prunasin hydrolase are two glycosidases, which catalyze the hydrolysis of amygdalin in a stepwise reaction by removing two glucose residues and releasing benzaldehyde and hydrogen cyanide (HCN).[8] Amygdalin hydrolase removes the terminal glucose of amygdalin and forms the monoglucoside prunasin, which is subsequently hydrolyzed by prunasin hydrolase. These enzymes are released following the crushing of moistened kernels containing amygdalin hydrolase. Certain human intestinal bacteria may also possess glycosidase activity, so that ingestion of amygdalin in the absence of this plant enzyme can cause cyanide toxicity. *In vitro* studies indicate that the addition of β-glucuronidase to amygdalin does not liberate hydrogen cyanide.[9]

Black Cherry

In black cherry (*Prunus serotina* Ehrh.) seed homogenates, (*R*)-amygdalin is degraded to HCN, benzaldehyde, and glucose by the sequential action of amygdalin hydrolase, prunasin hydrolase, and mandelonitrile lyase during a two-step process.[10] Upon seed disruption, amygdalin hydrolase catalyzes the hydrolysis of the β-1,6-glycosidic bond of amygdalin, yielding prunasin and D-glucose. Similarly, the action of prunasin hydrolyase on prunasin forms mandelonitrile and D-glucose. The complete hydrolysis of amygdalin requires both enzymes from the maceration of the cherry seeds. Subsequently, mandelonitrile dissociates either spontaneously or enzymatically in the presence of the α-hydroxynitrile lyase, mandelonitrile lyase, generating HCN and benzaldehyde.[11] In a similar way in disrupted black cherry leaves, prunasin hydrolase and mandelonitrile lyase degrade prunasin to HCN.

Elderberry

Sambunigrin is the main cyanogenic glycoside present in *Sambucus* species, but many species and strains of this genus do not contain cyanogenic glycosides.[12] The galactose-specific lectin, nigrin b, is a constituent of elderberry bark that contains a two-chain structure similar to ricin. However, the inhibitory enzymatic activity of nigrin b on ribosomes and protein synthesis is substantially less than ricin.[13] Elderberries contain relatively high concentrations of anthocyanin compounds (e.g., cyanidin-3-glucoside, cyanidin-3-sambubioside), which are food colorants with antioxidant properties.[14]

Hydrangea

Hydrangea species produce alkaloids, steroids, triterpenes, isocoumarins, secoiridoid glycosides, and flavanoids.[15] The isocoumarin fraction contains hydrangenol, a strong contact sensitizer.[16] Two secoiridoid glucoside complexes, hydramacrosides A and B possess some antihistamine properties.[17]

Poisonous Parts

Prunus Species

Bitter Almond. In a review of several studies on the HCN content of bitter almond, the estimated amount of HCN released from bitter almond was 0.8–4.7 mg/g.[9] Analysis of a homemade spirit produced from soaking chokecherries demonstrated cyanide concentrations of about 0.045 mg/g.[18]

Black Cherry. Like other rosaceous stone fruits, the leaves, bark, seeds, and immature fruits in black cherry accumulate the cyanogenic monoglucoside, (*R*)-prunasin.[10] The leaves are particularly cyanogenic because they possess prunasin hydrolase and mandelonitrile lyase in addition to (*R*)-prunasin. The related diglucoside, (*R*)-amygdalin, also occurs in high concentrations in the cotyledons of the mature seeds.[19] A study

of seed development indicated that amygdalin concentrations in the cotyledon declined by about 80% during the first 3 weeks following imbibition.[20] Although prunasin was not present in mature, nongerminated seeds, the seedling epicotyls, hypocotyls, and cotyledons did contain this monoglucoside compound. The mature fruit is edible when the seeds are discarded prior to consumption.

CHOKECHERRY. Although a case report in the older medical literature associated the ingestion of a large quantity of chokecherry seeds with a fatal intoxication similar to cyanide poisoning,[21] there are few data in the modern literature to indicate that chokecherries contain sufficient cyanide to produce serious toxicity. In Italy, chokecherries are soaked in alcohol to produce homemade spirits. A case report associated the onset of obtundation, respiratory insufficiency, and metabolic acidosis with the ingestion of 300 g chokecherries steeped in alcohol the previous evening.[22] Laboratory analysis of the chokecherries and the associated liqueur demonstrated cyanide concentrations of approximately 0.005–0.015 mg/g cherries and about 0.045 mg/g liqueur.

ELDERBERRY

The content of cyanogenic glycosides in American species of *Sambucus* varies much more than European species.[23] Although the mature elderberries are edible, leaves, stems, and especially roots contain cyanogenic glycosides. The consumption of a drink distilled from the crushed leaves, stems, and berries of an elderberry bush produced nausea, vomiting, abdominal pain, weakness, and numbness, but cyanide concentrations and metabolic acidosis were not demonstrated in these patients.[24]

Mechanism of Toxicity

Cyanogenic glycosides of these plants consist of a α-hydroxynitrile aglycone and a sugar moiety (e.g., D-glucose). Hydroxylation of nitriles to α-hydroxynitrile followed by glycosylation forms the cyanogenic glycosides. The initial metabolism of cyanogenic glycosides involves the cleavage of the carbohydrate moiety by one or more β-glycosidases, which yield the corresponding α-hydroxynitrile.[25] Hydroxynitrile compounds may decompose either spontaneously or enzymically in the presence of a hydroxynitrile lyase to produce hydrogen cyanide and an aldehyde or ketone. The separation of cyanogenic glycosides and the degrading enzymes in different compartments of the plant prevents the formation of significant amounts of cyanide until the physical disruption of the plant compartments. The production of cyanide occurs rapidly only when maceration of cyanogenic glycoside-containing plant tissues allows contact between these glycosides and the corresponding enzymes.

DOSE RESPONSE

Predicting toxicity of cyanogenic glycoside-containing products is difficult because of the variation in the content both of cyanogenic glycosides and degrading enzymes. The intravenous (IV) administration of Laetrile® does not usually produce cyanide poisoning because of the lack of hydrolytic enzymes to cleave hydrogen cyanide from the cyanogenic glycosides. Case reports suggest that the concomitant ingestion of cyanogenic glycosides and amygdalin hydrolase from foods (e.g., crushed bitter almond kernels) can cause fatal cyanide toxicity.[26] Frequently, the amygdalin content in illicit pharmaceutical formulations of Laetrile® varies significantly.[2,9] Laetrile® is much more toxic via the oral than the intravenous (IV) route of administration. The oral administration of 500 mg amygdalin to six volunteers 3 times daily produced blood cyanide concentrations up to 2.1 μg/mL, but there was no clinical or laboratory evidence of a toxic reaction.[27] A case report associated a fatal ingestion of an estimated dose of 45 mL or 10.5 g of an intravenous solution of Laetrile® with the immediate onset of severe headache, dizziness, coma, and convulsions.[28] Another case report indicated that an estimated ingestion of 0.5–2.5 g of Laetrile® (amygdalin) tablets by an 11-month-old child caused vomiting and listlessness within $\frac{1}{2}$ hour followed quickly by obtundation, depressed respirations, shock, and death 72 hours after ingestion.[29] An 18-year-old man developed coma, respiratory insufficiency, and hypotension following the ingestion of 3 grams (30 tablets) of Laetrile®.[30] He survived with supportive care.

The ingestion of vitamin C with amygdalin potentially increases the conversion of amygdalin to cyanide and reduces the detoxifying effects of cysteine. The ingestion of 3 grams amygdalin along with the daily use of 4.8 g vitamin C resulted in the development of severe cyanide poisoning (severe lactic acidosis, coma, respiratory failure).[31]

Ingestion of 12 bitter almonds produced vomiting, abdominal pain, coma, lactic acidosis, and transient pulmonary edema within 15 minutes after ingestion.[32]

TOXICOKINETICS

Absorption/Distribution

There are few human data on the toxicokinetics of cyanogenic glycosides. Limited animal studies suggest that

the gastrointestinal tract poorly absorbs (i.e., <3%) oral doses of amygdalin, whereas the oral bioavailability of prunasin is about 50%.[33] In animal models, the occurrence of peak whole blood cyanide concentrations after oral administration of amygdalin and linamarin depends on the rate of enzymatic hydrolysis. A study of female golden Syrian hamsters indicates that peak whole blood cyanide concentrations following the oral administration of amygdalin and linamarin occur 1 hour and 3 hours after administration, respectively.[34] The protein binding of amygdalin is minimal.

Biotransformation/Elimination

The biotransformation of cyanogenic glycosides begins with the cleavage of the carbohydrate moiety by one or more β-glycosidases that form α-hydroxynitrile. Depending on the plant species, two distinct pathways involve 1) the hydrolysis of cyanogenic disaccharides by the stepwise removal of the sugar residues, and 2) hydrolysis of the aglycone-disaccharide bond producing mandelonitrile and the corresponding disaccharides.[25] Figure 124.1 demonstrates these two pathways. Hydrolysis of amygdalin produces the active metabolite, prunasin (D-mandelonitrile-β-D-glucoside). Animal studies indicate that the elimination of amygdalin is rapid with most of absorbed dose (62–96%) excreted in the urine during the first 24 hours after ingestion as unchanged drug.[27,35] The hepatic excretion of amygdalin is relatively small compared with renal excretion.[36] Following intravenous administration of 500 mg amygdalin to 6 terminal cancer patients, the mean elimination half-life of amygdalin was approximately 1–2 hours with a mean plasma clearance of about 100 mL/min.[37]

CLINICAL RESPONSE

The clinical features associated with the acute ingestion of cyanogenic glycosides mimics cyanide poisoning, and the severity of the intoxication correlates to the dose of active cyanogenic compounds. The onset of vomiting, abdominal pain, weakness, dyspnea, diaphoresis, and lightheadedness followed by convulsions, stupor, disorientation, hypotension, metabolic acidosis, coma, respiratory failure, and cardiovascular collapse develops after exposure to high doses of cyanogenic glycoside-containing foods[38,39] and from the ingestion of Laetrile®.[26,40] Symptoms typically start within $\frac{1}{2}$ hour of consumption and progress quickly. A case series of wild apricot seed ingestions by Turkish children associated the sudden onset of vomiting and crying followed by fainting, lethargy, and coma with the ingestions.[41]

Rare case reports associate contact with hydrangeas with the development of contact dermatitis. Hydrangeas contain a strong contact sensitizer, hydrangenol, which causes chronic contact dermatitis (scaly erythema, painful fissures), particularly in the hands of workers chronically exposed to hydrangeas.[42–44]

DIAGNOSTIC TESTING

Analytical Methods

Methods to detect amygdalin include thin layer chromatography, high performance liquid chromatography (HPLC), and gas chromatography/mass spectrometry (GC/MS).[45] Amygdalin and prunasin can be quantitated in biological samples (urine, plasma) by HPLC on a reversed phase column with detection at 215 nm and

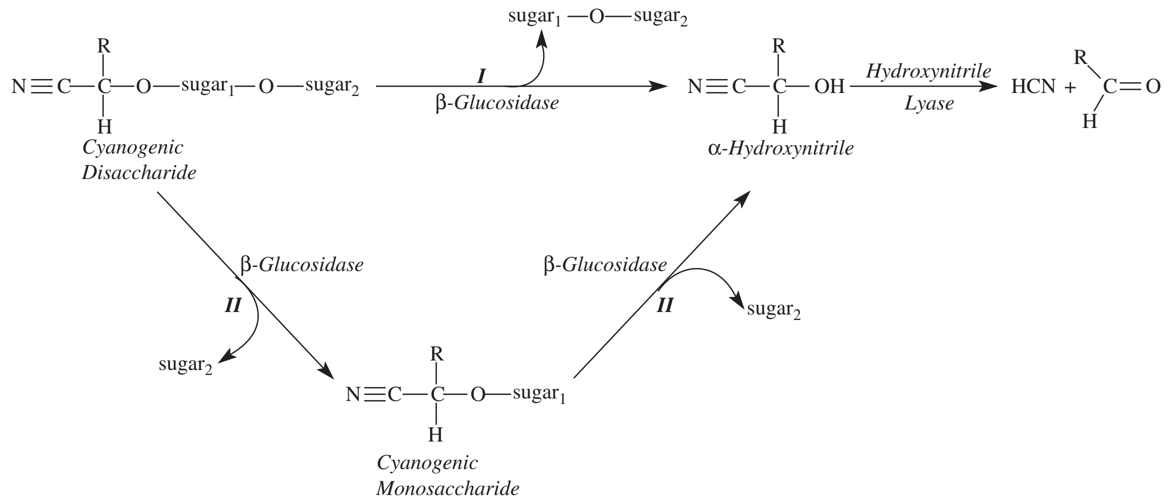

FIGURE 124.1. Biotransformation of cyanogenic glycosides.

confirmation by MS.[46] Methods for detecting hydrogen cyanide in biological samples include spectrometry, electrochemical analysis with cyanide ion-selective electrode, GC, GC/MS, and HPLC/MS.[47,48] The latter two methods are widely used methods for quantitating cyanide after headspace extraction or derivatization. More recent and rapid methods of detecting cyanide in biological specimens include capillary gas chromatography with cryogenic oven trapping [limit of detection (LOD): 2 ng/mL],[49] capillary electrophoresis with fluorescence detection (LOD: 0.1 ng/mL),[50] automated headspace GC (LOD: 13.8 µg/L),[51] and isotope-dilution GC/MS (LOD: 0.003–0.007 µg/g).[52]

Biomarkers

There are few data correlating blood cyanide concentrations to the ingestion of specific amounts of cyanogenic plants. In the presence of a compatible history, the presence of elevated blood cyanide concentrations confirms exposure to cyanogenic plants, but the results are not usually available to guide clinical management.

Abnormalities

Cyanide poisoning inevitably produces a metabolic acidosis that results in increased serum lactate concentrations from anaerobic metabolism.[53] The lack of metabolic acidosis in a symptomatic patient suggests a diagnosis other than cyanide poisoning.

TREATMENT

Treatment of poisoning from exposure to cyanogenic plants is similar to the treatment of cyanide poisoning. Decontamination measures are usually unnecessary because of the limited absorptive capacity of activated charcoal for cyanide and the risk of aspiration from the rapid onset of mental status changes. Mild to moderate ingestions usually require only supportive care. Indications for the use of an antidote include alteration in mental status, severe acidosis, continuous seizures, and refractory hypotension. The administration of the cyanide antidote kit to children requires the appropriate adjustments for weight and hemoglobin content to avoid methemoglobinemia. Clinical features that suggest an appropriate response to nitrites and thiosulfate include the following: normalization of vital signs (blood pressure, pulse), normal mentation, cessation of seizure activity, spontaneous respirations, and resolution of metabolic acidosis.[54] The presence of persistent metabolic acidosis may require a continuous infusion of sodium thiosulfate (2 g/h) for 24 hours.[55] The use of hydroxocobalamin is a safe and probably efficacious alternative to the cyanide antidote kit,[56] but there are few data on the efficacy of either antidote in the clinical setting of cyanide poisoning, particularly associated with cyanogenic plants or Laetrile®. The intravenous dose of hydroxocobalamin in adults without an allergy to vitamin B_{12} is 5–15 g over 30 minutes (more rapidly if clinically indicated), whereas the pediatric dose is 70 mg/kg. Additionally, adults should receive 12.5 g (50 mL 25% solution) sodium thiosulfate over 10–20 minutes. The pediatric dose of thiosulfate is 400 mg/kg up to the adult dose of 12.5 g. Survival has occurred in patients with Laetrile®-induced, severe cyanide intoxication (coma, metabolic acidosis, profound hypotension requiring aggressive support with vasopressors) following only supportive care.[57]

Chapter 125

DIEFFENBACHIA and OTHER OXALATE-CONTAINING PLANTS

HISTORY

The irritant properties of plants from the Araceae family (arum) have been known since the medical writing of the Greek physician and botanist, Dioscorides, during the 1st century. The 17th century physician, Bernardino Ramazzini, reported that an apothecary "has touched his genitals with an arum root and they became so acutely inflamed that gangrene resulted and a hemorrhage so acute that he nearly died."[1] The roots were boiled in wine as a concoction for the treatment of gout in the 18th century, and a tincture of the *Dieffenbachia* plant was a homeopathic treatment for sexual impotence in the 19th century.[2] Amazon Indians applied *Dieffenbachia* juice to their curare arrows, and rubbing the juice of this plant on the mouths of slaves was a method of punishment practiced by Jamaican slave traders.[3] In the Bahamas, anecdotal reports suggest that criminals rubbed *Dieffenbachia* stem on the lips of witnesses to prevent adverse testimony in court.[4] Medieval uses for extracts from the arum family included the treatment of gout, dropsy, and sexual impotence, and contraception. The Nazis conducted experiments on animal sterility induced by juice extracts, but they were unable to produce enough plants to expand their experimentation to concentration camp victims.

BOTANICAL DESCRIPTION

The Araceae family contains over 1,800 known species including a number of plants that produce mucosal irritation. *Dieffenbachia* species contain the most potent mucosal irritant within the Araceae family. Scientific (common) names for some common species in this family include the following: *Alocasia* spp. (elephant ears); *Arisaema* spp. (jack-in-the-pulpit, green dragon); *Caladium* spp. (caladium); *Calla palustris* L. (wild calla); *Colocasia esculenta* (L.) Schott (elephant ears, taro); and *Symplocarpus foetidus* (L.) Salisb. ex Nutt. (skunk cabbage).

Common Name: Dumbcane, Dumbplant, Mother-in-Law Plant

Scientific Name: *Dieffenbachia seguine* (Jacq.) Schott.

Botanical Family: Araceae (arum)

Physical Description: *Dieffenbachia* species grows up to 6ft (~2m) and has broad, shiny leaves that are variegated or spotted. The arrangement and number of ovules in the ovaries separate the genera *Colocasia* and *Alocasia* from the genus *Dieffenbachia*.

Distribution and Ecology: The natural habitat of the *Dieffenbachia* species is the Antilles archipelago and the tropical forests of South America.

Common Name: Schefflera, Brassaia, Ivy Palm, Octopus Tree, Umbrella Tree

Scientific (Common) Name: *Schefflera actinophylla* (Endl.) H.A.T. Harms

Botanical Family: Araliaceae

Physical Description: This fast-growing tree reaches 6–9m (~20–30ft) in height with ascending thick

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

branches marked by conspicuous leaf-scars. The leaves are palmate, containing an average of nine leaflets (range 7–15) with main petioles about 15–45 cm (~6–18 in.) long. The waxy, dark green leaflets are approximately 10–20 cm (~4–8 in.) long, elliptic-obovate, and all glabrous. Red flowers appear in small heads that produce fruit containing 10–12 seeds.

Distribution and Ecology: Most species of *Schefflera* are native inhabitants of the tropics and subtropics, but these species are houseplants in temperate climates.

EXPOSURE

The arum family contains popular ornamental plants with large leaves that are suitable for indoor locations. *Dieffenbachia, Caladium*, and *Philodendron* species are popular indoor plants that together are the most common plant exposures reported to US poison control centers.[5] Native Hawaiians prepared *Colocasia* root as a staple in their diet after detoxifying the root by boiling for 5 minutes. In Papua, New Guinea, sapal is a traditional food produced by fermenting a mixture of cooked, grated taro (*Colocasia esculenta*), corn, and coconut cream.[6] Reported traditional uses for *Dieffenbachia* species include the use of the extracts of this plant to treat dropsy, sexual frigidity, impotence, gout, and general inflammation.[4] In Thailand and China, extracts of the leaves from *Schefflera leucantha* R. vig. are used for the prevention and treatment of asthma attacks.[7] The ethanolic leaf extract of *Schefflera arboricola* (Hayata) Merr. is a traditional herbal treatment for analgesia, sprains, fractures, back pain, hypertension, and anxiety.[8]

PRINCIPAL TOXINS

Physiochemical Properties

Three major protein components of the juice from *Dieffenbachia* stalk have been separated by paper chromatography on the basis of molecular weight (above 150,000; 4,400 ± 300; 1,000–4,400).[9] These compounds are relatively unstable when exposed to air or to heat. The exact structure of these toxic components remains unknown. *Schefflera* species contain a variety of triterpenoid compounds including oleanane and ursane glycosides, benzyl glycosides, asiatic acid, and 3-epi-betulinic acid.[10–12]

Poisonous Parts

Exposure to fresh juice from the stalk of *Dieffenbachia* produces the most severe local reaction compared with other parts of the plant.[13] The leaves and stems are less irritating. The toxicity of roots of other members of the Araceae family is not well documented. The approximate concentrations of oxalic acid in samples of the whole plant and juice from *Dieffenbachia seguine* (Jacq.) Schott (*D. picta*) were 0.21% and 0.10%, respectively.[2] Table 125.1 lists some genera that contain calcium oxalate crystals.[14]

Mechanism of Toxicity

The most common toxic effects of the ingestion of plants from the arum family involve mucosal irritation. The exact cause of mucosal irritation is controversial, and several mechanisms of toxicity may be involved. *Dieffenbachia* species contain many insoluble calcium oxalate crystals. However, a number of edible plants contain similar concentrations of calcium oxalate crystals (e.g., beets, rhubarb), and the presence of oxalate crystals alone does not account for the toxicity of *Dieffenbachia* species.[2] *Dieffenbachia* leaves contain special cells known as idioblasts composed of needle-shaped calcium oxalate crystals (raphides) arranged in compact bundles.[15] Figure 125.1 displays a *Dieffenbachia* idioblast containing numerous raphides. When stimulated, idioblasts forcefully extrude the raphides for a distance of about two to three cell lengths.[16] In animal studies, an insoluble fraction of crude *Dieffenbachia* juice produced substantially more edema of the mouse paw than the insoluble fraction.[17] Consequently, the inflammation associated with plants from the arum family may involve the interaction of chemical (i.e., trypsin-like enzymes, proteases) and mechanical mechanisms.[3,18] In contrast to soluble calcium oxalate crystals, the insoluble crystals in these plants do not produce systemic toxicity because of poor bioavailability.

Schefflera species contain variable amounts of the sensitizer, falcarinol. Although there are three structurally related polyacetylene compounds (falcarindiol, falcarinone, dehydrofalcarinone), falcarinol probably is the primary sensitizer.[19] Falcarinone is an oxidation product of falcarinol.

DOSE RESPONSE

Exposure to plants from the arum family usually produces local irritation rather than systemic symptoms because the poor bioavailability of insoluble oxalate crystals. Variation in the severity of local reaction to oxalate crystals is expected between various genera based on differences in oxalate content and other factors, but there are few human data.

TABLE 125.1. Some Genera that Contain Oxalate Crystals Along with Oxalate Concentrations When Available

Family	Genus	Form	Amount
Agavaceae	*Agave*	Calcium oxalate	
Amaranthaceae	*Amaranthus*	Potassium acid oxalate	0.74–1%
Araceae	*Aglaonema*	Calcium oxalate	
	Alocasia	Calcium oxalate	
	Amorphophallus	Calcium oxalate	
	Anthurium	Calcium oxalate	
	Arisaema	Calcium oxalate	
	Arum	Calcium oxalate	
	Caladium	Calcium oxalate	
	Colocasia	Calcium oxalate	
	Dieffenbachia	Calcium oxalate	0.4% (stem)
	Epipremnum	Calcium oxalate	
	Monstera	Calcium oxalate	
	Philodendron	Calcium oxalate	0.7%
	Spathiphyllum	Calcium oxalate	
	Syngonium	Calcium oxalate	
	Xanthosoma	Calcium oxalate	
	Zantedeschia	Calcium oxalate	
Araliaceae	*Schefflera*		
Begoniaceae	*Begonia*	Calcium oxalate	
Bromeliaceae	*Ananas*	Calcium oxalate	
Caprifoliaceae	*Symphoricarpos*	Calcium oxalate	
Chenopodiaceae	*Beta vulgaris*	Soluble oxalate	>10%
	Halogeton	Sodium oxalate	>10–34.5%
	Sarcobatus	Sodium oxalate	>10%
Liliaceae	*Ornithogalum*	Calcium oxalate	
Oxalidaceae	*Oxalis*	Potassium acid oxalate	7–10%
Palmae	*Caryota*	Calcium oxalate	0.05% (berry)
Poaceae	*Setaria*	Ammonium oxalate	
Polygonaceae	*Rheum*	Potassium oxalate	0.28%

CLINICAL RESPONSE

Local reaction to contact with oxalate-containing plants varies between genera based on differences in oxalate content with exposures to arum plants among the best described cases. Most exposures to plants from the arum family are asymptomatic as reported to poison control centers.[20] Contact with sap from these plants can produce irritation of the oral mucous membranes, the conjunctiva, and the cornea.[21,22] Ocular toxicity following accidental contact with the sap from *Dieffenbachia* species includes severe pain, lacrimation, photophobia, blepharospasm, corneal abrasion, chemosis, and keratoconjunctivitis.[23] The chemical chemosis and keratoconjunctivitis resulting from ocular contact with

Dieffenbachia species usually resolves within 1 week after exposure.[24] The *potentially* most serious toxic effects following the ingestion of plants from the arum family involve salivation and local edema that may interfere with swallowing and/or breathing. Symptoms of potential airway obstruction include drooling, dysphagia, stridor, and facial edema. A case report documented the development of severe laryngeal and epiglottic edema after a 69-year-old man bit into the stem from a species of *Dieffenbachia*.[25] He developed stridor and respiratory distress unresponsive to intravenous steroids, inhaled racemic epinephrine, and nebulized albuterol; subsequently, an emergency tracheostomy was necessary. An 11-month-old boy died 17 days after ingesting leaves of a philodendron plant, and the autopsy demonstrated esophageal erosions and hyperemia.[26] Although the authors speculated that vagotonia secondary to the esophageal lesions was the cause of the sudden cardiac arrest, such a cause of death is unlikely, particularly in a witnessed cardiac arrest. After a 40-year-old woman bit into a *Dieffenbachia* stalk, she experienced sialorrhea, dysphagia, and intense burning of her mouth.[27] Physical examination revealed bullae of the mouth and tongue, severe edema of the face and tongue, and thick, almost unintelligible speech. However, no systemic or respiratory symptoms developed, but granulating oral lesions remained after 11 days. Case reports indicate that these lesions resolve without scar formation or permanent dysfunction.[28] European and African case studies document similar local toxic effects in children without systemic complaints except for mild transient central nervous system symptoms.[29,30] Occasionally, severe paresthesias and numbness are associated with local inflammation caused by ingesting plants from the arum family.[31]

Rarely, an allergic contact dermatitis or asthma develops in gardeners exposed to philodendron plants[32] or to *Schefflera* species.[33] In sensitized individuals, contact with these plants produces an acute vesiculobullous skin eruption in the areas of contact.[34] These individuals are usually allergic to a variety of antigens from fungi, dust mites, animal dander, trees, weeds, and pollens.

DIAGNOSTIC TESTING

There are no specific biomarkers for toxicity related to these plant species.

TREATMENT

Most exposures to these plants involve transient contact with the plant material, and treatment is supportive.[35] Therapeutic measures include the removal of all plant material from the mouth and the use of demulcents (milk, antacids, cool water).[29] Eye involvement requires irrigation and examination for corneal abrasions. The most serious sequela is the development of respiratory obstruction, which progresses over the first 6 hours. However, only those patients with substantial edema (i.e., intraoral edema, drooling) require direct medical observation. Patients without evidence of significant intraoral edema require only topical analgesics [e.g., Cepacol® (Bayer Consumer Care, Morristown, NJ), Orabase Plain® (Colgate-Palmolive Company, New York, NY)]. Gut decontamination measures are unnecessary.

Criteria for admission include the presence of respiratory obstruction and the inability to maintain fluid/electrolyte balance. Antihistamines are not indicated because of the lack of data supporting the role of histamine-induced edema.[27] The development of hypocalcemia is unlikely except in very large ingestions because the calcium oxalate crystals in the arum family are relatively insoluble. For patients ingesting large amounts of calcium oxalate-containing plants, generous fluid replacement (>2–3 $L/m^2/d$) is the most effective prophylactic treatment to prevent the deposition of calcium oxalate crystals in the kidney, bones, and muscles.[36] Sodium citrate (0.15 g/kg/d) is used as a treatment for primary and secondary oxalosis to inhibit the crystallization of calcium oxalate.

Chapter 126

DIGITALIS-CONTAINING FLOWERS
(Foxglove, Lily of the Valley)

HISTORY

Digitalis purpurea was well known to medieval herbalists of the 16th and 17th centuries.[1] As a result of his extensive botanical knowledge, William Withering, the son of an English apothecary, was able to identify *Digitalis purpurea* as the principal ingredient in the herbal preparation of a local herbalist that was used to treat congestive heart failure (dropsy).[2] In 1785, he published the first scientific treatise on the use of foxglove called *An Account of the Foxglove, and Some of its Medical Uses: With Practical Remarks on Dropsy, and Other Diseases.*[3] He attributed the herb's effectiveness in the treatment of congestive heart failure to diuresis. Hall Jackson, a physician in Portsmouth, New Hampshire read this treatise, and he received *D. purpurea* seeds from William Withering for use in North America. By 1799, John Ferriar recognized that the diuresis associated with the ingestion of foxglove resulted from the effect of the plant constituents on the heart.[4]

BOTANICAL DESCRIPTION

Common Name: Foxglove, Purple Foxglove

Scientific Name: *Digitalis purpurea* L.

Botanical Family: Scrophulariaceae (snapdragon)

Physical Description: This beautiful biennial herb has simple toothed leaves and a central stalk of purple, pink, yellow, or white tubular flowers. The small fruit are ovoid capsules that contain many minute seeds.

Distribution and Ecology: Foxglove is an ornamental plant in Michigan, Illinois, the US Pacific Coast, and northern United States. In many of these areas, this plant has become naturalized. Foxglove is native to Western Europe, the Mediterranean region, and northwest Africa. In addition to the United States and Canada, this plant has become naturalized in Asia, Africa, South America, and New Zealand.

Common Name: Lily of the Valley

Scientific Name: *Convallaria majalis* L.

Botanical Family: Liliaceae (lily)

Physical Description: This perennial plant has slender rootstock and fragrant white bell-shaped flowers originating from a central stalk. The leaves are long and broad, typical of the lily family.

Distribution and Ecology: Lily of the valley is a native European plant that is grown as a garden flower in the United States. Related species include *Convallaria majuscula* Greene (American lily of the valley) from the Appalachian Mountains and *Speirantha convallarioides* Baker. from eastern China.[5]

Common Name: Star-of-Bethlehem, Pyrenees Star-of-Bethlehem, Sleepydick

Scientific Name: *Ornithogalum umbellatum* L.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Botanical Family: Liliaceae (lily)

Physical Description: This perennial plant arises from a bulb basal, narrow, strap-like leaves that contain a light green midrib. The white to pale yellow flowers appear in a cluster at the top of a naked stem.

Distribution and Ecology: This bulb grows in gardens and moist meadows in the northeastern United States and eastern England.

EXPOSURE

Digitalis leaf is obtained for medicinal use by the grinding and milling of *D. purpurea* leaves. The European leaf preparations are derived from *Digitalis lanata* Ehrh., which contains primarily digoxin rather than digitoxin. Foxglove is a popular ornamental flower in the United States.

PRINCIPAL TOXINS

Physiochemical Properties

Cardioactive steroids are classified as cardenolide (5-membered lactone ring) or bufadienolide (6-membered lactone ring). The substitution of a sugar residue for a 3β-OH group on the cardenolide produces a cardiac glycoside (digitoxin, digoxin). Foxglove contains a number of cardiac glycosides, the most prominent of which is digitoxin. Each cardiac glycoside is a combination of an aglycone or genin (e.g., digoxigenin, digitoxigenin) and one to four molecules of a sugar (e.g., digitoxose or 2,6-dideoxyhexose). The lily of the valley plant contains cardiac glycosides, called convallatoxins, but apparently these glycosides are less potent than digoxin or digitoxin.

Poisonous Parts

D. purpurea contains primary glycosides including purpurea glycoside A, purpurea glycoside B, glucogitaloxin, and digitalinum verum. The plant enzyme, digipurpidase, transforms these primary glycosides into the corresponding secondary glycosides (digitoxin, gitoxin, gitaloxin, and strospeside, respectively). The mean concentration of purpurea glycoside A, purpurea glycoside B, and glucogitaloxin in dry leaf powder from *D. purpurea* was about 0.74 μg/mg, 0.39 μg/mg, and 1.91 μg/mg, respectively, as measured by high performance liquid chromatography (HPLC).[6] In five samples of dry *D. purpurea* leaf, the mean amounts of digitoxin, gitoxin, and gitaloxin in the dry leaf powder was approximately 0.22 μg/mg, 0.14 μg/mg, 0.55 μg/mg, and 0.02 μg/mg, respectively, as measured by HPLC.[7] The cardenolide content of foxglove plants varies with a variety of conditions including location and strain.[8]

DOSE RESPONSE

Most serious intoxications from digitalis-containing plants involve the ingestion of teas brewed from these plants. There are few data on dose response of these teas or plant parts.

TOXICOKINETICS

The cardiac glycosides of *D. purpurea* are hydrolyzed to digitoxin, gitoxin, and gitalin with only small amounts of digoxin formed from hepatic metabolism. Hence, *D. purpurea* toxicity may be prolonged because of the long serum half-life of digitoxin (4–5 days). Digitoxin undergoes metabolism to digitoxigenin, digitoxigenin monodigitoxoside, and gitoxin. Additionally, the kidneys excrete some digitoxin unchanged. Liquid chromatography/electrospray/mass spectrometry (LC/ES/MS) analysis of samples from a patient during the first 5 days after the ingestion of foxglove tea demonstrated digitoxin, digitoxigenin, gitoxin, and digitoxigenin monodigitoxoside in the serum and gitaloxin, digitoxin, digitoxigenin, gitoxin, and digitoxigenin monodigitoxoside in the urine.[9] Digitoxin was the digitalis glycoside present in the highest concentration (112.6 ng/mL) in the serum 8 hours after the ingestion. Relatively high serum concentrations of gitaloxin appeared only on the fifth day, when the serum gitaloxin concentration (112.6 ng/mL) exceeded the serum concentrations of all other cardiac glycosides.

CLINICAL RESPONSE

Foxglove toxicity resembles oleander and digitoxin poisoning. Gastrointestinal symptoms develop within several hours and are followed by changes in sensorium (e.g., confusion), cardiac conduction defects, bradycardia, hyperkalemia, and ventricular dysrhythmias.[10] Visual disturbances (e.g., yellow haloes) are classic symptoms of *Digitalis* leaf poisoning, and these visual changes do not usually occur following intoxication with pharmaceutical preparations of digoxin. Ventricular tachycardia, junctional rhythms, and atrial fibrillation with high-grade atrioventricular block requiring 6 days to revert to normal were reported in a foxglove tea poisoning.[11] After the ingestion of a foxglove tea, confusion and visual disturbances lasted 5 days and electrocardiogram (ECG) changes resolved in 10 days.[12] Two fatalities resulted from the ingestion of foxglove tea—an elderly woman, who was dead on arrival, and her

husband, who died of refractory ventricular fibrillation 17 hours after admission.[13] There are limited clinical data on intoxications associated with lily of the valley.

DIAGNOSTIC TESTING

Methods to quantitate cardiac glycosides in this herb include reverse-phase thin layer chromatography[14] and HPLC.[15] Near-infrared spectroscopy is a rapid technique for confirmation of the presence of cardiac glycosides.[16] Elevated serum digitoxin concentrations confirm the ingestion of digitalis-like compounds (in the absence of simultaneous consumption of *Digitalis* preparations), but digitoxin or digoxin concentrations do not necessarily guide management because of variable cross-reactivity with cardenolides in these plants. The presence of hyperkalemia indicates serious digitalis poisoning.

TREATMENT

Management of intoxication with digitalis-containing plants is similar to the management for oleander and digoxin poisoning. Gut decontamination measures are usually unnecessary. Because of the low potency of *C. majalis*, small, accidental ingestions probably do not require decontamination. The administration of activated charcoal to alert patients is a therapeutic option, when the patient ingests large amounts of foxglove less than 1 hour prior to presentation; however, there are no clinical data to indicate that activated charcoal improves the outcome of patients with foxglove intoxication. The efficacy of digoxin Fab fragments in foxglove or lily of the valley intoxication has not been established. Although the use of digoxin Fab fragments is a therapeutic option, these plants contain a variety of cardiac glycosides other than digitalis, and poisoning with extracts from foxglove have not been consistently reversed by the use of digoxin-specific Fab fragments.[10]

Chapter 127

JIMSON WEED and OTHER BELLADONNA ALKALOIDS

HISTORY

The toxic, mind-altering properties of belladonna alkaloids have been known since ancient times. The remains of mandrake were found in the casket of the Egyptian king, Tutankhamen. References to *Datura* and mandrake appeared in Homer's Odyssey,[1] and the Romans used mandrake as an anesthetic.[2] The Romans also used a sponge dipped in mandrake wine called *spongia somnifera* for administration to victims of crucifixion, and this "death wine" caused a stuporous state in the victims.[3] The Greek herbalist and surgeon to Nero's armies, Dioscorides, recommended the use of this plant with wine also as an anesthetic during the 1st century AD.[4,5] In the 11th century AD, Avicenna recommended the use of mandrake as an anesthetic, but he warned that overuse of this plant caused hallucinations, madness, and difficulty in breathing.[6] The use of mandrake (mandragora) as an aphrodisiac, fertility drug, hallucinogen, and herbal cure continued through medieval times and the Renaissance. The "cursed hebenon" of Shakespeare's Hamlet probably was the anticholinergic poison henbane.[7] During the Renaissance, Italian women used belladonna extracts to dilate their eyes for cosmetic purposes. References to mandrake appeared in Shakespeare's Romeo and Juliet as well as Anthony and Cleopatra.[8] Linnaeus named the deadly nightshade plant, "Atropo belladonna" after the eldest of the three fates, Atropos, whose duty was to cut the thread of life.[9,10]

Historical accounts of *Datura* poisoning in the United States date back to 1676 when British soldiers sent to Jamestown to extinguish the Bacon rebellion mistakenly ate *Datura*, "the effect of which was a very pleasant comedy, for they turned natural fools upon it for several days."[11] The intentions of the soldiers were suspect because the toxic effects lasted much longer (i.e., 11 days) than expected for a single, accidental ingestion. Indians from the southwestern United States used teas brewed from jimsonweed during religious rites and tribal ceremonies.[12] The aboriginal rock paintings by shamans from the California Chumash Indian tribe demonstrate designs of plants that suggest the shamans were under the influence of jimsonweed during the painting of these forms.[13] The use of *Datura* and *Brugmansia* species was probably imported to South America by Indian immigrants from the US Southwest and Mexico. Mayan uses for *Datura* included the treatment of hemorrhoids, skin ulcers, wounds, muscle spasms, gout, and night terrors.[14] In western South America and the upper Amazon, *Brugmansia* species were valued by local Indians for the medicinal and psychotropic properties, especially in their shamanistic religion that emphasized malevolent magic and supernatural causes of illness.[15] The preconquest Chibchas of Colombia concocted a mixture of *Brugmansia* species mixed with *chicha* (fermented beer) and tobacco that was administered to the slaves and wives of dead kings to induce a stupor prior to being buried alive with their dead masters and husbands.[15]

Modern medical reports of *Datura* intoxication date back over 200 years.[16] During the late 18th century in India, the British Physician-General of the East Indian Company, James Anderson, discovered the traditional

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

use of *Datura* in Ayurvedic medicine for asthma, and *Datura* preparations became popular anti-asthma treatments in apothecary shops during the 19th century in England.[17] Today, the most common cause of *Datura* poisoning involves the abuse of the mind-altering, anticholinergic properties of *Datura* species by ingesting *Datura* seeds or tea.[18] "Autumnal high" is a common name for this intoxication because the seeds appear in the fall.[19]

BOTANICAL DESCRIPTION

Anticholinergic plants include *Datura* species, *Atropa belladonna* L. (deadly nightshade), *Cestrum nocturnum* L. (night jasmine), *Mandragora officinarum* L. (mandrake), *Hyoscyamine niger* L. (henbane), and *Lycium halimifolium Mill*. (boxthorn, matrimony vine). Over 12 species of *Datura* grow as weeds throughout the United States, particularly near roadsides, waste areas, cornfields, and pastures. Common US *Datura* species other than jimsonweed include *D. inoxia* P. Mill. (angel's trumpet, moonflower, desert thornapple, sacred datura, prickly burr), and *D. suaveolens* (Humb. & Bonpl. ex Willd.) Bercht. & K. Presl (angel's tears). European species include *Datura sanguinea, Brugmansia arborea* (L.) Lagerh., and *Datura aurea* (Lagerh.) Saff. These European species cause anticholinergic symptoms similar to those produced by *D. stramoni*um.[20] In addition to *M. officinarum* and *M. autumnalis*, there are four other species of the genus *Mandragora* in the Eurasian continent including *M. acaulis* Gaertn., *M. caulescens* (C. B. Clarke) Diels, *M. turcomanica* Mizgir., and *M. vernalis* Bertol.

Common Name: Jimsonweed, Thornapple, Jamestown Weed, Mad Apple, Stinkwort, Moonflower

Scientific Name: *Datura stramonium* L.

Botanical Family: Solanaceae (potato, nightshade)

Physical Description: Jimsonweed is a common annual weed that grows 3–6 ft (~1–2 m) in height and emits a rank odor. It has a simple, large, white taproot and a strong, dichotomous stem. The leaves are large, waxy and dark green with pointed margins and scalloped borders. Attractive, white tubular flowers bloom in late spring and grow 3–4 in. (~8–10 cm) long. The green fruit grows to 5 cm (~2 in.) with spicules and the fruit matures in early fall. The dried pod may contain up to five hundred 2- to 3-mm kidney-shaped, brown-black seeds. Figure 127.1 displays a specimen of jimsonweed with maturing seed pods.

Distribution and Ecology: *Datura stramonium* is native to Asia and naturalized to Canada, West Indies, and the United States. This plant is the most common *Datura* species in the eastern United States.

FIGURE 127.1. *Datura stramonium* L. (jimsonweed) with maturing seed pods. Photograph courtesy of Kimberly Ann Barceloux, MFCC. See color insert.

Common Name: Deadly Nightshade

Scientific Name: *Atropa belladonna* L.

Botanical Family: Solanaceae

Physical Description: *A. belladonna* is a freely branching bush with oval leaves and purple-black fruit that reaches 2–4 ft (~1 m) in height.

Distribution and Ecology: Deadly nightshade is a native European plant that is cultivated in the eastern United States as an ornamental plant. This species does not grow well in wild areas.

Common Name: Black Henbane

Scientific Name: *Hyoscyamus niger* L.

Botanical Family: Solanaceae

Physical Description: The black henbane plant is a biennial herb averaging about 8–32 in. (~20–81 cm) in height. The lower leaves are oval to lance-shaped with winged stems, and the flowers are dark yellow with violet veins. The thimble-shaped fruit is cone-shaped with about 200 grayish-brown seeds. The

flowers appear from June to August and the seeds mature in August and September. The plant has an unpleasant odor that discourages use.

Distribution and Ecology: Henbane grows in sandy loam soils in waste areas and near roadsides.

Common Name: European Mandrake, Love Apple, Devil's Apple

Scientific Name: *Mandragora officinarum* L.

Botanical Family: Solanaceae

Physical Description: The roots of mandrake are similar to *Atropa belladonna*, except mandrake contains irregular crystals of calcium oxalate and sclereids.[21] Misidentification of this species for *Podophyllum peltatum* L. (American mandragora American mandrake) or *Borago officinalis* L. can cause toxicity.[22] The European mandrake has light green leaves that have irregular surfaces. Yellowish flowers appear in the spring in contrast to the fall for the autumn mandrake (*M. autumnalis*).

Distribution and Ecology: Mandrake is a native plant of the Mediterranean region and southern Europe.

EXPOSURE

Prior over-the-counter asthma preparations that contained extracts of *Datura* species include Asthmador (0.23–0.32% belladonna alkaloids),[23] Barter's Powder, Kinsman's Asthmatic Powder, Green Mountain Asthmatic Compound, and Haywood's Powder. Medicinal uses of these plants as Chinese herbs include the treatment of bronchitis, asthma, and pain.[24] Both *Datura* species and henbane are abused as aphrodisiacs and hallucinogens.[25]

PRINCIPAL TOXINS

Physiochemical Properties

The principal toxins in anticholinergic plant species are tropane belladonna alkaloids that primarily include hyoscyamine and scopolamine (*l*-hyoscine).[26] The ratio of hyoscyamine to scopolamine varies between anticholinergic plant species. The average ratios of hyoscyamine/scopolamine are relatively high for *A. belladonna* compared with *H. niger* and *D. stramonium*.[27] The distribution of tropane alkaloids in the plant kingdom is widespread outside the genera (*Datura*, *Brugmansia*, *Duboisia*) in the Solanaceae family including the following families: Brassicaceae, Convolvulaceae, Erythroxylaceae, Proteaceae, and Rhizophoraceae.[28] Analysis of antemortem and postmortem urine samples from patients ingesting *Datura* tea indicates that hyoscyamine and scopolamine (MW 303.36) are the main toxic compounds in *D. stramonium*.[29,30] Minor constituents include hyoscine and atropine (MW 289.37). Atropine is a racemic mixture of *d* (+) and *l* (−) hyoscyamine, but only the *l*-hyoscyamine is pharmacologically active. Figure 127.2 demonstrates the chemical structures of atropine and scopolamine.

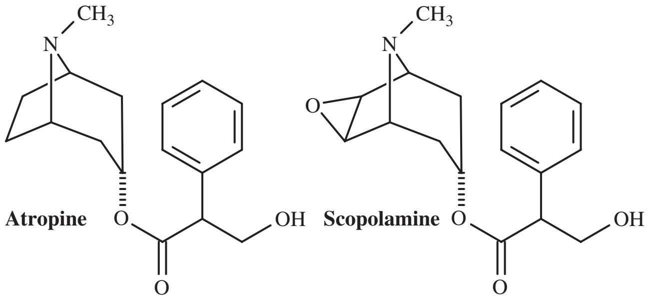

FIGURE 127.2. Chemical structures of scopolamine and atropine (*d,l* hyoscyamine).

Poisonous Parts

All parts of the *Datura* plant contain belladonna alkaloids, and case reports associate anticholinergic poisoning with teas brewed from plant parts,[29] ingestion of leaves and flowers,[31] and smoking of stramonium cigarettes.[32] However, seeds contain the highest atropine concentration (~0.1 mg/seed). A variety of factors affect the alkaloid concentrations including cultivation practices, environmental factors (temperature, moisture), storage techniques, age of the plant, part of the plant, and interspecies variation.

Datura Species

In a study of tropane alkaloid content in *D. stramonium*, tender stems from young plants and mature seeds contained mean atropine concentrations of 0.915 µg/mg and 0.384 µg/mg, respectively.[27] During a subchronic feeding study using seeds from *D. stramonium*, the mean atropine and scopolamine content of the seeds were 2.71 µg/mg and 0.66 µg/mg, respectively.[33] The ratio of atropine to scopolamine varies between *Datura* species. In a sample of seeds from *Datura stramonium* and *Datura ferox*, this ratio was approximately 5:1–7:1 in *D. stramonium* seeds, whereas the seeds from *D. ferox* had an atropine to scopolamine ratio of approximately 1:6–1:8.[34] The formation of atropine may occur during the extractive process by racemization of hyoscyamine.[27]

Atropa belladonna (Deadly Nightshade)

The alkaloid *l*-hyoscyamine represents almost all (90–95%) of the total alkaloid content, with most of the remainder being scopolamine.[35] Minor alkaloids include apoatropine, aposcopolamine, hydroxy-hyoscyamine, and tigloyloxytropane. The roots and leaves have the highest total alkaloid content (0.6% and 0.4%, respectively), followed by seeds and berries. Stems have an approximate total alkaloid concentration of 0.05% by weight. *A. belladonna* does not contain clinically significant amounts of solanine. Cooking berries from deadly nightshade does not prevent atropine toxicity.[36]

Hyoscyamus niger (Henbane)

All plant parts contain tropane alkaloids with the leaves containing from 0.05–0.15% of the total alkaloid content. Although most of the tropane alkaloids in henbane are *l*-hyoscyamine similar to *A. belladonna*,[37] the scopolamine (*l*-hyoscine) content of *H. niger* is substantially higher than *A. belladonna*. The alkaloid content averages about 0.08% in roots, 0.17% in leaves, and 0.3% in seeds.[38]

Mandragora officinarum (Mandrake)

All plant parts contain *l*-hyoscyamine and lesser amounts of scopolamine in addition to small amounts of the alkaloid, mandragorine (cuscohygrine). The estimated alkaloid content of the underground parts (rhizome, root) from mandrake varies from approximately 0.2–0.6%.[2]

Mechanism of Toxicity

Tropane belladonna alkaloids are strong anticholinergic compounds, which act as competitive antagonists to acetylcholine at central and peripheral muscarinic receptors. Peripheral muscarinic receptors innervate exocrine glands (sweating, salivation), smooth muscle, and cardiac muscle. These tertiary amines penetrate the blood–brain barrier and bind to acetylcholine receptors in the cortex and subcortical regions of the brain, producing acute psychosis. At low doses, tropane alkaloids cause peripheral anticholinergic signs including decreased salivation and sweating, mydriasis, loss of accommodation, increased pulse rate, and sinus tachycardia. As the dose increases, ileus, urinary retention, and elevated temperature occurs followed by the beginning of central nervous system (CNS) effects (confusion, agitation). Volunteer studies indicate that the peripheral effects on heart rate and blood pressure begin before CNS effects (impairment of vision, cognitive performance, and psychomotor skills), and the CNS effects persist longer than the cardiovascular effects.[39] High doses of belladonna alkaloids produce delirium, hallucination, and coma with the CNS effects being somewhat greater for scopolamine than for atropine.

DOSE RESPONSE

Because of the variable tropane alkaloid content of these plants, predicting toxicity based on the ingestion of plant parts is difficult. Based on calculations of hyoscyamine content, 50–100 *Datura* seeds contain enough atropine (3–6 mg) to produce serious anticholinergic poisoning.[11] Hall et al analyzed *Brugmansia suaveolens* (formerly *Datura suaveolens*; angel's trumpet) flowers and stated that paralysis and convulsions were likely after ingestion of six flowers or the tea from nine flowers.[31] Consumption of one half to two seed pods and alcohol produced symptoms of atropine poisoning that lasted 18 hours to 9 days. Blurred vision is the most persistent symptom. Consumption of 10 mandrake fruits (*Mandragora officinarum*) caused confusion, tachycardia, mydriasis, blurred vision, and facial flushing, which resolved in 20 hours.[40]

TOXICOKINETICS

The absorption of belladonna alkaloids is rapid through the gastrointestinal tract and the skin based on experimental studies and case reports of toxicity by these routes of exposure.[41,42] Case reports also document the onset of hallucinations and confusion after the transdermal application of scopolamine.[43] Volunteer studies indicate that the kidneys excrete about one-half of a therapeutic dose of atropine unchanged; hepatic metabolism accounts for the remainder of the dose.[44] Major metabolites include noratropine and atropine-*N*-oxide, whereas tropine and tropic acid are minor metabolites. The elimination half-life of atropine following therapeutic doses is about 2–4 hours.[45] During acute intoxication with cooked berries from *Atropa belladonna*, the plasma elimination half-life of atropine was about $2\text{–}2^1/_2$ hours with most of the belladonna alkaloids eliminated from the blood within 24 hours.[44] However, the clinical effects of belladonna poisoning may last up to 48 hours, and tropane alkaloids are present in urine samples during this period.[36]

CLINICAL RESPONSE

Exposure to plants containing tropane belladonna alkaloids classically produce an anticholinergic poisoning syndrome described by the phrase "blind as a bat, hot as a hare, dry as a bone, red as a beet and mad as a wet

hen."[46,47] Clinical features range from asymptomatic mydriasis to severe alteration of mental status (agitation, hallucination, coma).[48] Symptoms typically begin within 1–6 hours after ingestion of plant parts, but the onset of symptoms is much more rapid (<1 hour) after the ingestion of teas brewed from plant parts containing belladonna alkaloids.[49–51] The classical presentation of a severe intoxication includes fever, erythema, dilated pupils, blurred vision, myoclonic jerks, delirium, and hallucinations. In a case series of 31 Turkish children hospitalized after ingesting black henbane (*Hyoscyamus niger*), most patients demonstrated flushing, pupillary dilation, dizziness, ataxia, agitation, and tachycardia.[52] The differential diagnoses of anticholinergic poisoning secondary to belladonna alkaloids include intoxication with antihistamines (cold preparations, over-the-counter sleep aids), antispasmodic preparations [Donnatal® (A.H. Robins, CO., Richmond, VA), dicyclomine], benactyzine, muscle relaxants, tricyclic antidepressants (doxepin, amitriptyline, desipramine, nortriptyline, protriptyline), and antipsychotics.

Jimsonweed

Case series indicate that agitation, confusion, hallucinations, and combative behavior are common clinical manifestations of jimsonweed poisoning in patients presenting to emergency departments for treatment, particularly in adolescents who drank tea brewed from these plants.[53,54] In a review of case studies of jimsonweed intoxication from the smoking of *D. stramonium* cigarettes, dryness of the mouth and pupillary dilation were the earliest signs of intoxication.[32] Other clinical signs of toxicity in these cases included hallucinations (83%), disorientation (54%), dilated pupils (54%), dry mucous membranes (46%), fever (31%), ataxia (26%), rapid pulse (20%), amnesia (19%), and flushing (19%). Hallucinations usually involve simple images in natural colors, in contrast with the brilliant visual displays seen with lysergic acid diethylamide (LSD). The presence of bowel sounds and diaphoresis suggests an adrenergic (cocaine, amphetamine) excess rather than an anticholinergic (jimsonweed) poisoning. Tactile hallucinations are uncommon. Amnesia may last up to 24 hours during anticholinergic intoxication.[55] Seizures occur rarely during jimsonweed intoxication,[31,56,57] but patients may present in coma, particularly following the ingestion of teas.[58] Fatalities usually result from trauma or drowning rather than medical complications (respiratory failure, arrhythmias).[32,49,59] Symptoms typically resolve in 24 to 48 hours, although pupillary dilation may continue up to 1 week.[60,61] Proliferation of jimsonweed in cornfields has led to an occupational disease known as cornpicker's pupil in which the pulverized jimsonweed dust caused mydriasis for several days after mechanical harvesting.[62,63] Asymmetrical anisocoria can occur in patients following ocular contact with parts of *Datura* species, and this effect usually resolves within 3 days.[64]

Deadly Nightshade

The ingestion of berries from deadly nightshade (*Atropa belladonna*) produces the clinical features of atropine poisoning. Following the ingestion of deadly nightshade berries by an elderly man was associated with delirium, hallucinations, tachycardia, fever, diffuse hypertonia, and amnesia that resembled delirium tremens.[46] His symptoms resolved the day after ingestion. Respiratory failure associated with the ingestion of deadly nightshade berries may require ventilatory support for 24–30 hours. The delirium and hallucination usually resolve within 48 hours, but mydriasis may persist for several more days.[36]

Mandrake

Ingestion of mandrake causes gastrointestinal distress and anticholinergic symptoms similar to other plant species containing tropane alkaloids. The ingestion of leaves from *Mandragora autumnalis* by a 72-year-old woman was associated with nausea, hallucination, confusion, agitation, tachypnea, tachycardia, and mydriasis.[65] She recovered with supportive care. Other clinical effects of the ingestion of mandrake include hypertension, dry mouth, urinary retention, and flushed skin.[66]

DIAGNOSTIC TESTING

Analytical methods to quantitate tropane alkaloids (hyoscyamine, scopolamine) include thermospray high performance liquid chromatography/mass spectrometry (HPLC/MS),[67] HPLC/tandem mass spectrometry (MS/MS),[68] and gas chromatography/mass spectrometry techniques using special columns and dichloromethane extract with a limit of detection ranging down to 5 ng/mL.[69] There are limited forensic data on scopolamine and atropine concentrations. In a serum sample from a mild case of *Datura inoxia* poisoning, the serum hyoscyamine concentration was 12 ng/mL, while the scopolamine concentration was below the limit of quantitation (<5 ng/mL).[69] A 19-year-old man, who was found dead, intentionally ingested an unknown quantity of *Datura stramonium* seeds.[70] Postmortem blood samples contained hyoscyamine and scopolamine concentrations of 1.1 μg/mL, and 0.2 μg/mL, respectively. Two case reports detailing the postmortem blood samples of two men following the fatal ingestion of atropine and scopol-

amine demonstrated atropine and scopolamine concentrations of 0.4 mg/kg and 0.13 mg/kg, respectively.[71] Both men were found dead and their stomach contents contained detectable amounts of these substances. Laboratory abnormalities include elevated concentrations of serum hepatic aminotransferases, lactate dehydrogenase (LDH), and bilirubin;[56] however, the role of liver necrosis in these cases is unclear because postmortem examinations of the liver demonstrate only subcapsular petechiae.[29] Some of these changes may result from rhabdomyolysis secondary to agitation, decerebrate posturing, and myoclonic jerking during anticholinergic intoxication. Electroencephalographic changes during periods of altered mental status include prominent lambda activity, high-amplitude slow wave activity, and occasionally periodic short bursts of high-voltage sharp waves.[72] No marked suppression of background activity usually appears between bursts of sharp wave activity.

TREATMENT

Stabilization

Most patients respond well to supportive and protective measures. The patient should be placed in a reassuring, low-stimulus environment with a familiar person. Pharmacological intervention should be limited to those patients who remain severely agitated after supportive measures. Hypertension is usually transient and antihypertensive therapy is typically unnecessary.

Decontamination

There are few clinical data to guide management of patients with anticholinergic intoxication after exposure to belladonna alkaloids in plants from the Solanaceae family. Although tropane belladonna alkaloids are well absorbed from solution, the anticholinergic properties of these compounds may delay the absorption of these compounds from plant parts and seeds. Theoretically, patients may benefit from decontamination measures (i.e., activated charcoal) beyond the usual 1 hour after ingestion. However, the occurrence of altered mental status (delirium, confusion, agitation) during anticholinergic poisoning increases the risk of aspiration. Consequently, decontamination measures are usually unnecessary.

Measures to Enhance Elimination

There is no clinical evidence to support the use of hemodialysis or forced diuresis to increase the elimination of belladonna alkaloids during anticholinergic poisoning.

Antidotes

Physostigmine is an antagonist to serious atropine poisoning (severe CNS or peripheral anticholinergic symptoms, dysrhythmias, seizures, hypertension or hallucinations). The initial adult dose is 0.5–2 mg (0.01–0.03 mg/kg) intramuscularly or intravenously over 2–5 minutes. Improvement usually occurs within 15 minutes and a second dose may be repeated in 20–30 minutes. The onset of action for intravenous physostigmine is 3–8 minutes and the duration of action is 30–60 minutes. Signs of cholinergic excess (bradycardia, heart block, excessive secretions) indicate excessive doses of physostigmine. Repeated doses should be given only if symptoms reappear. Relative contraindications to the administration of physostigmine include a history of cardiovascular disease, gangrene, asthma, glaucoma, and gastrointestinal or genitourinary obstruction. Because symptoms usually resolve within 24 hours, only three to four doses are usually necessary.[56] Physostigmine is not routinely administered for mild cases of anticholinergic poisoning. Patients with persistent signs of anticholinergic poisoning (agitation, hallucination, seizures) should be admitted for at least 24 hours of observation.

Supplemental Care

Benzodiazepines (diazepam, lorazepam) are the initial drugs of choice for agitation during anticholinergic intoxication. Phenobarbital, phenothiazine compounds, and haloperidol should be administered cautiously, if at all, because of potential potentiation of anticholinergic effects (phenobarbital, phenothiazines) or lowering of seizure thresholds (haloperidol).[73] Vital signs should be monitored every 15–20 minutes until improvement occurs. Hypertension is usually transient and requires no therapy. Hyperthermia may be treated with a cooling blanket or a sponge bath. Catheterization may be necessary for urinary retention. Baseline laboratory tests for patients with severe anticholinergic poisoning (seizures, muscle rigidity, hyperthermia) include hepatic transaminases, bilirubin, creatine kinase, prothrombin time, and urinalysis for myoglobin. Patients who exhibit CNS symptoms (e.g., disorientation, hallucinations, delusions) should be observed until those symptoms resolve. Patients with mild symptoms may be discharged from the emergency department after 4–6 hours of observation, if symptoms resolve.

Chapter 128

LUPINES and FALSE LUPINE

HISTORY

Many species of lupines contain teratogenic quinolizidine and piperidine alkaloids. Although lupine seeds contain these toxic alkaloids, a "debittering" process used by natives in the Andean Highlands allowed the use of these seeds as a food crop for many years.[1] Since the late 1800s, western US stockmen recognized the toxicity associated with the ingestion of lupine hay by grazing animals. Large losses of livestock occurred in Montana and other western states as a result of the heavy grazing of lupine pods and seeds by cattle and sheep during the late summer and early fall.[2] In the 1950s, the eponym "crooked calf disease" was given to the lupine-induced skeletal malformations associated with the ingestion of lupines by pregnant cows.[3]

BOTANICAL DESCRIPTION

Common Name: Lupines, Lupins

Scientific Name: *Lupinus* (genus)

Botanical Family: Fabaceae (Leguminosae)

Physical Description: Lupines have alternate, palmately compound leaves (5–17 oblong to lanceolate leaflets) and a variety of colored flowers (red, yellow, blue, white, purple). The plant flowers in early to mid-summer with pods appearing in late summer and early fall.

Distribution and Ecology: There are more than 500 species of annual, perennial, and soft woody lupines worldwide with about 200–300 species in North and South America and approximately 12 species in Europe and Africa.[4] In the United States, lupines are most common in the West, with 150 species growing west of the Rocky Mountains.

Common Name: False Lupine, False Lupin, Prairie Buckbean, Golden Banner, Mountain Thermopsis, Mountain Pea, Yellow Pea, Buffalo Pea, Golden Pea

Scientific Name: *Thermopsis rhombifolia* (Pursh) Richardson (*T. montana*)

Botanical Family: Fabaceae (Leguminosae)

Physical Description: The foliage and inflorescence of this species resembles lupines. This erect perennial herb has palmately compound leaves with three leaflets. The pea-like, showy flowers are yellow or purple with lupine-like racemes. Flowers bloom in May to July and subsequently produce long pods reaching 5–8 cm (~2–3 in.) in length.

Distribution and Ecology: *Thermopsis rhombifolia* is adapted to a variety of habitats including grasslands, desert shrub areas, and mountain meadows. This plant inhabits areas from the Pacific Coast to the eastern Rocky Mountains. Several other similar species inhabit meadows of Southeast woodlands including Carolina lupine [*T. villosa* (Walt.) Fern. & Schub.] and Allegheny Mountain goldenbanner [*T. mollis* (Michx.) M.A. Curtis ex Gray]. Central and eastern Asia has other varieties of *Thermopsis* species.

EXPOSURE

Lupines are cultivated in Australia, South America, Eastern Europe, and the Mediterranean region as supplemental feed for livestock with regulatory limitations of 100 μg alkaloids/g material. Humans also consume the "sweetened" seeds in dishes containing lupine flour. Increasing the protein and total amino acid content of wheat flour by the addition of legume seed flour improves the nutritional content of the bread. The high-lysine, low-methionine content of lupine seed flour complements the low-lysine, high-sulfur-containing amino acids in wheat flour.[5] Sweetened lupine seeds are an appetizer in southern Spain. In southern Europe and the Middle East, boiled lupines are home remedies for diabetes. In the Russian *Pharmacopoeia*, extracts of *Thermopsis lanceolata* were substitutes for ipecac.[6]

PRINCIPAL TOXINS

Physiochemical Properties

The lupine (*Leguminosae*) family contains more than 150 quinolizidine alkaloids including lupanine, 13-hydroxylupanine, sparteine, and the teratogen, anagyrine. Lupanine (CAS RN: 550-90-3, $C_{15}H_{24}N_2O$) and sparteine (CAS RN: 90-39-1, $C_{15}H_{26}N_2$) are structurally similar compounds as demonstrated in Figure 128.1 and Figure 128.2. Lupanine is a ketonic derivative of sparteine, and animal studies suggest that lupinine is substantially less toxic than sparteine.[7] Analysis of lupine seeds indicates that lupanine is the most prevalent alkaloid in the seeds.[1] Other major alkaloids include sparteine, 4-hydroxylupanine, and 13-hydroxylupanine. Alkaloid content varies with environmental conditions, season, stage of growth, and species with high alkaloid content during the early growth stages, decreasing during the flowering stage, and increasing during the seeding.[4,8] Prolonged soaking in water and cooking are necessary to remove toxic amounts of alkaloids in lupine seeds.[9] Lupine extracts contain low-molecular-weight compounds that are waste products from the removal process for bitter (high-alkaloid) lupine seeds.[10] Table 128.1 lists some of the physical properties of sparteine. Alkaloids in *T. rhombifolia* include cystisine, *N*-methylcystisine, hydroxylupanine, thermopsine, and anagyrine.[6] Trace amounts of lupinine (CAS RN: 486-70-4, $C_{10}H_{19}NO$) and 17-oxosparteine also occur in this plant species.

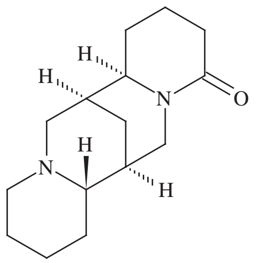

FIGURE 128.1. Chemical structure of lupanine.

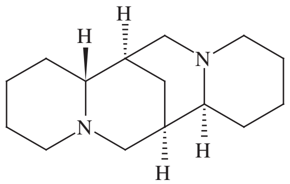

FIGURE 128.2. Chemical structure of sparteine.

Poisonous Parts

The concentrations of major alkaloids are highest in the stems and leaves early in the growth phase, and these alkaloids decrease as the plant matures.[11] The exception is the intact mature seed, which retains the highest alkaloid concentrations of all plant parts. Sweet lupine refers to seeds from cultivars of the narrow-leafed lupine (*Lupinus angustifolius* L.) with low alkaloid content compared with the bitter, wild-type lupine seeds. The "sweeting" (i.e., "debittering") process that converts bitter lupine seeds to edible food sources reduces the alkaloid content from about 3% to approximately 0.02%.[1] The seeds of modern cultivars of *L. angustifolius* contain <200 mg alkaloids/kg compared with bitter varies that contain 5–40 g alkaloid/kg.[12] The typical alkaloid content of sweet lupines is approximately 42–59% lupanine, 24–45% 13-hydroxylupanine, 7–15% angustifoline, and 1–1.5% α-isolupanine.[12] Tracer studies indicate that shoot tissues synthesize the majority of quinolizidine alkaloids (e.g., lupanine, 13-hydroxylupanine), and redistribution of these alkaloids occurs by translocation in the phloem.[13]

TABLE 128.1. Some Physical Properties of Sparteine

Property	Value
Melting Point	30.5 °C/86.9 °F
Boiling Point	325 °C/617 °F
log P (Octanol-Water)	2.730
Water Solubility	3040 mg/L (22 °C/71.6 °F)
Vapor Pressure	1.79E-04 mmHg (25 °C/77 °F)
Henry's Law Constant	1.16E-08 atm-m³/mole (25 °C/77 °F)
Atmospheric OH Rate Constant	1.26E-10 cm³/molecule-second (25 °C/77 °F)

The highest concentrations of alkaloids in *Thermopsis rhombifolia* occur in the sprouts with decreasing amounts in the flowering and fruiting tops. Analysis of alkaloid content indicate that *N*-methylcytisine is abundant in early collections of leaves and stems, but the flowers and fruiting tops contain minimal amounts of this substance.[6] This study indicated that maximum hydroxylupanine concentrations occurred late in the growing season. The ingestion of the seeds or flowers is the most common cause of poisoning.[14]

Mechanism of Toxicity

Some of the quinolizidine alkaloids in *Lupinus* species possess varying degrees of muscarinic and nicotinic activity. Lupanine, 13-hydroxylupanine, and sparteine block nicotinic cholinergic receptors and possess weak antagonism of muscarinic cholinergic receptors.[7] In animal studies, both lupanine and sparteine are substantially (i.e., 6- to 10-fold) more toxic following intravenous than oral administration.[15]

Lupinus species contain quinolizidine (anagyrine) and piperidine (ammodendrine) alkaloids that produce congential birth defects (cleft palate, multiple congential contractures, bowed limbs, scoliosis, kyphosis, torticollis) in pregnant goats gavaged with plant material during gestation days 30–60.[16,17] Lupinosis is a veterinary disease characterized by hepatic steatosis, anorexia, weight loss, jaundice, and stupor. The disease occurs in animals grazing on *Lupinus* species contaminated by a mycotoxin-producing species of the genus *Phomopsis*. There are no case reports of a similar disease in humans.

In animals, ingestion of dry foliage of *T. rhombifolia* produces a severe muscle degeneration manifest by persistent recumbency.[18] The presence of the teratogen, anagyrine, suggests that the grazing of animals on this plant may produce defects of limb rotation, arthrogryposis, or other teratogenic effects similar to those that occur from the grazing of lupines.

DOSE RESPONSE

The ingestion of an estimated 24 mg lupanine/kg body weight produced acute toxicity in an adult ingesting bitter lupine beans.[19] Pediatric case reports associate the ingestion of six peas and two to three flowers from *T. rhombifolia* with nausea, vomiting, lethargy, and headache.[14] The ingestion of an estimated 20 flowers produced similar symptoms.

TOXICOKINETICS

Volunteer studies indicate that the kidneys excrete most of a 10 mg dose of lupanine and 13-hydroxylupanine unchanged in the urine.[12] During this study, the mean elimination half-lives of these compounds were approximately 6 hours.

CLINICAL RESPONSE

The ingestion of "debittering" water used to remove toxic alkaloids from lupine seeds produced anticholinergic poisoning manifest by generalized weakness, palpitations, sinus tachycardia, premature ventricular contractions, dry mouth, and urinary retention within 1 hour of the ingestion.[20] Most of the symptoms resolved within several hours. Case reports associate an anticholinergic syndrome (tachycardia, blurred vision, anxiety, generalized weakness, tachypnea, mydriasis) with the ingestion of seeds[21] or the bitter water from boiling lupine seeds in water.[22] Analysis of the bitter water demonstrated the dibasic quinolizidine alkaloid, sparteine. Impaired hydroxylation of sparteine may predispose some patients (i.e., slow metabolizers) to the toxic effects of sparteine. Ingestion of lupine beans can cause pupillary dilation, blurred vision, orthostatic hypotension, and an elevated heart rate.[23] Allergic responses to lupine seeds may occur, particularly in patients with allergies to peanuts.[24] Rarely, anaphylaxis (e.g., angioedema, dyspnea) develops following the ingestion of lupine flour.[25]

The peas from *Thermopsis rhombifolia* are strong emetics. Case reports associated the ingestion of peas and flowers from this plant with nausea, vomiting, and headache that usually resolves within 12–24 hours. Almost all ingestions result in nausea and vomiting. Symptoms of dehydration may occur, but systemic effects usually are minimal after the incidental ingestion of parts of this plant.[26]

DIAGNOSTIC TESTING

Analytical methods for the detection and quantitation of lupine alkaloids (lupanine, anagyrine, sparteine) include gas chromatography with flame ionization or nitrogen phosphorus detection and gas chromatography/mass spectrometry (GC/MS).[27] Detection limits for the latter method of detection ranged from 0.025–0.2 μg/g sample.[28] A high performance liquid chromatographic (HPLC) method can detect sparteine and the 2-dehydro and 5-dehydro metabolites in biological samples with a limit of detection in the range of 2 ng/mL.[29]

TREATMENT

Treatment is supportive. Pediatric patients should be evaluated for dehydration and electrolyte imbalance. The incidental ingestion of plant parts by children is not

usually associated with systemic complications, and decontamination measures are unnecessary. Most causal ingestions may be managed as outpatients unless dehydration occurs.

Chapter 129

MAYAPPLE
(*Podophyllum peltatum* L.)

HISTORY

The resin extract of *Podophyllum peltatum* was used as a cathartic during the 19th century. The crystalline substance, podophyllotoxin was isolated in 1880, but the chemical structure of podophyllotoxin was not determined as a diastereoisomer until 1951.[1] In 1942, Kaplan introduced the use of 25% podophyllum as a single, topical treatment for venereal warts (condyloma acuminatum).[2]

BOTANICAL DESCRIPTION

The US variety of mayapple is *Podophyllum peltatum*; the Indian variety is *Podophyllum hexandrum* Royle (Himalayan mayapple or *Podophyllum emodi*).

Common Name: Mayapple
Scientific Name: *Podophyllum peltatum* L.
Botanical Family: Berberidaceae (bayberry)
Physical Description: Mayapple is a perennial plant with a horizontal fleshy rootstock, thick fibrous roots, and large, circular, multilobed leaves. Solitary flowers produce a fruit that becomes yellow upon ripening.
Distribution and Ecology: Mayapple grows in wet meadows, open woodland, and disturbed areas along the roadside, often as a group of plants in the eastern half of the United States. *P. hexandrum* is indigenous to Asia, and this plant does not grow naturally in the United States.

EXPOSURE

Native Americans used the root from *P. peltatum* as a cathartic. USP Podophyllum resin is an alcohol extract of the dried rhizomes and roots of *Podophyllum peltatum* used to treat condyloma acuminatum in the United States since 1942.[3] The self-administration of 0.15–0.5% purified podophyllotoxin (podofilox) preparations applied twice daily for 3 days is a safe alternative for the treatment of condyloma acuminatum compared with the use of nonstandardized USP podophyllum resin.[4] Etoposide and teniposide are chemotherapeutic agents that are semisynthetic derivatives of podophyllotoxin derived from the Himalayan mayapple (*P. hexandrum*) and the US species (*P. peltatum*).[5,6] These semisynthetic podophyllotoxins (e.g., etoposide 7a, teniposide 7c) are used to treat a variety of tumors including germ cell tumors, Hodgkin's disease, small cell lung cancer, acute myelogenous leukemia (AML), acute lymphocytic leukemia (ALL), Kaposi's sarcoma, ovarian and testicular cancers, and retinoblastoma.[7] Bajiaolian is a traditional Chinese remedy derived from a species of the Mayapple family that has been used for the treatment of condyloma acuminata, snake bite, generalized weakness, lymphadenopathy, and tumors.

PRINCIPAL TOXINS

Physiochemical Properties

Traditional podophyllum resin solutions contain 25% podophyllum extract as well as vehicles such as tincture

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

of benzoin, salicylic acid, cantharidin, penederm, castor oil, ethanol, and acetone. The podophyllum extract is a complex, nonstandardized mixture of organic substances that contains at least 16 active physiological compounds including podophyllotoxin (podofilox), picropodophyllin (cis isomer of podophyllotoxin), deoxypodophyllotoxin, 4-demethylpodophyllotoxin, lactones (α- and β-peltatin), rutin, and quercetin.[8] The active toxic ingredient in podophyllum extract is podophyllotoxin (CAS RN: 518-28-5, $C_{22}H_{22}O_8$,), and the amount of podophyllotoxin varies from about 25–100 mg/mL depending on the source and storage conditions (light, heat).[9,10] Figure 129.1 displays the chemical structure of podophyllotoxin. Officially, podophyllum is a resin extract of the American source (*Podophyllum peltatum*) rather than the Indian source (*Podophyllum hexandrum*). Podophyllotoxin (podofilox) is available as a stable, low-concentration (0.5% solution, 5 mg/mL) commercial gel. Table 129.1 lists some physical properties of podophyllotoxin.

Poisonous Parts

Most human poisonings result either from ingestion of the commercial extract or excessive topical application rather than from the ingestion of plant parts. The green fruit, stem, leaves, and roots contain podophyllotoxin. Analysis of a sample of pulverized plant parts that produced severe nausea and vomiting after ingestion demonstrated a podophyllotoxin content of approximately 0.4%.[11] In samples of *P. hexandrum* from the Kumaun region of the Indian Central Himalaya, the podophyllotoxin content of rhizomes ranged between 0.36–1.08% (dry weight).[12] The ripe fruit is edible and ingestion of the ripe fruit does not produce toxicity. Podophyllum poisoning may result from the ingestion of herbs contaminated by *Podophyllum* species.[13]

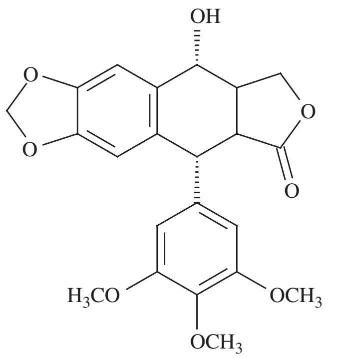

FIGURE 129.1. Chemical Structure of Podophyllotoxin.

TABLE 129.1. Some Physical Properties of Podophyllotoxin

Physical Property	Value
Melting Point	183 °C/361.4 °F
log P (Octanol-Water)	2.01
Water Solubility	155 mg/L (25 °C/77 °F)
Vapor Pressure	8.34E-15 mmHg (25 °C/77 °F)
Henry's Law Constant	3.80E-18 atm-m³/mole (25 °C/77 °F)
Atmospheric OH Rate Constant	2.20E-10 cm³/molecule-second (25 °C/77 °F)

Mechanism of Toxicity

Podophyllotoxin is a potent spindle poison that blocks mitosis in metaphase. Both colchicine and podophyllotoxin disrupt the assembly and function of microtubules and other microtubule-dependent processes.[14] Additionally, podophyllotoxin demonstrates a wide variety of actions including inhibition of enzymes involved in the tricarboxylic acid cycle, inhibition of purine synthesis, blockade of RNA synthesis, damage to the endothelial lining of small vessels, induction of interleukin-1 and interleukin-2, suppression of immune responses, and inhibition of lymphocyte response to mitogens.[15–17]

DOSE RESPONSE

The recommended maximum therapeutic dose of podophyllum extract is 2 mL of 20% podophyllum resin (100 mg/m²). However, case reports associate bone marrow suppression and a severe sensorimotor neuropathy in a 20-year-old woman with topical application of 3 mL of a 20% podophyllum resin solution that remained on the skin after use.[18] The calculated dose based on patient recall was 150 mg (100 mg/m²). The ingestion of 10 mL of an 8% podophyllum resin solution by a child produced fever, hypotension, and coma.[19] Based on animal studies, the estimated toxic dose of podophyllum extract is above 300 mg/m² body surface area.[20] Case reports from the modern medical literature associate fatalities with the estimated ingestion of 10–11 g podophyllum extract,[21] and survival with the estimated ingestion of 2.8 g podophyllum extract.[22] During early clinical studies of podophyllotoxin as a chemotherapeutic agent at daily doses of 0.5–1 mg/kg, an average cumulative dose of 6 mg/kg produced bone marrow depression and gastrointestinal toxicity.[23]

TOXICOKINETICS

The dermal absorption of podophyllotoxin is limited. In a study of adults with anogenital warts, the topical application of 0.05 mL of 0.5% podophyllotoxin (0.25 mg) was not associated with detectable serum concentrations of podophyllotoxin as measured by high performance liquid chromatography (HPLC).[24] About 1–2

hours after topical application of podophyllotoxin doses of 7.5 mg, the maximum serum concentration of podophyllotoxin ranged up to 17 ng/mL. The serum half-life of podophyllotoxin following dermal application was approximately 1–4.5 hours.

CLINICAL RESPONSE

The ingestion of podophyllum produces neurologic, gastrointestinal, and hematological toxicity. Features of systemic toxicity include nausea, vomiting, ileus, fever, peripheral neuropathy, and obtundation. Severe intoxication produces coma, hypotension, oliguria, and death. Tachypnea usually results from the presence of a metabolic acidosis rather than direct damage to the lungs.

Clinical Pattern

Classically gastrointestinal symptoms begin within 2 hours of ingestion, and the persistence of gastrointestinal symptoms after several days suggests the presence of a paralytic ileus.[25] Central nervous system (CNS) symptoms develop about 5–20 hours after exposure.[19] Signs of peripheral neuropathy (ataxia, paraesthesias, hyporeflexia) occur after symptoms of CNS involvement resolve (i.e., about 24–48 hours after ingestion). Hematological changes (leukopenia, thrombocytopenia) develop about 5–7 days after exposure and resolve within 3 weeks. Although mild hepatorenal dysfunction commonly develops, liver or kidney failure is uncommon unless multiple organ failure occurs.

Central and Peripheral Nervous System

During podophyllum intoxication, patients develop changes primarily in sensorium and in peripheral nervous system function. In serious cases, lethargy and obtundation progress to convulsions, confusion, delirium, and prolonged coma.[20] Over the course of the first several days, a symmetrical, distal sensorimotor peripheral neuropathy develops manifest by profound bilateral weakness in upper and lower extremities. In addition, loss of deep tendon reflexes, vibration, position sense, and distal light touch occurs.[19] Changes in sensorium may persist 1–2 weeks.[26] Peripheral neuropathies usually resolve, but residual effect may continue for several years after the incident.[18,27] Postural hypotension may complicate recovery.

Pregnancy

Podophyllum is contraindicated during pregnancy because of the potential effects from the diffusion of a spindle poison (i.e., podophyllotoxin) from the maternal to fetal circulation. Case reports associate fetal demise and premature labor with the use of podophyllum resin extract.[28]

DIAGNOSTIC TESTING

Analytical methods to quantitate podophyllotoxin and derivatives in plasma include HPLC[24] and HPLC with UV detection.[29] Bone marrow aspiration during podophyllum intoxication demonstrates sudden maturational arrest of both erythroid and myeloid precursors.[20,25] Initially, a profound leukocytosis occurs along with the presence of metamyelocytes and immature band forms in the blood. The leukocyte and platelet counts reach a nadir within the first week after exposure. Severe poisonings produce mild to moderate elevation of serum creatine kinase and hepatic aminotransferase concentrations, but clinically significant hepatic or renal failure is rare. Other laboratory abnormalities include glycosuria, pyuria, and hyperamylasemia.

TREATMENT

Decontamination

Any topical podophyllum resin solution should be removed with soap and water. There are limited data on the efficacy of decontamination measures following the ingestion of podophyllum extract. Because of the potential of serious and delayed toxicity, all alert patients who ingest podophyllum resin within 1–2 hours of presentation to the emergency department should receive activated charcoal. Symptomatic patients should be hospitalized. Children who ingest potentially toxic quantities (i.e., one swallow or 5 mL of the 20% podophyllum resin solution) should be directly observed for at least 8 hours.[19]

Elimination Enhancement

There are inadequate data documenting that hemodialysis or hemoperfusion improve clinical outcome. The high lipid solubility of podophyllotoxin theoretically limits the effectiveness of hemodialysis. A case report on podophyllum toxicity associated clinical improvement with the use of hemoperfusion.[30] However, the use of hemoperfusion removed only 29 mg of podophyllotoxin compared with an estimated ingestion of 400 mg podophyllotoxin.

Supplemental Care

Replacement of fluid and correction of electrolyte imbalance (Na^{++}, K^{+}, Ca^{++}) is the most important aspect

of supportive care. The acid-base balance should be monitored, particularly in dyspneic patients. Symptomatic patients should be observed for at least 24 hours. Although fever may occur during podophyllum intoxication, patients should be evaluated for a potential source of infection (e.g., sepsis, pneumonia), particularly when the fever occurs during the periods of leukopenia (i.e., fourth through seventh day after exposure). Clinical judgment dictates the necessity of broad-spectrum antibiotics. During severe podophyllum poisonings, complete blood counts, platelet counts, and coagulation profiles should be determined daily until evidence of hematological improvement occurs typically at the end of the first week after exposure.

Chapter 130

MISTLETOE

HISTORY

Mistletoe has a long medicinal history including use by herbalists for infertility, epilepsy, asthma, and nervous tension. Until 1978, a mistletoe-containing prescription drug, Felsol, was available in Britain as a treatment for asthma.[1]

BOTANICAL DESCRIPTION

Mistletoe is a hemiparasite (facultative parasite) on the branches of trees or shrubs that can live either as a parasite or as an evergreen plant capable of photosynthesis. These plants rely on their host primarily for water and minerals, and these parasitic plants are adapted to specific hosts. There are over 20 species of the genus *Phoradendron* (mistletoe) in the United States beside the oak mistletoe, including the Christmas mistletoe [*Phoradendron tomentosum* (DC.) Engelm. ex Gray], Pacific mistletoe [*Phoradendron villosum* (Nutt.) Nutt.], mesquite mistletoe (*Phoradendron californicum* Nutt.), and the Colorado Desert mistletoe [*Phoradendron macrophyllum* (Engelm.) Cockerell]. The Christmas mistletoe is a native species of scrub areas of Oklahoma, Texas, and Louisiana.

Common Name: Oak Mistletoe

Scientific Name: *Phoradendron leucarpum* (Raf.) Reveal & M.C. Johnston (*Phoradendron flavescens, Phoradendron serotinum*)

Botanical Family: Viscaceae (mistletoe)

Physical Description: The oak mistletoe is a perennial, facultative parasite that grows primarily on oak trees. The light green leaves and hairy stems grow as a bush 1–4 ft (~0.3–1 m) in height among oak branches. Small white berries appear in grape-like clusters.

Distribution and Ecology: The oak mistletoe is distributed across oak forests in the southwestern, southern, and eastern regions of the United States.

Common Name: European Mistletoe

Scientific Name: *Viscum album* L.

Botanical Family: Viscaceae (mistletoe)

Physical Description: The European mistletoe has oval leaves with smooth edges. The leaves appear as pairs on a woody stem. In contrast to the long cluster (>10) of berries on the oak mistletoe, the European species has shorter, dense clusters (2–6) of waxy, white berries.

Distribution and Ecology: The European mistletoe is the only native mistletoe species is England and most of Europe.

EXPOSURE

Mistletoe is a common, herbal remedy traditionally used for treating hypertension and cancer, particularly breast cancer.[2] Commercial European mistletoe preparations are aqueous extracts of the whole plant, capsules containing dried portions of the whole plant, and teas

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

brewed from leaves. Iscador® (Weleda AG, Arlesheim, Switzerland) is a European extract of *Viscum album* L. distributed by anthroposophic clinics for the treatment of metastatic cancer and HIV as part of a therapeutic program that includes homeopathic extracts, dietary manipulation, and movement therapies.[3] Other European mistletoe extracts include Isorel, Vysorel, or Helixor (sterile extract for subcutaneous injection). Although mistletoe extracts are widely used in the alternative treatment of cancer, rigorous trials of mistletoe extracts fail to demonstrate efficacy of these therapies as an adjuvant to cancer chemotherapy.[4,5] In the semiarid areas of northern Mexico, aqueous extracts of *Phoradendron tomentosum* (Raf.) Engelm. ex Gray are used to treat hyperglycemia associated with diabetes mellitus.[6] *Phoradendron liga* (Gill. Ex H. et A.) Eichl. is an herbal substitute for European mistletoe (*Viscum album* L.) that is used in Argentina for the treatment of hypertension.[7] In the United States, the Food and Drug Administration (FDA) lists mistletoe as a food additive that should not be used until safety has been established. The berries and leaves are commonly used as Christmas decorations.

PRINCIPAL TOXINS

Physiochemical Properties

The major constituents of mistletoe are carbohydrate-binding proteins or lectins (e.g., viscumin), polypeptides (i.e., viscotoxins with a basic chemical structure of thionins), and a number of phenolic compounds (digallic acid, *o*-coumaric acid). The three classes of potential toxins in mistletoe include gastric irritating alkaloids, cardiac toxins (viscotoxins, phoratoxins), and lectins. Viscotoxins are toxic peptides with 46 amino acids and a molecular weight of about 5 kDa. These compounds are present in European mistletoe and are physiologically similar to cobra venom.[8] However, the amino acid sequences and acetylcholine agonist/antagonist properties of mistletoe and cobra toxins are quite different.[9] Viscotoxins contain three disulfide bridges (six cysteine residues) with a chemical structure related to α- and β-thionins. There are at least six isoforms (A1, A2, A3, B, 1-PS, U-PS) of these low-molecular-weight, basic polypeptides.[10] These compounds cause vasoconstriction, bradycardia, and negative inotropic effects when administered intravenously to cats. Substantial variation in physiological effects occurs between the cardiotoxins in different mistletoe species. Phoratoxins (A-F) are small basic proteins extracted from the American oak mistletoe (*Phoradendron leucarpum*).[11] These proteins cause effects quantitatively different from those of viscotoxins from the European mistletoe (*Viscum album*).[12] To cause bradycardia, hypotension, and decreased inotropy, the required parenteral dose of phoratoxin is 10 times higher than the dose of viscotoxins.

Poisonous Parts

All parts of the plants are poisonous. The concentration of viscotoxins in European mistletoe varies with individual strains, but the concentration of these compounds is relatively stable during the harvesting season.[13] Dried stems and leaves contain viscotoxins[12] and lectins.[14] The concentration of viscotoxins varies between plant parts. For example, the concentration of viscotoxin A1 is substantially higher in seeds than in young shoots.[15] The berries of mistletoe contain a gastrointestinal irritant.

Mechanism of Toxicity

Viscotoxins apparently alter cell membrane permeability and polarity by displacing calcium.[8] In high doses, viscotoxins are cardiotoxic as a result of the inhibition of papillary muscle function. A toxic lectin, viscumin, occurs in the European mistletoe. Like ricin, viscumin is composed of an A chain (type II ribosome-inactivating protein, ribotoxin) and a D-galactose binding B chain that allows entry into the cell rather than inhibit protein synthesis.[16,17] Unlike those of ricin, the toxic and hemagglutinating properties cannot be separated. The contribution of viscumin to human toxicity is unclear.

DOSE RESPONSE

In a retrospective case series of 92 US patients reporting exposure to mistletoe, there were six cases of gastrointestinal upset, two cases of mild drowsiness, and one case of ataxia.[18] The reported amount ingested ranged up to 20 berries and five leaves. A review of 1,754 exposures to mistletoe reported to the American Association of Poison Control Centers national data collection system from 1985–1992 did not demonstrate any major effects attributed to exposure to mistletoe.[19]

TOXICOKINETICS

Although mistletoe contains a number of potential oral toxins (e.g., phenylethylamine, tyramine, viscotoxins, phoratoxins), the degree of gastrointestinal absorption remains poorly documented.

CLINICAL RESPONSE

Although ingestion of large quantities of mistletoe berries potentially causes gastroenteritis, the toxic

effects resulting from ingestions of mistletoe are not well documented in the literature.[1] In 1874, a 14-year-old boy reportedly ate some mistletoe berries and developed a "state of intoxication" characterized by conjunctival erythema, amnesia, dilated pupils, and slow, bounding pulse that resolved by the following day.[20] The National Clearinghouse for Poison Control Centers reported a death from tea brewed from berries 12 hours after the onset of acute gastroenteritis. This case was the first mistletoe poisoning case reported in the Quarterly Cumulative Medical Index since 1930. The family reported that a 28-year-old woman suddenly developed copious vomiting and diarrhea several hours after drinking an unknown quantity of mistletoe tea. The patient presented to the emergency department in shock with confusion, diaphoresis, and no detectable blood pressure. She died within 10–15 minutes after arrival, and no dysrhythmias were recorded. Significant autopsy findings included a slightly enlarged uterus containing placental tissue that suggested the possibility of sepsis or the use of abortifacients. Rare adverse reactions associated with the use of European mistletoe extract include eosinophilia[21] and severe anaphylaxis (generalized urticaria, angioedema, dyspnea, vomiting).[22] Immunoblotting of serum from the patient with severe anaphylaxis demonstrated IgE binding to 5-kDa proteins in mistletoe extract that corresponds to the molecular weight of viscotoxins.

DIAGNOSTIC TESTING

High performance liquid chromatographic methods are available for the quantitation of viscotoxins in mistletoe extracts, such as Iscador®.[23]

TREATMENT

Because mistletoe causes significant gastrointestinal irritation following ingestion, decontamination measures are usually unnecessary. The ingestion of one to three berries or one to two leaves probably would not cause toxic effects in a child.[24] Symptomatic patients should be monitored for vital sign and cardiac rhythm abnormalities. There are no specific antidotes to mistletoe toxicity. The potential for adverse cardiac effects theoretically exists based on the presence of parenteral cardiotoxins in mistletoe, but there are few human data to indicate that these cardiotoxins cause clinically significant cardiac abnormalities following causal ingestions. Patients with dysrhythmias or electrolyte imbalance should be hospitalized for observation overnight. Asymptomatic patients may be discharged after several hours of observation.

Chapter 131

POISON HEMLOCK
(*Conium maculatum* L.)

HISTORY

The early Greeks used poison hemlock as a means of suicide. In the Socratic dialogue *Phaedo*, Plato implied that Socrates died in 399 BC from *Conium* poisoning as was the custom in Greek executions.[1] The passage described a slowly ascending paralysis beginning in the feet and progressing to the chest with preservation of mental function until close to death. However, Plato's *Phaedo* did not specifically mention hemlock as the poison, and his description of Socrates' death was more metaphorical than historical.[2] The calm death characterized by ascending paralysis and terminal asphyxia suggests that the death cup drunk by Socrates may have contained other compounds, such as opium.[3] Gieseche isolated coniine in 1827 and Landenburg synthesized this alkaloid in 1886.[4] The London and Edinburgh *Pharmacopoeias* contained medical references to the dried leaf and juice of *Conium maculatum* from 1864 to 1898, and the last officially recognized passage to the medicinal use of hemlock appeared in the British *Pharmacopoeia* of 1934.[5]

BOTANICAL DESCRIPTION

The term hemlock has been loosely applied to several plants and trees that vary in toxicity. Other toxic varieties of hemlock include the water hemlock plant (*Cicuta* spp.) and the ground hemlock (*Taxus canadensis* Marshall). The hemlock tree is a conifer (*Tsuga* spp.) and is nontoxic.

Common Name: Poison Hemlock, Poison Fool's Parsley, California or Nebraska Fern

Scientific Name: *Conium maculatum* L.

Botanical Family: Apiaceae (carrot, formerly Umbelliferae)

Physical Description: This large biennial weed produces a large, forked, white to yellow taproot. Lacy, fern-like leaves reach 8–10 ft (~2–3 m) in height. The whole plant exudes a fetid odor. The stems are erect, smooth, stout, and hollow with characteristic brownish-red to purple spots on the lower portions. The numerous triangular leaves are multiply pinnate and deeply divided into minute leaflets. The flowers are small, white, and clustered into multiple umbrella-shaped groups. The plant is mistaken for wild parsnip, the seeds for anise, and the leaves for parsley. The water hemlock (*Cicuta virosa* L.) lacks the purplish spots and mousy odor present on *Conium maculatum*, and the water hemlock has a branched root system with a lateral tuber rather than a single taproot present on the poison hemlock.

Distribution and Ecology: *Conium* species grow as prolific weeds along roadsides, ditches, and open areas throughout the United States, especially in the north. This plant prefers damp ground, river banks, roadsides, pastures, and meadows including waste land. *C. maculatum* was introduced into the United States from Europe as an ornamental plant.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

EXPOSURE

C. maculatum was listed in the *British Pharmaceutical Codex* until 1934 and in the *US National Formulary* until 1936 as an antispasmodic, sedative, and analgesic.[6] Prior herbal uses of *C. maculatum* include the treatment of gout, herpes, erysipelas, breast tumors, edema, and stomach pains. Poisonings usually result from mistaken identification during foraging for natural food; however, the bitter taste of the plant usually discourages consumption.

PRINCIPAL TOXINS

Physiochemical Properties

Conium toxicity results from piperidine alkaloids, which are structurally related to the pyridine nicotine. These propyl piperidine alkaloids are among the simplest alkaloids and appear in other plant families (Crassulaceae, Punicaceae). At least eight piperidine alkaloids are present in *C. maculatum* with the major alkaloids being coniine (2-propylpiperidine), *N*-methylconiine, and γ-coniceine.[6] γ-Coniceine is the precursor of conhydrinone, *N*-methylconiine, conhydrine, *N*-methylconhydrine, pseudoconhydrine, and 2-methylpiperidine.[7] Investigations with $^{14}CO_2$ revealed that the biosynthetic sequence is CO_2 → γ-coniceine → coniine → *N*-methylconiine.[8] The interconversion of γ-coniceine and coniine suggests that these compounds are members of an oxidation-reduction system.[9] Figure 131.1 displays the chemical structures of various *Conium* alkaloids. Coniine is heat stable.

Poisonous Parts

Although all vegetative organs, flowers, and fruits contain alkaloids, the alkaloid content varies significantly between species, plant parts, season, time of day, moisture, temperature, and geographic locations. The alkaloid content of plant parts during the flowering stage is relatively low. As the plant matures, the alkaloid concentration increases respectively in the stems, leaves, and fruit, but the roots consistently contain the largest alkaloid concentrations. Analysis of *C. maculatum* during the growing season indicates that γ-coniceine (an unsaturated alkaloid) predominates in the wet season during active growth, whereas saturated alkaloids (e.g., coniine, conhydrine) predominate during the dry season.[10] Thus, γ-coniceine predominates in the early (vegetative and flowering) stages of plant growth, whereas coniine is the major alkaloid during the development of fruits. During the latter stage, the coniine content of the fruit is about 10–20 times greater than the γ-coniceine content (e.g., 87 μg vs. 5 μg, respectively).[7] In the ripe fruits, *N*-methylconiine is the predominant alkaloid.[9] The concentration of leaves from a *C. maculatum* plant associated with *Conium* intoxication averaged about 850 μg γ-coniceine/g plant, wet weight.[11] The estimated average alkaloid content of various parts of *Conium maculatum* is as follows: roots, 0–0.5%; stems,

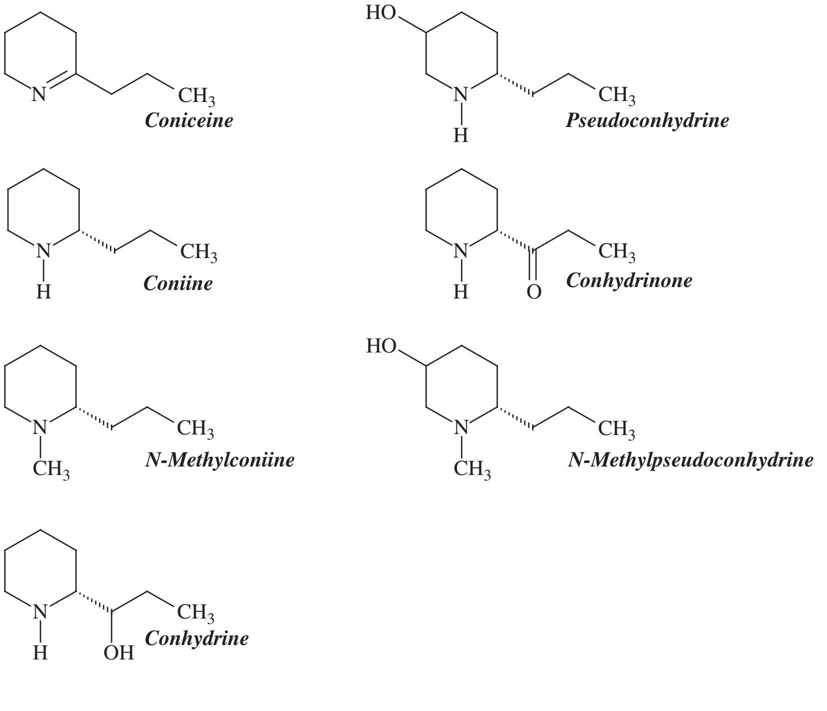

FIGURE 131.1. Conium alkaloids.

0.02–0.7%; leaves, 0.3–1.5%; flowers, 1%; unripe fruit 1.6–3%; ripe fruit 0.2–1%; and seeds, 0.02–0.9%.[12]

Mechanism of Toxicity

The pharmacological actions of *Conium* alkaloids (coniine, *N*-methylconiine, γ-coniceine) are similar to nicotine.[5] These alkaloids are nondepolarizing blocking agents in high doses that produce respiratory failure as well as peripheral nicotinic effects (mydriasis, salivation, tachycardia). Postmortem examinations of fatalities associated with *Conium* poisoning demonstrate nonspecific findings (e.g., pulmonary congestion).[13]

DOSE RESPONSE

There are inadequate human data to determine the dose response for the ingestion of poison hemlock.

TOXICOKINETICS

There are no data on the toxicokinetics of coniine, a known animal teratogen, in humans. The variable response of different animal species (e.g., rats, hamsters, and chickens are not susceptible) to *Conium* alkaloids suggests that there are species-related differences in the metabolism of these compounds.[14]

CLINICAL RESPONSE

Conium intoxication in animals is commonly manifest by ataxia, salivation, convulsions, and coma. In animal studies, congenital joint and spinal abnormalities similar to those of crooked calf disease associated with consumption of lupine developed after the feeding of fresh green *Conium* plants to pregnant cows.[15] Based on animal data and the structural similarity of *Conium* alkaloids, the expected clinical features of *Conium* poisoning would include initial stimulation (tremor, ataxia, mydriasis), nausea, vomiting, and sore throat followed by cardiorespiratory depression (bradycardia, paralysis, coma) and ascending paralysis. Respiratory failure and death potentially result from the ingestion of high doses of *Conium* alkaloids.[16] Case reports associate exposure to *Conium maculatum* with respiratory failure,[17] coma, and death.[13] Although laboratory analysis confirmed exposure to *Conium maculatum*, there were limited clinical data and the exact contribution of *Conium maculatum* to the clinical course of these individuals is unclear. In contrast to *Cicuta* (water hemlock) poisoning, convulsions are not usually associated with *Conium* intoxication.

DIAGNOSTIC TESTING

Gas chromatographic methods with nitrogen phosphorus detectors are available to confirm exposure to *Conium* alkaloids (e.g., coniine) at detection limits ranging between 0.025–0.2 μg/g sample.[18] Intratubular deposition of myoglobin and acute tubular necrosis may complicate *Conium* poisoning as a result of rhabdomyolysis.[19] The presence of γ-coniceine in blood and urine samples confirms exposure to *Conium* species.

TREATMENT

Treatment is supportive. Decontamination measures are usually unnecessary.

Chapter 132

POKEWEED
(*Phytolacca americana* L.)

HISTORY

This native North American plant was used by Native Americans in the eastern United States for the treatment of a variety of illnesses including dysentery, cancer, and rheumatism. The powdered root was an emetic and cathartic. During the 19th century, this herb was one of the treatments for syphilis. The name pokeweed is derived from the Virginian Indian word "pocon," which means plant with red dye.

BOTANICAL DESCRIPTION

Common Name: Pokeweed, Pokeberry, Poke, Pokeroot, Inkberry, Crowberry, Pigeonberry, American Cancer, American Nightshade, Scoke, Jalap, Garget

Scientific Name: *Phytolacca americana* L.

Botanical Family: Phytolaccaceae (pokeweed)

Physical Description: Pokeweed is a large perennial herb that grows from a long fleshy taproot each spring to reach a height of 3–10 ft (~1–3 m). The smooth, purple-green leaves have smooth margins and sharp tips. In late summer and early fall, white to purplish flowers produce round clusters of dark purple berries with red juice. The roots may be mistaken for parsnips or horseradish, and the shoots unwittingly substituted for asparagus. Figure 132.1 displays the branches and berries of the pokeweed plant.

Distribution and Ecology: Pokeweed is a native weed of the eastern United States that grows abundantly in rich, moist areas in open fields and roadsides. Occasionally, pokeweed grows in the western United States.

EXPOSURE

Folk remedies containing pokeweed are used as a salve for pruritus and as a bronchodilator. The fresh root was applied as a poultice on bruises and painful joints. Poke salad is a regional delicacy of the rural southern United States that requires special preparation. In the spring, young, tender leaves are boiled twice, the washing water is discarded, and the leaves are rinsed carefully before eating. Powdered poke root is available as an herbal tea.

PRINCIPAL TOXINS

Physiochemical Properties

Pokeweed contains the glycoside, phytolaccine, which produces gastrointestinal irritation. The concentration of phytolaccine increases as the plant matures. Salt extraction of pokeweed produces five nonspecific mitogens that possess hemagglutinating and mitotic activity.[1] Noncardioactive steroids and triterpenoid glycosides (saponins) also occur in pokeweed,[2] but the contribution of these substances to pokeweed poisoning remains unclear. In general, saponins are irritants and produce foaming in solutions. Pokeweed lectin is a lectin specific for *N*-acetylglucosamine-containing saccharides that stimulates peripheral lymphocytes to undergo mitosis by binding to their cell surfaces.[3] The name inkberry was

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

FIGURE 132.1. Pokeweed (*Phytolacca americana* L). Photograph courtesy of Lewis Nelson, MD. See color insert.

given to pokeweed because of the purplish stains that result from contact with the mature berries. Pokeweed contains a ribosome-inactivating protein (ribotoxin) that has a mechanism of action similar to ricin; however, the effects are much less severe.[4] The role of this lectin in producing toxicity after ingestion of pokeweed is unclear.

Poisonous Parts

All parts of the pokeweed plant are potentially toxic depending on preparation, individual susceptibility, plant part, and growing season. Toxicity generally increases with maturity with the exception that green berries are more toxic than ripe berries. The root is particularly toxic with the leaves, the stems, and the berries demonstrating progressively less toxicity. Double washing of pokeweed leaves does not guarantee edibility.

Mechanism of Toxicity

Although phytolaccine is a recognized gastrointestinal (GI) irritant, the important toxins in pokeweed are not well delineated. Saponins may potentiate GI toxicity. Pokeweed mitogen is a glycoprotein that promotes leukocytosis and stimulates the production of interferon.[5]

DOSE RESPONSE

The severity of clinical symptoms depends on individual sensitivity as well as the dose of pokeweed. Of 46 campers who ate "properly prepared" pokeweed on a New Jersey nature expedition, 20 developed gastroenteritis.[6] In a case series of boy scouts eating pokeberry pancakes, only a few individuals developed mild diarrhea.[7] Anecdotal case reports associate the ingestion of a large amount of juice from pokeberries with a fatal outcome for a 5-year-old girl, but this case report is not well documented.[8]

TOXICOKINETICS

The toxins in pokeweed have not been well defined, and there are few toxicokinetic data on suspected toxins.

CLINICAL RESPONSE

The GI effects of pokeweed ingestion are highly variable depending on a variety of variables including the preparation method and season. Although properly prepared pokeweed is a delicacy, the ingestion of pokeweed can produce symptoms ranging from a burning sensation of the GI tract to severe hemorrhagic gastritis. Early gastrointestinal symptoms predominate in pokeweed poisoning depending on the amount of pokeweed ingested. Reported clinical features of an outbreak of pokeweed poisoning from the ingestion of salad containing pokeweed included nausea (86%), stomach cramps (86%), vomiting (81%), headache (52%), dizziness (48%), burning of mouth or stomach (38%), and diarrhea (29%).[6] The mean onset of illness was 3 hours with a range of $^1/_2$ to $5^1/_2$ hours. Symptoms resolved within 1–48 hours. The diarrhea may contain foam as a result of the action of saponins on the contents of the gastrointestinal tract. A case report documented the onset of lethargy, weakness, paresthesias, blurred vision, vertigo, sweating, salivation, urgency, syncope, respiratory depression, and convulsions 30 minutes after the ingestion of a brewed tea of pokeweed leaves and roots.[9]

Peripheral and central cholinergic signs may occur during severe pokeweed intoxications. Hypotension and tachycardia commonly occur after serious pokeweed poisoning.[10] However, serious cardiac dysrhythmias are uncommon.[11] Rate-related ST depression in a 65-year-old woman was associated with the ingestion of a folk remedy containing pokeweed.[12] She recovered without sequelae. Most case reports of fatalities associated with pokeweed poisoning appeared in the older medical literature before modern medical diagnostic testing and therapy. There are no reports of long-term sequelae from pokeweed intoxication.

DIAGNOSTIC TESTING

A peripheral plasmacytosis may occur after pokeweed ingestion as a result of the effects of pokeweed mitogen.

In four of five children exposed to pokeweed, a significant increase in the number of both immature and mature plasma cells occurred after the ingestion of pokeweed.[13]

TREATMENT

The treatment of pokeweed poisoning is supportive. Dehydration and hypotension are the most common serious effects of pokeweed intoxication that require immediate medical treatment. Patients symptomatic during pokeweed intoxication usually respond to antiemetic drugs and restoration of fluid and electrolyte balance. Occasionally, the administration of vasopressors may be necessary. Because pokeweed contains a powerful gastrointestinal irritant, decontamination measures are unnecessary. Serious pokeweed intoxications typically involve ingestion of pokeweed teas and these patients may require hospitalization for the monitoring of hypotension and electrolyte imbalance. Symptoms usually resolve within 24–36 hours. There are no specific antidotes to pokeweed toxins and atropine does not effectively reverse the effects of pokeweed intoxication.

Chapter 133

EUROPEAN BITTERSWEET and OTHER *SOLANUM* SPECIES

BOTANICAL DESCRIPTION

The Solanaceae (potato) family contains annual and perennial herbs, shrubs, and trees that grow worldwide. The leaves are simple and alternate. The flowers have five widely spreading petals; the stamens are grouped conically in the center. The ovary of the flower matures into a fruit. In the United States, *Solanum* (nightshade) contains over 100 native and introduced species. This genus has a number of species that are toxic to grazing animals including *Solanum carolinense* L. (Carolina horsenettle), *Solanum elaeagnifolium* Cav. (silverleaf nightshade, tropillo), *Solanum nigrum* L. (black or common nightshade), and *Solanum triflorum* Nutt. (cutleaf nightshade).

Common Name: European Bittersweet, Woody Nightshade, Climbing Nightshade, Blue Nightshade

Scientific Name: *Solanum dulcamara* L.

Botanical Family: Solanaceae (potato)

Physical Description: This slender, woody, climbing perennial vine grows from rhizomes. The leaves are ovate, alternate, simple or deeply lobed with pointed tips. The bluish to deep purple flowers arise from stalks. The mature fruit is orange-red and almost round.

Distribution and Ecology: This native species of Eurasia inhabits thick woods and moist environments of low woods, thickets, and roadsides from Nova Scotia and Minnesota south to Texas and Florida.

Common Name: Jerusalem Cherry

Scientific Name: *Solanum pseudocapsicum* L.

Botanical Family: Solanaceae (potato)

Physical Description: This perennial plant produces red berries during Christmas that are similar in appearance to cherry tomatoes.

Distribution and Ecology: This native, frost-tolerant Peruvian plant is an ornamental house and garden plant that has been naturalized in areas of Australia, southeastern United States, Texas, and New England.

Common Name: Bhankatiya, Devil's Fig, Fausse Aubergine, Kausoni, Prickly Solanum, Terongan, Turkey Berry, Susumber Berry

Scientific Name: *Solanum torvum* Sw.

Botanical Family: Solanaceae (potato)

Physical Description: This broad-leaved, evergreen, shrub or small tree grows up to 4 m (~13 ft) in height. The stems contain straight or lightly curved thorns. The alternate leaves have a prominent midvein that also has thorns. Leaf margins are shallowly and irregularly lobed. Small, white flowers appear in large clusters that produce small yellow berries about 10–15 mm in diameter. The glabrous, globose fruit contains many seeds.

Distribution and Ecology: This plant is a major weed in pastures, roadsides, and wasteland that prefers moist, fertile soil. In tropical areas of the United States (e.g., Hawaii, Florida), this weed forms

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

impenetrable thickets. Susumber berry is native to tropical areas from Mexico to Peru and Venezuela as well as the Caribbean Islands and Bermuda. *S. torvum* is widely cultivated throughout the world for its edible fruit.

EXPOSURE

Leaves and fruit from *Solanum nigrum* have been used in the Middle East, North Africa, and India as herbal treatments for toothache, skin lesions, burns, scabies, and anxiety.[1] The susumber berry is used in traditional Jamaican cooking after washing and boiling in water to a tender, crisp state. The berries are picked in various stages of development, and the cooked berries are added to sautéed salted codfish, peppers, onions, and tomatoes.

PRINCIPAL TOXINS

There are few data on the toxic constituents of *Solanum* species, including potentially toxic glycoalkaloids (α-chaconine, α-solamargine, α-solanine, solasonine, sycophantine, α- and β-solamarine, soladulcidine, (tomatine), and aglycones (e.g., solanidine, solanocapsine, solasodine, tomatidine). Analysis of unripe berries from *S. dulcamara* by gas chromatography/mass spectrometry demonstrated the presence of the glycoalkaloid aglycones, solasodine (CAS RN: 126-17-0) and diosgenin (CAS RN: 512-04-9).[2] The latter compound is the steroidal aglycone of the saponin, dioscin. Tropane alkaloids (e.g., atropine, hyoscyamine) were not detected in the berries. Other glycoalkaloids include α-, β-, γ-, and δ-solamarine, soladulcidine, tomatine, and tomatidenol. The specific compounds responsible for the toxic effects associated with exposure to *Solanum* species are not well defined, in part, because of the variable concentration of these compounds in different strains grown under diverse conditions. Animal studies and epidemiological data indicate that ripe berries of the Jerusalem cherry do not usually contain substantial amounts of solanine or other toxic glycoalkaloids.[3] The ingestion of unripe berries typically causes a mild gastroenteritis. The toxin in susumber berries has not been identified, but analysis of toxic berries by high performance liquid chromatography (HPLC) with UV detection suggests that these berries contain toxins in addition to α-chaconine and solanine.[4]

DOSE RESPONSE

There are inadequate data to determine a dose-response relationship between exposure to *Solanum* species and toxic effects.

TOXICOKINETICS

The toxic principals in *Solanum* species have not been identified; therefore, there are few toxicokinetic data.

CLINICAL RESPONSE

There are few reported cases of poisoning associated with woody nightshade or the Jerusalem cherry in the medical literature. The existing case reports do not confirm the presence of biomarkers (e.g., glycoalkaloids) of *Solanum* species in biological samples from these patients. A case report of a 7-year-old girl associated the ingestion of berries from *S. dulcamara* with a self-limited gastroenteritis and mydriasis,[5] whereas a 4-year-old girl developed sinus tachycardia, confusion, disorientation, mydriasis, elevated temperature, and tremor after ingesting woody nightshade berries.[2] More serious clinical effects associated with peripheral and central anticholinergic syndrome include tachycardia, weakness, headache, diaphoresis, mydriasis, urinary retention, fever, and central nervous system (CNS) effects (disorientation, confusion, ataxia, agitation, seizures, coma, respiratory failure). However, there are few well-documented reports of serious central anticholinergic symptoms temporally related to exposure to woody nightshade or Jerusalem cherry plants. A four-year-old girl developed memory disturbances, hallucinations, ataxia, seizures, fever (39.4 °C/102.9 °F), tachycardia, facial flushing, mydriasis, and dry mucous membranes.[6] The parents reported gastrointestinal symptoms in the girl several days *prior* to the onset of CNS effects. The patient stated that she ate seeds and other parts of *Solanum pseudocapsicum*, and her urinalysis contained solanocapsin-related compounds consistent with ingestion of this plant. Fatalities from solanine poisoning are unusual with modern supportive care, but case reports before 1950 associate fatalities with woody nightshade (*Solanum dulcamara*). An older case report associated the ingestion of berries from woody nightshade by a 9-year-old girl with a hemorrhagic gastritis, dehydration, and dyspnea.[7] She died after 36 hours of treatment by methods currently not used, including stomach lavage without respiratory protection, soap-and-water enemas, nikethamide, and rectal fluids. Rare case reports associate the consumption of susumber berries with the development of gastrointestinal and neurological symptoms. Three adult members of a family ate a traditional evening meal containing codfish, ackee, and susumber berries.[4] All three family members became ill the following morning with symptoms ranging from mild diarrhea to facial droop, blurred vision, dry mouth, dysarthria, and facial paresthesias. The most seriously ill member of the

family developed hypertension, confusion, proximal upper extremity weakness, and respiratory failure that required intubation. She recovered after a prolonged hospitalization.

DIAGNOSTIC TESTING

Methods to identify and quantify the content of glycoalkaloid compounds in solid samples include HPLC/electrospray ionization/mass spectrometry[8] and HPLC.[9] The limits of detection for α-solanine and α-chaconine using the latter method were 1.2 and 1.3 ng/mL, respectively.

TREATMENT

Treatment is supportive. Decontamination measures are usually unnecessary. The administration of activated charcoal to alert patients is a therapeutic option, when the patient ingests large amounts of *Solanum* species less than 1 hour prior to presentation; however, there are no clinical data to indicate that activated charcoal improves the outcome of patients with *Solanum* intoxication. The use of physostigmine is not usually indicated because of the lack of a clear anticholinergic syndrome following exposure to these plants.

Chapter 134

SWEET PEA and OSTEOLATHYRISM

HISTORY

Neurolathyrism has been known to occur after the ingestion of the grass pea or chickling pea (*Lathyrus sativus*) at least since the time of Hippocrates, but the occurrence of skeletal abnormalities from the ingestion of sweet peas (*Lathyrus odoratus*) is less well documented. In animal experiments during the early 1930s, the administration of peas from *Lathyrus odoratus* (sweet pea) produced growth retardation, skeletal deformities, and aortic dissections when the sweet peas accounted for more than 25% of the diet.[1]

BOTANICAL DESCRIPTIONS

There are more than 100 *Lathyrus* species in the United States and Europe, and a number of these species (*Lathyrus hirsutus* L., *Lathyrus latifolius* L., *Lathyrus odoratus* L., *Lathyrus pusillus* Elliot, *Lathyrus sphaericus* Retz., *Lathyrus splendens* Kellogg, *Lathyrus alefeldii* (T.G.White) Bradshaw, *Lathyrus sylvestris* L.) have been associated with toxic effects in animals. There are several species of the genus *Lathyrus* associated with osteolathyrism (odoratism) including *Lathyrus odoratus* L., *Lathyrus hirsutus* L. (singletary pea, caley pea), and *Lathyrus pusillus* Elliot (low pea vine, tiny pea).[2]

Common Name: Sweet Pea

Scientific Name: *Lathyrus odoratus* L.

Botanical Family: *Fabaceae* (pea)

Physical Description: This commonly cultivated vine has showy flowers in erect racemes that mature into legume pods containing many broad flat seeds.

Ecology and Distribution: This plant is an introduced species in North America including northeastern United States, California, Ohio, and Mexico. This climbing annual plant inhabits sunny areas and light woodlands in southern Europe (Italy, Sicily, Crete), Asia, northern Africa, and Australia.

Common Name: Caley Pea, Singletary Pea, Hairy Bitter Vetch

Scientific Name: *Lathyrus hirsutus* L.

Botanical Family: *Fabaceae* (pea)

Physical Description: This legume has winged stems that reach up to about 100 cm (~3 ft) in length. The compound leaves have two long, narrow leaflets that end in a branched tendril up to approximately 10 cm (~4 in.) in length. The small, reddish-blue, pea-like flowers produce distinctive pods, covered with hairs and small, raised areas. Each pod is about 3–4 cm (~1–2 in.) and contains 4–10 mottled, round seeds.

Ecology and Distribution: This plant is an introduced species in the United States, inhabiting areas in California, the Southwest, the Southeast, and north central United States. The singletary pea is widely distributed in Europe, North Africa, temperate areas of Asia, and the Indian subcontinent.

Common Name: Low Peavine, Tiny Pea

Scientific Name: *Lathyrus pusillus* Elliot

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Botanical Family: *Fabaceae* (pea)

Physical Description: This slender, annual climbing plant grows to 60 cm (~2 ft) in length three-branched tendrils. The outer ring of flower parts (calyx) is green and there are one to two blue flowers. The brown pods are 3–6 cm (~1–2 in.) long, and they contain many blue seeds with a broad hilum.

Ecology and Distribution: This native US species inhabits Oregon, Texas, the southern midwestern United States, Virginia, North Carolina, and Florida as well as areas of Central and South America (Argentina, Peru).

EXPOSURE

L. odoratus is widely cultivated as a sweet-smelling ornamental plant. An essential oil from L. *odoratus* is an ingredient in perfumery. The seeds of this plant are not edible. There are no definite medicinal uses of this plant. The singletary pea is a traditional cover crop and winter forage that becomes naturalized in open areas.

PRINCIPAL TOXINS

Physiochemical Properties

Osteolathyrism is a disease of collagen tissue that affects animals grazing on certain *Lathyrus* species (e.g., *L. odoratus*). Compounds associated with osteolathyrism in experimental animals include β-aminopropionitrile (*L. odoratus*), γ-glutamyl-β-aminopropionitrile (*L. pusillus*), and L-2,4-diaminobutanoic acid (*L. latifolius* L.).[3,4] Table 134.1 lists some physical properties of β-aminopropionitrile (CAS RN: 151-18-8, $C_3H_6N_2$). Neurolathyrism in humans results from the ingestion of chickling peas (*Lathyrus sativus* L.), which do not contain β-aminopropionitrile.[5] However, the shoots from *L. sativus* do contain an unstable compound [2-(2-cyanoethyl)isoxazolin-5-one] that potentially may be metabolized to β-aminopropionitrile.[6] Cooking sweet peas for several hours in water does not prevent the development of osteolathyrism in experimental animals when sweet peas represent >25% of the diet.[1]

TABLE 134.1. Some Physical Properties of β-Aminopropionitrile

Physical Property	Value
Melting Point	<25 °C/77 °F
Boiling Point	185 °C/365 °F
log P (Octanol-Water)	–1.130
Atmospheric OH Rate Constant	1.26E-12 cm^3/molecule-second (25 °C/77 °F)

Poisonous Parts

The ingestion of both seedlings and seeds from sweet pea can produce osteolathyrism.[7]

Mechanism of Toxicity

In experimental animals, β-aminopropionitrile inhibits lysyl oxidase, which causes a decrease in the formation of cross-links in collagen and elastin.[8] The development of skeletal abnormalities in animals is called osteolathyrism. The destruction of cross-linking produces abnormal collagen and elastin with poor tensile strength as a result of the replacement of normal amino acids with β-aminopropionitrile and the inhibition of lysyl oxidase. The human variety of lathyrism is a chronic neurologic disease (neurolathyrism) that results from the excessive consumption of the chick pea (*L. sativus*) during periods of food shortages.[9] Skeletal lesions in patients with neurolathyrism are minor because the most common species responsible for neurolathyrism (*L. sativus*) does not contain significant amounts of β-aminopropionitrile. Furthermore, β-aminopropionitrile is not neurotoxic, and osteolathyrism does not occur in humans consuming sweet peas.[8] Other compounds also produce osteolathyrism in experimental animals including thiosemicarbazide derivatives.[10]

DOSE RESPONSE

The dose response for acute or chronic toxicity from the ingestion of sweat peas is not well defined. In rodent studies, rats feed diets containing 0.2% β-aminopropionitrile or 50% crude sweet pea meal develop signs of osteolathyrism.[11]

TOXICOKINETICS

There are few data on the toxicokinetics of β-aminopropionitrile in humans. In a study of one volunteer receiving 250 mg β-aminopropionitrile, unchanged β-aminopropionitrile appeared in the urine within 1 hour of ingestion, and renal excretion of β-aminopropionitrile was completed within 7 hours.[12] Following the administration of 250 mg β-aminopropionitrile 4 times daily for 21 days, the renal excretion of the deaminated, inactive metabolite, cyanoacetic acid, continued at least 2 days after the cessation of the 21-day treatment. During treatment, unchanged β-aminopropionitrile in the urine accounted for approximately 16% of the dose.

CLINICAL RESPONSE

In osteolathyrism, connective tissues fibers do not polymerize properly and animals grazing on sweet peas may develop osteolathyrism. However, the occurrence of osteolathyrism or neurolathyrism is not well documented in humans chronically ingesting sweet peas (*Lathyrus odoratus*). The toxic compound in sweet pea (β-aminopropionitrile) is not neurotoxic; therefore, neurolathyrism is unlikely to occur in humans ingesting sweet peas. Skeletal abnormalities resembling osteolathyrism in animals occurs rarely in humans ingesting chick peas (*Lathyrus sativa*).[13] In a follow-up study of 45 former German concentration camp victims with neurolathyrism from the ingestion of chick peas, five former prisoners had skeletal abnormalities including nonfusion of the iliac crest, ischial apophysis, and vertebral epiphysis, as well as bowing and structural changes of the femur.[14] At the time of exposure to chick peas, the secondary centers of ossification probably were not fused. Rare case reports associate occupational exposure to *Lathyrus odoratus* with rhinitis and asthma in sensitized workers.[15]

DIAGNOSTIC TESTING

The toxic principals in *Lathyrus* species are not well defined. Isoxazolinone compounds are *N,O*-heterocyclic compounds derived from this genus that are precursors to potentially toxic metabolites. The presence of β-(isoxazolin-5-on-2-yl)propionitrile and 2-(3-amino-3-carboxypropyl)isoxazolin-5-one are highly suggestive of *L. sativus* or *L. odoratus*. The isoxazolinone compounds are sensitive to alkaline conditions and UV radiation. Identification of these compounds involves high performance liquid chromatography with pre-column phenyl isothiocyanate derivatization or capillary zone electrophoresis.[16] Using the latter method, limits of detection for these compounds range between 3 μg/mL and 7.7 μg/mL.

TREATMENT

Management involves primarily supportive care. Decontamination measures are unnecessary.

Chapter 135

TREE TOBACCO and OTHER PIPERIDINE-CONTAINING PLANTS

BOTANICAL DESCRIPTION

Nicotiana genus consists of about 60 plant species in North and South America, Australia, and the South Pacific. *N. rustica* L. (Aztec tobacco) is native to Virginia, but the commercial value of this plant is substantially less than the South American native, *N. tabacum* L. (cultivated tobacco). Cultivated tobacco does not persist well in the wild in contrast to native species (e.g., *Nicotiana obtusifolia* Mertens & Galeotti or desert tobacco from the southwestern United States).

Common Name: Tree Tobacco
Scientific Name: *Nicotiana glauca* Graham
Botanical Family: Solanaceae
Physical Description: This plant is a large, evergreen, loose branching tree that grows up to 6–18 ft (~2–6 m) in height. The pithy, hairless stems have ovate leaves and a waxy, blue-green cuticle. The distinctive flowers are tubular and yellow.
Distribution and Ecology: *N. glauca* is a native plant of South American (Paraguay, Argentina) that is naturalized in temperate climates in Central America, Mexico, California, Texas, New Mexico, and Arizona. This drought-resistant plant tolerates a wide variety of habitats, particularly in waste areas, dry river beds, and roadsides.

Common Name: Coyote Tobacco
Scientific Name: *Nicotiana attenuata* Torr. ex S. Wats. (*Nicotiana trigonophylla* Dunal)
Botanical Family: Solanaceae
Physical Description: This branching, annual plant has long, tubular white flowers that open at night.
Distribution and Ecology: This native plant of the United States inhabits dry areas and streambeds of the West and Southwest.

Common Name: Indian Tobacco
Scientific Name: *Lobelia inflata* L.
Botanical Family: Lobeliaceae (lobelia)
Physical Description: An annual weed that has simple alternate leaves with inconspicuous blue flowers in a terminal raceme.
Distribution and Ecology: This plant is a native species of the midwestern and eastern United States that inhabits dry areas of waste areas, open woods, meadows, fields, and roadsides. Several other *Lobelia* species (*L. berlandieri* A. DC., *L. cardinalis L. syphilitica* L.) are native species in moist woodlands.

EXPOSURE

Previously, nicotine was used as a pesticide and veterinarian anesthetic, but less toxic products are now available for these applications. As a substitute for smoking, nicotine transdermal patches deliver about 7–21 mg nicotine per day. Anabasine was extracted from *Anabasis aphylla* L. in Russia for use as a pesticide.[1] Tree tobacco (*N. glauca*) was one of several *Nicotiana* species

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

used as smoking tobacco by early California Native Americans, particularly northern California tribes (e.g., Karok). Northeastern Native Americans used the dried herb, *Lobelia inflata*, as a purgative and emetic. These Native Americans also incorporated the herb into tobacco leaves for smoking. Lobeline sulfite has been advocated as a tobacco substitute to aid people in breaking the smoking habit, but there are inadequate data to support the use of lobeline as a tobacco substitute.

PRINCIPAL TOXINS

Physiochemical Properties

Nicotiana Glauca

This plant contains primarily piperidine alkaloids including an isomer of nicotine, anabasine [1-(3-pyridyl) piperidine]. Anabasine (CAS RN: 494-52-0, $C_{10}H_{14}N_2$) is a minor alkaloid in the common tobacco plant leaf, but this alkaloid is a major constituent of the *N. glauca* leaf as well as the stalks of *N. tabacum*.[2] Figure 135.1 displays the chemical structure of anabasine. Native Australian species of *Nicotiana* that contain anabasine include *N. debneyi* Domin. and *N. rotundifolia* Lindl. Anabasine is a diprotic base with a pK_{a2} of 3.21. Table 135.1 lists some physical properties of anabasine and Table 135.2 lists some physical properties of nicotine.

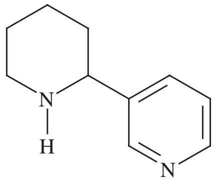

FIGURE 135.1. Chemical structure of anabasine.

TABLE 135.1. Some Physical Properties of Anabasine

Physical Property	Value

Atmospheric OH Rate Constant	1.01E-10 cm^3/molecule-second (25 °C/77 °F)

Lobelia Inflata

Lobelia inflata contains at least 14 different piperidine alkaloids including lobeline and the emetic alkaloids, lobelanine and lobelanidine. Lobeline is structurally and pharmacologically similar to nicotine.

Poisonous Parts

Nicotine (CAS RN: 54-11-5, $C_{10}H_{14}N_2$) is the major toxic alkaloid in *N. tabacum* (tobacco) leaves averaging about 2–4% with a range of approximately 1.5–5.4% dry weight.[3] Figure 135.2 displays the chemical structure of nicotine. The nicotine isomer, anabasine, is the primary alkaloid in *Nicotiana glauca* with nicotine occurring in minor amounts. The approximate anabasine content in the dry plant, root, and leaves is about 1.3%, 1%, and 0.2%, respectively.[4,5] Analysis of three South African specimens of *N. glauca* demonstrated anabasine concentrations in flowers and leaves of approximately 1.4–1.5 mg/g wet weight and 1.8–2.0 mg/g wet weight, respectively.[6] Lobeline is the principal alkaloid in *Lobelia inflata* with a typical concentration of approximately 0.3%. Although cytisine and lobeline produce nicotine-like peripheral effects, animal studies indicate that the potency of these two alkaloids is much lower than nicotine.[7]

Mechanism of Toxicity

Nicotinic cholinergic receptors are composed of a ligand-gated ion channel consisting of five subunits;

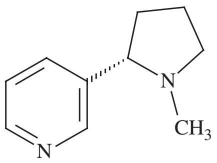

FIGURE 135.2. Chemical structure of nicotine.

TABLE 135.2. Some Physical Properties of Nicotine

Physical Property	Value
Melting Point	–7.90E + 01 °C/33.8 °F

Henry's Law Constant	3.00E-09 atm-m^3/mole (25 °C/77 °F)
Atmospheric OH Rate Constant	9.10E-11 cm^3/molecule-second (25 °C/77 °F)

these receptors occur in the brain, autonomic ganglia, and the neuromuscular junction.[8] Nicotinic receptors appear throughout the brain including the amygdala, septum, locus ceruleus, and brainstem motor nuclei; however, the highest concentrations of binding sites occur in the cortex, interpeduncular nucleus, and the thalamus.[9] Initially, nicotine stimulates the nicotinic cholinergic receptors stereoselectively in the sympathetic and parasympathetic ganglia of autonomic nervous system as well as in the neuromuscular junction.[10] *l*-Nicotine is the active stereoisomer, whereas *d*-nicotine is a weak agonist at the cholinergic receptors. Depending on the dose of nicotine, the stimulatory phase may be transient with prolonged ganglionic blockade resulting from persistent membrane depolarization.

DOSE RESPONSE

Although the commonly quoted estimated lethal adult dose of nicotine is approximately 60 mg,[11] there are few data correlating nicotine toxicity with dose. The suicidal ingestion of a nicotine dose exceeding 5 grams (71 mg/kg) by a 17-year-old male smoker resulted in hypotension, intractable seizures, ventricular fibrillation, and death.[12] A case report associated the ingestion of 10–12 fried, tree tobacco leaves with the development of severe muscle weakness, bulbar palsy, hypertension, vomiting, and respiratory insufficiency.[13] The patient recovered with supportive care.

TOXICOKINETICS

Absorption

Case reports document the absorption of clinically significant amounts of nicotine from the skin,[14] lungs, and gastrointestinal tract.[15] The absorption of nicotine is highly pH dependent and toxicity depends on pH, formulation, mastication, and nicotine content. Experimental studies demonstrated that absorption of nicotine from a solution buffered to a pH of 1, 7.4 and 9.8 was 3.3%, 8.2%, and 18.6%, respectively.[16] Absorption of nicotine from the stomach is limited because of acid pH, whereas nicotine absorption is much higher in the alkaline environment of the duodenum. Symptoms of nicotine toxicity develop rapidly after large doses. Case reports from the older medical literature indicates that death can occur within 5–10 minutes of the ingestion of liquid pesticide containing 40% nicotine.[17,18] Dermal absorption of a 95% nicotine solution caused coma and respiratory failure.[19]

Distribution

Nicotine distributes extensively and rapidly into tissues with a volume of distribution (V_d) ranging from about 1–3 L/kg.[20] The average V_d following the intravenous administration of a nicotine dose equivalent similar to the dose of nicotine present in cigarettes was approximately 1.7 times body weight.[21] Although there is substantial interindividual variation, nicotine concentrations in plasma samples are generally higher in arterial blood than venous blood, with the latter double the former shortly after the beginning of smoking.[22]

Biotransformation/Elimination

Hepatic cytochrome P450 enzymes catalyze the metabolism of about 70–80% of administered dose of nicotine to inactive metabolites (e.g., cotinine, nicotine-1′-*N*-oxide) via C-oxidation. Experimental studies of poor and extensive metabolizers of dextromethorphan, a probe for CYP2D6 activity, suggests that CYP2D6 is not a major cytochrome P450 isoenzyme for the metabolism of nicotine or cotinine.[23] The kidneys excrete nicotine metabolites as 3′-hydroxycotinine, unchanged compounds or glucuronide conjugates.[9] About 5–10% of the absorbed dose of nicotine from cigarette smoking appears in the urine unchanged.[24] The average plasma elimination half-life of nicotine following intravenous administration is about 2–3 hours, whereas the half-life of the inactive metabolite cotinine is about 16 hours. Elimination of nicotine is similar in smokers and nonsmokers.[25]

CLINICAL RESPONSE

Nicotine

The onset of symptoms is usually rapid (15–30 minutes) beginning with gastrointestinal distress (vomiting, nausea, salivation, abdominal pain, diarrhea). Vomiting is almost always present following the ingestion of tobacco products, but the absence of vomiting does not necessary exclude the development of potentially serious nicotine toxicity.[26] Symptoms in mild nicotine poisoning resolve in several hours. Severe nicotine poisoning involves a stimulatory phase followed by an inhibitory phase that occurs over 24 hours. Transiently, hypertension and tachycardia may develop followed by hypotension, bradycardia, decreased deep tendon reflexes, fasciculations, paralysis and cardiovascular collapse. Neurologic symptoms include headache, diaphoresis, ataxia, lightheadedness, weakness, confusion, and, in severe poisonings, convulsions, coma, and respiratory failure.[15] Nicotine acts unpredictably as an agonist of the

muscarinic receptors; therefore, the occurrence of cholinergic symptoms (miosis, salivation, lacrimation, bronchorrhea, diarrhea, bradycardia) is variable.[27]

Tree Tobacco

The ingestion of tree tobacco leaves (*N. glauca*) produces clinical features similar to nicotine poisoning with initial hypertension, tachycardia, vomiting, headache, salivation, and altered mentation followed by neuromuscular blockade and respiratory failure sometimes requiring intubation.[13,28] The onset of symptoms following the ingestion of tree tobacco leaves are slightly delayed (i.e., up to several hours) compared with commercial tobacco because the absorption of anabasine is slower than nicotine. Sudden cardiac arrest may occur during severe poisoning from the ingestion of anabasine in tree tobacco.[29]

In experimental piglets, consumption of *N. glauca* produces congenital defects, including cleft palate and limb defects. The principal alkaloid of the common tobacco plant, nicotine, apparently is not the teratogenic agent in this plant. Anabasine is a potential animal teratogen based on its structural similarity to other known piperidine teratogens (e.g., coniine and γ-coniceine in *Conium maculatum* L.).[30]

DIAGNOSTIC TESTING

Analytical Methods

Methods to detect toxic alkaloids (e.g., anabasine, nicotine) following ingestion of tree tobacco include gas chromatography/mass spectrometry,[4,5] capillary electrophoresis with sequential light-emitting diode-induced fluorescence and electrochemiluminescence detection,[31] and high performance liquid chromatography (HPLC)/photodiode array/mass spectrometry.[6] The limits of detection and quantitation with the latter method were 250 ng/mL and 500 ng/mL, respectively. A reverse-phase HPLC method is available for the determination of lobeline and cytisine in plasma.[7]

Biomarkers

The mean plasma nicotine concentration following the smoking of one cigarette ranges from about 5–30 ng/mL.[32] In a study of volunteers undergoing treatment for nicotine addiction, the steady state serum nicotine and cotinine concentrations two weeks after the daily administration of 22 mg nicotine via transdermal patches ranged from approximately 10–50 μg/L and 35–249 μg/L, respectively.[33] Serum nicotine concentrations exceeding 2,000 μg/L indicate serious toxicity. A case report of a woman, who died of asphyxia from a plastic bag following the placement of multiple nicotine patches on her body, suggests that some postmortem distribution of nicotine may occur; however, the distribution of the nicotine patches on the body may also alter the heart to femoral blood ratio.[34] Case reports of victims found dead after ingesting *Nicotiana glauca* document the presence of anabasine concentrations in postmortem blood of 1.15 mg/L[4] and 2.2 mg/L.[5]

Abnormalities

Leukocytosis and glycosuria may develop following nicotine intoxication, but most laboratory values are normal.

TREATMENT

Stabilization

Respiratory failure represents the greatest risk, and patients with suspected *Nicotiana* intoxication should be evaluated carefully for signs of respiratory distress (e.g., ventilatory rate, oxygen saturation, dyspnea). Patients with altered sensorium should receive intravenous lines, cardiac monitoring, oxygen, pulse oximetry, and arterial blood gases in addition to rapid evaluation of serum glucose concentrations and intravenous naloxone, if indicated. The initial hypertension and tachycardia should not be aggressively treated unless signs of cardiovascular compromise are present because a depressive phase of bradycardia and hypotension often follows the initial stimulatory phase.

Decontamination

Because nicotine stimulates the emetic center in the medulla oblongata, spontaneous vomiting occurs in most nicotine ingestions and decontamination measures are usually unnecessary. Most children only taste parts of *Nicotiana* or *Lobelia* plants, and these children do not usually develop symptoms. Additionally, the potential for rapid onset of changes in consciousness and seizures during serious *Nicotiana* or *Lobelia* intoxications increases the risk of using decontamination measures. Consequently, most of these ingestions require no decontamination measures. All skin contaminated with nicotine solutions should be washed thoroughly with a nonalkaline soap and cool water.

Elimination Enhancement

There are inadequate clinical data to recommend any methods to enhance the elimination of toxins associated

with ingestions of *Nicotiana* or *Lobelia* species. Continuous nasogastric suction and serial activated charcoal are theoretically advantageous, but there are few clinical data to guide management. Acidification of the urine also has theoretical advantages, but the lack of data to support this method, the short duration of nicotine action, and complications associated with acid diuresis limit the usefulness of this method.

Antidotes

Atropine may improve bradycardia and hypotension, but this drug does not reverse neuromuscular weakness during nicotine intoxication.

Supplemental Care

The treatment of nicotine poisoning is supportive. Serious poisoning must be followed closely in an intensive care setting for the development of respiratory failure within the first 12 hours. Seizures are treated with benzodiazepines (diazepam, lorazepam).

Chapter 136

VERATRUM ALKALOIDS

HISTORY

The use of *Veratrum* alkaloids in sorcery dates back hundreds of years in Europe. During the Middle Ages, *Veratrum* alkaloids were folk treatments for cardiac aliments and counterirritants for neuralgias. *Veratrum viride* Aiton was part of the potions used by American Indians to test the endurance of young braves. During the 1950s, *Veratrum* alkaloids were tested as antihypertensive agents, but the administration of these agents was discontinued because of adverse effects.

BOTANICAL DESCRIPTION

The genus *Veratrum* includes the following species: *Veratrum album* L. (white false hellebore), *Veratrum californicum* Dur. (California false hellebore), *Veratrum fimbriatum* Gray (fringed false hellebore), *Veratrum insolitum* Jepson (Siskiyou false hellebore), *Veratrum nigrum* L. (false hellebore), *Veratrum tenuipetalum* Heller (Colorado false hellebore), and *Veratrum viride* Aiton (green false hellebore). The most common *Veratrum* species in the United States is *V. viride*. Intoxication with *Veratrum* alkaloids occurs when *Veratrum* species are misidentified as skunk cabbage [*Symplocarpus foetidus* (L.) Salisb. ex Nutt.], pokeweed (*Phytolacca americana* L.), or ramps (*Allium tricoccum* Ait.). *Veratrum californicum* Dur. is the related *Veratrum* species that grows in moist woodlands of the coniferous forest in the Pacific Coast and northern Rockies up to an elevation of 11,000 ft (3,353 m). The European and Asian species are *Veratrum album* L. and *Veratrum japonicum* (Baker) Loesener, respectively. *Veratrum album* also inhabits Alaska. In western and central Europe, misidentification of *Veratrum* species as *Gentiana lutea* L. (yellow gentian) results in *Veratrum* toxicity when *Veratrum* species are used to make homemade gentian wine.

Common Name: Green False Hellebore, Hellebore, White Hellebore, Indian Poke

Scientific Name: *Veratrum viride* Aiton

Botanical Family: Liliaceae (lily)

Physical Description: This tall perennial herb grows to 4–6 ft (~1–2 m) in height with alternate, pleated leaves. Small flowers emerge from a large terminal panicle.

Distribution and Ecology: *V. viride* is an indigenous plant present in moist woodlands of Canada as well as the Pacific Coast and eastern United States. This perennial herb is found from Canada and northern United States to North Carolina, Georgia, and Tennessee.

EXPOSURE

Past medicinal uses of *Veratrum* alkaloids include the treatment of hypertension, cardiac failure, and toxemia of pregnancy. Li-lu is a crude Chinese drug prepared from the dried roots and rhizomes of several *Veratrum* species and used to treat vascular disease. In agriculture, these alkaloids have been used as pesticides. Cyclopa-

mine (11-deoxojervine, CAS RN: 4449-51-8) is an experimental chemotherapeutic agent for several types of cancer including medulloblastoma as well as a potential dermatological agent (psoriasis, basal cell carcinoma) that inhibits Sonic hedgehog (Shh) signal transduction.[1,2]

PRINCIPAL TOXINS

Physiochemical Properties

Veratrum species contain over 200 alkaloids.[3] The most important constituents of these species include the following classes of alkaloids: veratranine (veratridine, veratramine, veratrosine), jervanine (jervine, pseudojervine, isorubijervine), and cevanine [cevadine, cevine, zygadenine, veracevine, germine, germerine, germidine, 15-*O*-(2-methylbutyroyl)-germine, protoverine].[4] Figure 136.1 displays the chemical structure of veratridine (CAS RN: 71-62-5, $C_{36}H_{51}NO_{11}$). Table 136.1 lists some chemical properties of veratridine. Jervine and 11-deoxojervine (cyclopamine) are suspected teratogens in grazing animals feeding on *V. californicum* during Day 14 of gestation.[5]

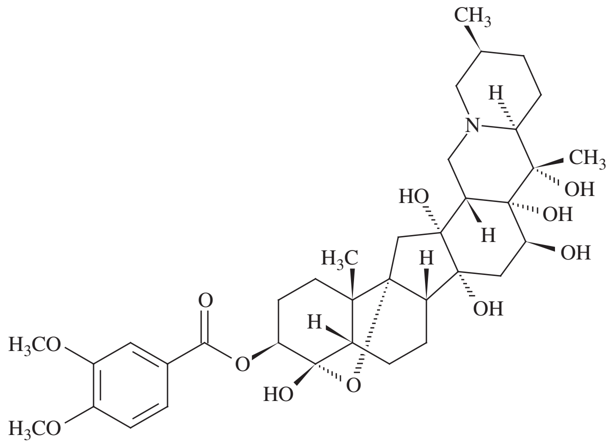

FIGURE 136.1. Chemical structure of veratridine.

TABLE 136.1. Some Physical Properties of Veratridine

Physical Property	Value
Melting Point	180 °C/356 °F
pKa Dissociation Constant	9.54
log P (Octanol-Water)	3.760
Atmospheric OH Rate Constant	1.60E-10 cm^3/molecule-second (25 °C/77 °F)

Poisonous Parts

All parts of *Veratrum* species contain a mixture of *Veratrum* alkaloids, but the concentration of specific *Veratrum* alkaloids varies substantially between *Veratrum* species and plant parts. For example, *V. viride* contains significant concentration of the hypotensive alkaloids, whereas *V. californicum* does not. In general, higher concentrations of *Veratrum* alkaloids occur in the root (i.e. ~2.0%) than in the leaves (i.e., ~0.5%).[6]

Mechanism of Toxicity

The steroidal alkaloid veratridine is a depolarizing agent that activates voltage-sensitive sodium channels resulting in hyperexcitability and depolarization. Voltage-gated Na^+ channels are heteromeric membrane glycoproteins responsible for the generation of action potentials. Veratridine is a lipid-soluble toxin that binds to receptor sites on the S6 segments of the Na^+ channel alpha-subunit on voltage-gated Na^+ channels. This binding affects gating function of Na^+ channels, and increases permeability to calcium and sodium.[7] Veratridine also binds to μ-opioid ligands on receptor sites in the rat cerebral cortical and hypothalamic slices, but the clinical significance of this property is not clear.[8] This compound causes the release of GABA, perhaps by increasing the permeability of the nerve terminals to sodium. The afferent vagal fibers of the coronary sinus and left ventricle appear to be most sensitive to the depolarizing effects of *Veratrum* alkaloids. Cardiac parasympathetic stimulation results in a decrease in peripheral α-adrenergic tone, bradycardia, and hypotension (Bezold-Jarisch reflex). The hypotensive effect of *Veratrum* alkaloids is independent of heart rate, and the use of atropine in *Veratrum*-intoxicated experimental animals only partially reverses the hypotension associated with the use of *Veratrum* alkaloids.[9] Direct stimulation of the peripheral receptors by *Veratrum* alkaloids produces sneezing.[10] Postmortem examination of fatal *Veratrum* intoxications usually reveals nonspecific findings.[11]

DOSE RESPONSE

The clinical response to the ingestion of *Veratrum* alkaloids depends on species, form, and extraction methods (e.g., soup, powder), plant part, and individual hypersensitivity.[12,13] Ingestion of 0.75–1 g of *Veratrum* alkaloids by adults produces gastrointestinal distress, bradycardia, lightheadedness, and salivation.[10]

TOXICOKINETICS

There are few data on the toxicokinetics of toxic *Veratrum* alkaloids.

CLINICAL RESPONSE

Veratrum toxicity classically causes vomiting, bradycardia, and hypotension.[11,14] An initial burning sensation of the oropharynx begins about $^1/_2$–4 hours after ingestion followed by pain in the upper abdomen, nausea, vomiting, diaphoresis, blurred vision, lightheadedness, headache, and confusion.[15] Massive *Veratrum* intoxication causes atrioventricular block, junctional and idioventricular escape rhythms, atrial dysrhythmias, ST abnormalities, T wave inversions, and QT prolongation.[16] Neurological signs are not usually a prominent part of *Veratrum* intoxication. Other clinical features of *Veratrum* intoxication include dilated pupils, paresthesias, muscle cramps, weakness, and syncope. Myoclonus and seizures are uncommon except during severe *Veratrum* intoxication. Dermal contact with powder containing *Veratrum* alkaloids may cause severe conjunctival irritation, lacrimation, and erythema. The clinical effects of *Veratrum* intoxication usually resolve within 24–48 hours. Although there are no data associating *Veratrum* alkaloids with reproductive abnormalities in humans, congenital limb malformations occurred in sheep grazing on *V. californicum*.[17,18]

DIAGNOSTIC TESTING

Analytical Methods

Concentrations of veratridine and cevadine below 1 ng/mL are detectable in biological samples by liquid chromatography/electrospray ionization/mass spectrometry.[6]

Biomarkers

During the postmortem examination of two fatalities from the ingestion of *Veratrum* seeds, the heart blood contained veratridine concentrations of 0.17 ng/mL and 0.40 ng/mL and cevadine concentrations of 0.32 ng/mL and 0.48 ng/mL.[6] The bodies were submerged in water for 1 month before discovery. The postmortem findings were nonspecific except for the presence of a large amount of *Veratrum* seeds in the stomachs.

Abnormalities

Electrocardiographic changes are the most common abnormalities associated with intoxication by *Veratrum* alkaloids including bradycardia and variable degrees of conduction block.

TREATMENT

Treatment is supportive.[19] Decontamination measures are usually unnecessary because of the rapid onset of profuse vomiting. The administration of activated charcoal to alert patients is a therapeutic option, when the patient ingests large amounts of *Veratrum* alkaloids less than 1 hour prior to presentation; however, there are no clinical data to indicate that activated charcoal improves the outcome of patients with *Veratrum* intoxication. Atropine usually reverses the bradycardia, but the effect of atropine on hypotension is usually limited. Fluids and vasopressors may be required. Cardiac monitoring and electrocardiograms should be instituted in severely poisoned patients because of the potential of digitalis-like dysrhythmias. Symptoms and signs (with the exception of eye irritation) usually resolve within 12–15 hours.[10]

(*Tradescantia fluminensis* Vellozo)

BOTANICAL DESCRIPTION

Species in the genus *Tradescantia* include two common houseplants, the Mexican native, *Tradescantia pallida* (Rose) D. Hunt and the silver-lined, variegated *Tradescantia zebrina* Bosse.

Common Name: Small-Leaf Spiderwort, Small Leaf Spiderwort, White-Flowered Wandering Jew

Scientific Name: *Tradescantia fluminensis* Vellozo [*T. albifora* (Kunth)]

Botanical Family: Commelinaceae (spiderwort)

Physical Description: This common houseplant is a creeping, perennial, branching plant with erect tips that forms a dense ground cover when naturalized. The leaves are simple, alternate, and glossy green with purple-tinged tips. The oblong to ovate leaf blades arise from a short sheath. Small clusters of white flowers appear at the tip of the stems. The flowers produce small, three-part capsules that contain pitted, black seeds.

Distribution and Ecology: *Tradescantia fluminensis* is a native species of the tropical rainforests of southeastern Brazil that has been introduced into New Zealand, southeastern Australia, Portugal, Italy, Russia, Japan, and the southeastern United States. In these areas, this plant is a persistent invasive weed that disrupts native vegetation.

EXPOSURE

The wandering Jew is a popular indoor ornamental plant, which has become a serious threat to natural vegetation. In subtropical regions, this plant forms dense covers in forested areas that smother low-growing plants and disrupts the regeneration of taller native species.

PRINCIPAL TOXINS

The toxic principal in *Tradescantia* species has not been identified. Case reports suggest that these plants contain allergens.

DOSE RESPONSE

There are inadequate data to determine a dose-response relationship between *Tradescantia* species and clinical effects. Some responses to exposures to these plants result in allergic responses rather than toxic effects.

TOXICOKINETICS

The toxic constituents of *Tradescantia* species have not been identified, and there are no toxicokinetic data.

CLINICAL RESPONSE

Casual exposure to this plant does not usually cause clinical effects. Rarely, vomiting occurs within 2 hours

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

of ingestion. Atopic individuals can develop an immediate hypersensitivity reaction manifest by pruritus, facial swelling, wheezing, conjunctival irritation, dyspnea, and wheezing following contact with this plant.[1]

DIAGNOSTIC TESTING

There are no specific biomarkers for exposure to *Tradescantia* species.

TREATMENT

Treatment is supportive. Decontamination measures are unnecessary. The contact dermatitis associated with *Tradescantia* species usually responds to topical steroids (0.05% fluocinonide) and antihistamines as necessary.

Chapter 138

WATER HEMLOCK and WATER DROPWORT

HISTORY

The 17th century Swiss pathologist, Johann Jakob Wepfer, reported the first cases of *Cicuta* toxicity in his book *Cicutae Aquaticae Historia Et Noxae Commentario Illustrata*.[1] In 1814, Stockbridge reported the first three cases in the United States. In 1876, Boehm isolated a toxic substance from the European species of hemlock water dropwort, *Oenanthe crocata*, which he named oenanthotoxin. In 1949, Clark et al purified oenanthotoxin,[2] and Anet et al identified oenanthotoxin as the highly unsaturated higher alcohol, *trans*-heptadeca-2:8:10-triene-4:6-diene-1:14-diol in 1953.[3] The hemlock water dropwort (*O. crocata*) probably is the most poisonous indigenous plant in the United Kingdom, and ingestion of the roots from this plant caused death in 9 of 13 reported cases since 1900.[4] Beside amatoxins, cicutoxin is the most lethal plant toxin in North America. *Cicuta* toxicity is one of the best described serious plant poisonings in the American literature. Between 1900 and 1975, Starrevekl and Hope identified 83 cases of *Cicuta* poisoning with an overall mortality rate of 30%.[5]

BOTANICAL DESCRIPTION

Common Name: Water Hemlock, Cowbane, Snakeweed, Wild Carrot, Poison Parsnip, Spotted Hemlock, Masquash Root, Beaver Poison, False Parsley

Scientific Name: *Cicuta* spp.

Botanical Family: Apiaceae (carrot)

Physical Description: These perennial weeds have multiple, thick tuberous roots and a hollow stalk reaching 8 ft (~2 m) in height. The leaves are large and pinnate with narrow, saw-toothed leaflets several inches long. Small white clustered flowers appear in an umbrella shape by June or July. The combination of fasciculated, tuberous roots, multicolored swollen root-stock, yellowish oily exudate, and pungent odor of raw parsnips distinguishes *Cicuta* species from other members of the carrot family.[6]

Distribution and Ecology: At least nine distinct species of *Cicuta* occur throughout the United States, and all these species grow along moist areas such as marshes or streams. Common US species include *Cicuta bulbifera* L. (bulb water hemlock), *Cicuta douglasii* (DC.) Coult. & Rose (Douglas water hemlock), *Cicuta maculata* L. (common water hemlock), and *Cicuta virosa* L. (Mackenzie's water hemlock).

Common Name: Hemlock Water Dropwort, Dead Men's Fingers, Five Finger Death

Scientific Name: *Oenanthe crocata* L.

Botanical Family: Umbelliferae

Physical Description: This tall plant grows up to 4–6 ft (~1–2 m) in height. The hollow, grooved stems contain leaves that are similar to celery. White flowers occur in terminal compound umbels with 12–40 rays and a wine-like scent. The root (tuber)

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

resembles small clusters of parsnips. The cut surface of the tuber extrudes a yellow oil liquid from oil ducts, and exposure to air turns this liquid brown. Microscopic examination of the numerous oil ducts after staining with iodine helps identify this plant.

Distribution and Ecology: Common European species of water hemlock are *Oenanthe crocata* and *Cicuta virosa. O. crocata* grows in moist areas (e.g., canal banks, drainage ditches, wet meadows) of western and southern Britain.

EXPOSURE

Most human toxic reactions result from causal contact by children or the misidentification of *Cicuta* species or *O. crocata* for wild edible species (e.g., wild carrot, wild parsnip, Jerusalem artichoke).[7] There are no medicinal uses for water hemlock.

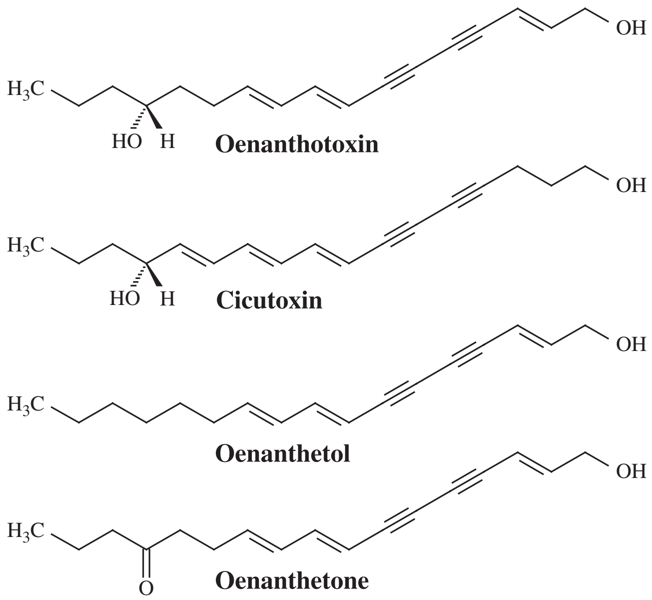

FIGURE 138.1. Comparative chemical structures of cicutoxin and major components of *Oenanthe crocata*.

PRINCIPAL TOXINS

Physiochemical Properties

Cicutoxin, as isolated from *C. virosa*, is structurally similar to oenanthotoxin with exception that cicutoxin has the triene substitutions in the C8, C10, and C12 positions and an opposite configuration at C14.[3] Figure 138.1 displays the chemical structure of cicutoxin and oenanthotoxin. Oenanthetol (C_{14}-deoxyoenanthotoxin) and oenanthetone (C_{14}-ketone of C_{14}-deoxyoenanthotoxin) are also major constituents of *O. crocata*, but these compounds possess relatively mild toxicity.[8] In mice, oenanthotoxin is more toxic than cicutoxin, but the clinical syndrome is similar. Seasonal variation in toxin content is a more important variable of toxicity than relative potency.

Case reports suggest that cooking does not destroy these toxins.[9]

Poisonous Parts

Although toxins occur throughout the plant, the root is the most toxic portion of these plants. Case reports indicate that ingestions of the root produce convulsions, whereas ingestions of flowers and leaves produce nonspecific symptoms and gastrointestinal complaints.[10,11] Most poisonings occur in the spring when roots contain the highest concentration of oenanthotoxin.[3]

Histopathology and Pathophysiology

Mechanism of Toxicity

Ingestion of cicutoxin and oenanthotoxin produce similar clinical syndromes. The major toxicity results from the central nervous system (CNS) stimulant properties of these toxins; the proconvulsant properties of these toxins distinguish cicutoxin and oenanthotoxin from coniine (poison hemlock), which causes CNS depression rather than seizures. Death following ingestion of water hemlock results from status epilepticus, perhaps caused by excessive stimulation of cholinergic receptors in the basal ganglia and brainstem. Respiratory failure then ensues. Hypotension usually results from fluid depletion secondary to gastrointestinal distress. Intravenous alcohol extracts of hemlock water dropwort (*O. crocata*) cause hypotension within 1 minute of intravenous injection into animals, but the applicability of this model to clinical situations is unclear.[12]

Postmortem Changes

Pathological abnormalities in a 14-year-old boy, who died 20 hours after ingesting root material from water hemlock, included bilateral, blood-tinged pleural fluid and congestion of the lungs, liver, and brain.[13] Neuropathological changes included cerebellar and cerebral

edema with cortical gyral flattening and obliteration of the ventricular system, cerebellar tonsillar swelling with medullary compression, diffuse ischemic injury, and eosinophilia.

DOSE RESPONSE

The ingestion of the tubers of *Cicuta* species or *O. crocata* produces serious toxicity. A case report associated the death of an 8-year-old boy with the ingestion of a piece of one *Cicuta* root.[14]

TOXICOKINETICS

Although most cases involve ingestion, a case report suggests the possibility that dermal absorption of the toxin occurs following direct contact with the juice from plant parts. In 1911, Egdahl reported two deaths from the use of *Cicuta* extracts as a topical antipruritic agent.[9] However, the report lacked descriptive and laboratory data, and there are no other clinical or experimental data to determine the extent of dermal absorption of toxins in water hemlock.

CLINICAL RESPONSE

Typically, severe gastrointestinal symptoms (i.e., nausea, vomiting, abdominal pain) begin within 15–90 minutes of ingestion of the root. Depending on the severity of the ingestion, convulsions and coma may occur.[15–17] Occasionally, seizures develop in these patients up to 10 hours after ingestion.[7] Profuse salivation, diaphoresis, low-grade fever, mydriasis, flushing, muscle spasm, trismus, and dizziness commonly appear.[4] The patient may progress to status epilepticus, respiratory arrest, and death. Several recent case studies[1,5] document the presence of severe opisthotonus and hemiballismus. These movements appear centrally mediated because human nerve conduction studies were normal. Furthermore, spinal studies in animals demonstrate abolishment of spastic movement after CNS destruction.[18]

Cardiovascular abnormalities are uncommon with the exception of orthostatic hypotension and volume depletion.[1,19] Significant dysrhythmias or conduction disturbances do not usually occur during intoxication by these plants except during the terminal phase characterized by status epilepticus, apnea, bradycardia, and hypotension.[20] Aspiration pneumonia may complicate the clinical course.

DIAGNOSTIC TESTING

Analytical Methods

UV absorption spectrometry is a sensitive method for analysis of extracts of stomach contents for cicutoxin or oenanthotoxin with confirmation by high performance liquid chromatography with photodiode array/tandem mass spectrometry,[21] or gas chromatography/mass spectrometry.[8,22] Oenanthotoxin has an intense, highly characteristic UV absorption spectrum, particularly at 313 nm.

Abnormalities

A severe metabolic acidosis occurs in patients with seizure activity after the ingestion of toxins from these plants.[23] Evidence of rhabdomyolysis and acute oliguric renal failure may complicate the course of *Cicuta* toxicity.[24] Other laboratory abnormalities include transient hematuria, hyperbilirubinemia, mildly elevated hepatic transaminases, glycosuria, and proteinuria.[1,4]

TREATMENT

Stabilization

Patients with *Cicuta* intoxication may develop seizures suddenly; therefore, intravenous access should be established and all patients should be monitored for cardiac dysrhythmias, hypotension, and hypoxia. There are limited data on the efficacy of any specific anticonvulsant during intoxication by these plants.[29] In the emergency department, actively seizing adult patients should receive lorazepam or diazepam. Both these compounds have similar time to cessation of seizures, but the duration of action of lorazepam is longer than diazepam.[25] The recommended adult dose of lorazepam is 0.05–0.2 mg/kg at the rate of 2 mg/min up to 8 mg, whereas the adult dose for diazepam is 0.15–0.25 mg/kg. Phenobarbital is probably a second-line anticonvulsant because of the synergistic action of phenobarbital with GABA agonists and the limited effect of phenytoin on the lowered seizure threshold commonly associated with toxin-induced seizures.[26] The recommended dose of phenobarbital is 20 mg/kg intravenously infused at 50–75 mg/min.[27] Adverse effects of phenobarbital use include respiratory depression and hypotension; therefore, these patients must be monitored carefully for the need for intubation and measures to treat hypotension (fluids, vasopressors). Serum electrolyte and acid–base status should also be monitored closely. Therapeutic options for refractory seizures include a midazolam

infusion (0.2 mg/kg slow intravenous bolus followed by 0.75–10 μg/kg/min), an additional intravenous phenobarbital dose (5–10 mg/kg), or a propofol infusion (1–2 mg/kg loading dose, followed by 2–10 mg/kg/h). Experimental therapy for refractory seizures includes intravenous valproate and intragastric topiramate.[25]

Decontamination

The presence of vomiting limits the efficacy of decontamination measures. Additionally, the potential for rapid onset of changes in consciousness and seizures during serious water hemlock intoxication increases the risk of using decontamination measures. Consequently, most of these ingestions require no decontamination measures.

Elimination Enhancement

There are no data on the elimination of cicutoxin or oenanthotoxin. Hemodialysis improves the hyperosmolality and metabolic acidosis associated with cicutoxin-induced status epilepticus, but efficacy of hemodialysis to enhance the elimination of these toxins and to improve the clinical course is unproven.[28]

Antidotes

No specific antidotes are available. In animal studies, anticholinergic agents do not alleviate seizures or the cholinergic effects of *Cicuta* toxicity.[29]

Supplemental Care

Muscle spasticity usually responds to diazepam. Supportive care for these cases involves monitoring ventilation, acid–base status, electrolytes, and volume status. Appropriate laboratory studies include a complete blood count, electrolytes, creatine phosphokinase (CK), creatinine, hepatic transaminases, arterial blood gases, and urinalysis. Grossly elevated serum CK concentrations (>1000 Units/L) suggest the need for generous fluid replacement and possibly alkalinization of the urine. All patients with CNS symptoms (including spasticity) or cardiac instability should be admitted. All other patients should be observed at least 4–6 hours before discharge.

Chapter 139

WHITE SNAKEROOT
[*Ageratina altissima* (L.) King & H.E. Robins]

HISTORY

During colonial times and the first half of the 19th century, milk sickness caused numerous deaths in humans and livestock in the eastern and midwestern United States.[1] Dr. Thomas Barbee first described the symptoms associated with milk sickness in 1809.[2] In 1818, Abraham Lincoln's mother, Nancy Hanks Lincoln, died of what is now recognized as milk sickness.[3] Thomas Lincoln then left Indiana for Illinois with his new wife, Sarah, and Abraham Lincoln. Despite the seriousness of poisoning produced by ingesting milk from cow that graze on white snakeroot, the causal relationship between milk sickness and white snakeroot was not recognized until Dr. Anna Pierce Hobbs advocated the eradication of white snakeroot in the 1840s. Although settlers continued to suffer from milk sickness during the 19th century, the incidence of milk sickness decreased as cultivated land replaced the forests of the Midwest. The etiology of milk sickness remained unclear until the early 20th century, when Couch isolated a crude extract (tremetol) that reproduced a disease similar to trembles in livestock and milk sickness in humans.[4] The specific toxin in this crude extract remains unknown, and toxicity in horses and goats grazing on white snakeroot remains a problem in the United States.[5] The appearance of milk sickness was rare during the 20th century.[6]

BOTANICAL DESCRIPTION

Common Name: White Snakeroot, Fall Poison, Richweed, Pool Root, White Sanicle, Indian Sanicle, Deer Wort, Pool Wort, Squaw Weed

Scientific Name: *Ageratina altissima* (L.) King & H.E. Robins (*Eupatorium rugosum* Houtt., *E. urticaefolium*)

Botanical Family: Asteraceae (sunflower)

Physical Description: This slender, erect, branching plant grows up to 1–5 ft (~0.3–2 m) in height. The large ovate leaves have serrated edges and a purplish color with large veins on the undersurface. Clusters of white flowers at the ends of numerous branches appear in late summer and produce small fruit.

Distribution and Ecology: These native US plants are shade-loving weeds found along steep canyons, damp open areas, and rivers in the East and Midwest from North Dakota to Texas, Georgia, and Maine.

EXPOSURE

Native Americans used the root as a diaphoretic, diuretic, antipyretic, stimulant, and an herbal remedy for diarrhea, toothache, kidney stones, snake bite, and urinary diseases. The plant is not edible.

PRINCIPAL TOXINS

Physiochemical Properties

Tremetol is the crude extract of the snakeroot plant that causes illness both in humans and animals. This substance is not a pure compound and contains several ketones, such as tremetone (CAS RN:4976-25-4,

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

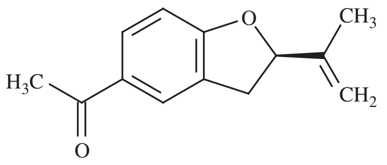

FIGURE 139.1. Chemical structure of tremetone.

$C_{13}H_{14}O_2$), dehydrotremetone, and hydroxytremetone.[7] Figure 139.1 displays the chemical structure of tremetone. The identity of the specific toxin responsible for the illness associated with the ingestion of snakeroot by livestock remains unknown.[8] The southern goldenbush [*Isocoma pluriflora* (Torr. & Gray) Greene] is a perennial shrub indigenous to the southwestern United States that also contains tremetone and causes milk sickness. Synonyms for this plant include rayless goldenrod [*Isocoma wrightii* (Gray) Rydb., *Haplopappus heterophyllus* (Gray) Blake]. The odor and consistency of tremetol resembles turpentine.[1] The 2-isopropenyl-2,3-dihydrobenzofuran skeleton of tremetone has been synthesized.[9]

Poisonous Parts

This disease (milk sickness) results from the ingestion of milk from cows grazing on the white snakeroot plant.

Mechanism of Toxicity

The entire plant contains ketones and glycosides that accumulate in the milk of cows grazing on this plant. The afebrile epidemic illness (milk sickness) results from ingestion of contaminated milk. Modern milk-processing procedures have eliminated milk sickness, but consumption of unprocessed milk represents a potential danger. Postmortem findings are nonspecific with fatty degeneration of the liver and kidney.[10]

DOSE RESPONSE

Milk sickness is a chronic illness. The toxin in tremetol has not been identified and consequently there are inadequate dose-response data.

TOXICOKINETICS

In vitro studies indicate that tremetone is biotransformed to a toxic metabolite.[11] In plants, tremetone is converted to dehydrotremetone, but these microsomal activation studies suggest that dehydrotremetone is not physiologically active.

CLINICAL RESPONSE

Milk sickness is an insidious disease causing weakness, anorexia, nausea, vomiting, tremors, headache, constipation, dizziness, delirium, and, in serious cases, coma, convulsions, and death. Older synonyms for milk sickness include puking fever, sick stomach, tires, slows, and trembles (grazing animals). Symptoms are typically prolonged.

DIAGNOSTIC TESTING

Milk sickness is associated with ketosis, mild hypoglycemia, and lipemia without evidence of diabetes mellitus, salicylate intoxication or infectious processes. The acidosis is sometimes refractory to therapy.[12]

TREATMENT

Treatment is supportive. Decontamination measures are unnecessary because milk sickness is a chronic illness.

V Shrubs and Vines

Chapter 140

BARBADOS NUT
(*Jatropha curcas* L.)

BOTANICAL DESCRIPTION

The genus *Jatropha* (nettle spurge) contains over 20 species. Several species have been associated with human toxicity including *J. curcas* L. (Barbados nut), *J. gossypiifolia* L. (bellyache bush), *J. macrorhiza* Benth. (ragged jatropha, ragged nettle spurge), and *J. multifida* L. (coral bush).[1]

Common Name: Barbados Nut, Purging Nut Tree, Black Vomit Nut, Physic Nut, Purgeerboonijie (South Africa)

Scientific Name: *Jatropha curcas* L.

Botanical Family: Euphorbiaceae (spurge)

Physical Description: This large shrub reaches 6m (~20ft) in height, and has undulating, five-lobed leaves. The thick stem is green with a woody base, and the yellow-green flowers are inconspicuous. The elliptical fruit is about 2.5cm (~1in.) in length and contains black seeds when ripe.

Distribution and Ecology: This succulent probably originated in Mexico and Central America. This evergreen plant now inhabits wastelands in arid and semiarid areas (grassland-savannah, thorn forest scrub) throughout tropical Africa, the Indian peninsula, and Asia.

EXPOSURE

Jatropha curcas is a perennial shrub commonly used as a hedge in tropical and subtropical climates. Traditional medicinal uses for extracts (yellow oil or hell oil) of *Jatropha* seeds include a purgative, abortifacient, antipyretic, anthelminthic, treatment of gout and gonorrhea, a styptic for the control of local hemorrhage, a chemotherapeutic agent for cancerous growths (root), and a diuretic. Animal studies indicate that the administration of extracts of the fruit of *Jatropha curcas* increases fetal resorptions when administered soon after implantation.[2] In some areas of Africa and Mexico, properly prepared young leaves and nuts are food sources, and the ashes from the woody parts of the plant are a cooking salt. Jatropha oil is a potential fuel and burning oil. Physic nut oil was used in engines in Mali during World War II. Leaf juice stains red and constituents of this plant are useful as marking ink.

PRINCIPAL TOXINS

Viscous, astringent latex exudes from damaged portions of *Jatropha* species that dries to a bright red-brown film resembling shellac. The toxins in *Jatropha* species are not well defined. This latex contains a proteolytic enzyme, curcin, with a molecular weight of about 22,000Da,[3] and an octapeptide (curcacycline A) with *in vitro* anticomplement activity.[4] The effect of the latex on coagulation is complex. *In vitro* testing indicates that the whole latex has procoagulant activity, whereas dilute latex demonstrates anticoagulant activities.[5] The oil (oleum ricini majoris, hell oil, oleum infernale, ratanjyot) extract from the seeds of *Jatropha curcas* contains curcanoleic acid, which is structurally similar to ricinoleic acid in the castor bean (*Ricinus comminus* L.) and

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

polyunsaturated esters of the tigliane-type diterpenoids (e.g., 12-deoxy-16-hydroxyphorbol).[6] Animal models indicate that this oil produces severe diarrhea and gastrointestinal inflammation.[7] The purgative oil represents about 40% of the seed by weight, and one of the constituents of this oil is the purgative and skin irritant, 12-deoxy-10-hydroxyphorbol.[8] Other constituents include lathyrane and podocarpane type diterpenoid compounds, triterpenes, and oleanolic acid.[9] The material remaining after the extraction of the oil contains a toxalbumin, curcin, which demonstrates hemostatic properties.[10] Experimental studies indicate that curcin inhibits protein synthesis similar to ricin, but curcin is approximately 1,000 times less potent than ricin.[11] This compound has antitumor activity in *in vitro* studies.[12]

DOSE RESPONSE

In a series of 20 children admitted to an emergency department with vomiting and loose stools, the median number of Barbados nuts ingested was two with a range of one to four.[13] There was no evidence of dehydration and all children recovered without sequelae within 5–6 hours.

TOXICOKINETICS

There are few human data on curcin or other potential toxins in the Barbados nut.

CLINICAL RESPONSE

Ingestion of seeds from *Jatropha curcas* causes severe gastroenteritis manifest by profuse vomiting, diarrhea, and abdominal cramps along with burning of the throat.[14] The gastrointestinal symptoms begin within 30 minutes to several hours of ingestion, and the severity of the vomiting and diarrhea can cause significant dehydration in children.[15] Recovery usually occurs within 6–24 hours without sequelae. Other *Jatropha* species (e.g., *Jatropha multifida* L., coralbush) also produce severe gastroenteritis, myalgias, dehydration, lethargy, and hypotension.[1,16]

DIAGNOSTIC TESTING

There are no commercial biomarkers of exposure to *Jatropha* species. Evidence of subclinical hepatic inflammation (i.e., elevated serum hepatic aminotransferases) may develop during acute intoxication, but liver dysfunction does not usually occur.[16]

TREATMENT

Treatment of acute intoxication from *Jatropha* species involves supportive care for the fluid and electrolyte imbalance associated with severe gastroenteritis. Decontamination is unnecessary because of the presence of profuse vomiting and diarrhea. There are no specific antidotes. Intravenous fluids may be necessary to correct the fluid and electrolyte deficits associated with gastrointestinal inflammation. Diagnostic tests include monitoring of electrolytes, acid–base status, complete blood count, and hepatorenal function. Patients can be safely discharged after 6–8 hours if the gastroenteritis subsides and fluid and electrolyte balance is restored.

Chapter 141

BOXWOOD
(*Buxus sempervirens* L.)

BOTANICAL DESCRIPTION

Common Name: Boxwood, Boxtree, Box, Common Box

Scientific Name: *Buxus sempervirens* L.

Botanical Family: Buxaceae

Physical Description: This broad-leaf, evergreen shrub is commonly cultivated as a hedge that possesses thick, leathery leaves and small white flowers.

Distribution and Ecology: *Buxus sempervirens* is a perennial shrub that occurs naturally throughout Eurasia as well as sections of the eastern United States (Virginia, Tennessee, Ohio, North Carolina, New York). The habitat of this plant includes dry scrub and forested areas.

EXPOSURE

Herbal uses of *Buxus sempervirens* include the treatment of rheumatism, fever, and malaria. This plant is a popular ornamental for hedges and sculptured plants.

PRINCIPAL TOXINS

Buxus species contain over 135 steroidal alkaloids containing 9,19-cyclo-9,10 secobuxus, buxane (9,19-cyclobuxus), and 9,10-seco-buxa-9(11),10(19)diene skeletons.[1,2] In particular, *B. sempervirens* contains numerous steroidal alkaloids including spirobuxus alkaloids, buxenone, buxene, sempervirone, and benzamide alkaloids as well as volatile oils in its leaves and stems.[3–5]

DOSE RESPONSE

The principal toxin in boxwood has not been identified.

TOXICOKINETICS

There are few data on the toxicokinetics of toxic constituents of boxwood.

CLINICAL RESPONSE

There are few data on the clinical features of intoxication from *Buxus sempervirens*. Potentially, this perennial shrub is a gastrointestinal irritant.

DIAGNOSTIC TESTING

There are few data on the diagnostic testing of samples from patients with exposure to boxwood. Clinically significant laboratory abnormalities after exposure to boxwood are unlikely with the possible exception of abnormalities related to fluid and electrolyte imbalance.

TREATMENT

Treatment is supportive. Decontamination measures are unnecessary.

Chapter 142

BUCKTHORN

[*Karwinskia humboldtiana* (J.A. Schultes) Zucc.]

BOTANICAL DESCRIPTION

The buckthorn family contains several genera of buckthorn including *Frangula, Karwinskia, Rhamnus*, and *Sageretia*.

Common Name: Coyotillo, Wild Cherry, Tullidora, Buckthorn

Scientific Name: *Karwinskia humboldtiana* (J.A. Schultes) Zucc.

Botanical Family: Rhamnaceae (buckthorn)

Physical Description: This spineless, woody shrub or small tree reaches up to 1–5 ft (~30–150 cm) in height and has opposite, 1–3 in. (~3–8 cm) long leaves on a stalk. Clusters of greenish flowers produce brownish black berries.

Distribution and Ecology: This shrub grows in semi-arid environments along canyons and gullies of the southwestern United States, northern and central Mexico, Central America, and northern Colombia. The species of common buckthorn (*Rhamnus* species) are ornamental hedges that have been naturalized in the eastern United States. Cascara buckthorn [*Frangula purshiana* (DC.) Cooper] is a small deciduous tree indigenous to the Pacific Northwest.

EXPOSURE

There are no specific medical indications for the use of *K. humboldtiana. In vitro* studies have investigated the potential antineoplastic effects of a constituent (i.e., T-514 toxin) of this plant.[1]

PRINCIPAL TOXINS

Physicochemical Properties

The fruit from *K. humboldtiana* contains at least four dimeric anthracenone neurotoxins identified by their molecular weight (T-496, T-514, T-516, T-544).[2] The exact role of each compound in the production of neurotoxicity is unclear. In animal models, the administration of the green fruit produces liver, lung, and renal damage with T-514 being more cytotoxic than T-544.[3] Experimental animals given T-544 develop classic ascending paralysis as well as somewhat less hepatic and pulmonary damage than T-514. Species of common buckthorn (*Rhamnus* spp.) also contain glycosides that are strong cathartics.

Poisonous Parts

All the plant parts are toxic, but the green fruit contains the highest concentration of neurotoxins. The amount of T-544 neurotoxin varies with season and location. In a series of seven fruit samples from different locations in Mexico, the T-544 content of the fruits from *K. humboldtiana* ranged from 0.69–1.6% (green fruit) and 0.4–1.26% (ripe fruit).[4]

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Mechanism of Toxicity

In experimental animals, the administration of anthracenone neurotoxins from the fruit of *K. humboldtiana* for 2–3 weeks causes a progressive, ascending paralysis similar to Guillain-Barré syndrome.[5] However, the specific toxin has not been identified. Observable effects during the first week after administration of fruit from the buckthorn included lethargy, hypersensitivity to stimuli, and weight loss followed by a quiescent period.[6,7] An ascending paralysis developed by the second to third week characterized by segmental demyelination of large peripheral nerve fibers, probably as a result of the disruption of Schwann cell metabolism and axon transport.[8] Animal studies also indicate that this fruit produces acute nephrotoxicity characterized by marked reduction in renal perfusion pressure, hydropic degeneration of the proximal convoluted tubules, and increased sodium excretion in the urine.[9] *In vitro* studies suggest that oxidative stress mediated by reactive intermediates may cause the cytotoxicity produced by T-514.[10]

DOSE RESPONSE

The specific neurotoxin has not been identified. Potentially toxic anthracenone compounds include T-514 (peroxisomicine A1), T-516, T-544, and T-496.[11] The amount of buckthorn fruit necessary to produce neurotoxicity is not well defined.

TOXICOKINETICS

There are few data on the toxicokinetics of suspected toxins (T-496, T-514, T-516, T-544) in buckthorn.

CLINICAL RESPONSE

Case reports indicate that chronic consumption of *K. humboldtiana* causes a progressive, symmetrical polyneuropathy characterized by a flaccid quadriplegia without sensory changes.[12] Deep tendon reflexes are usually absent, and cranial nerve signs are normal. Occasionally, respiratory insufficiency and pneumonia complicate the ascending neuropathy.[13] The onset of paralysis ranges between about 1–6 weeks after ingestion of the fruit.[14] A slow, gradual recovery usually occurs, although some reflex deficits may remain. Exposure to other *Rhamnus* species may cause diarrhea, but neurological abnormalities occur only following exposure to *K. humboldtiana*. The differential diagnosis of chronic buckthorn neuropathy includes Guillain-Barré syndrome and poliomyelitis.

DIAGNOSTIC TESTING

In case reports of chronic buckthorn intoxication, sural nerve biopsy demonstrated distal segmental demyelination and axon degeneration with swelling of the Schwann cells due to phagocytosis of the myelin.[12,14] Lymphocytic infiltration does not usually occur. Animal studies suggest the changes in the Schwann cells may be secondary to direct axon toxicity.[15] Motor conduction velocities are reduced with an absence of conduction in the extremities in severe cases. Marked reduction in compound muscle action and fibrillation potentials consistent with axonal damage occurs rarely.[12] Analysis of cerebrospinal fluid (CSF) does not demonstrate any abnormalities, and CSF protein and glucose concentrations are typically normal.

TREATMENT

Treatment is supportive. Decontamination is unnecessary.

Chapter 143

CACTUS

BOTANICAL DESCRIPTION

The Cactaceae family (cactus) contains about 40 genera and about 2,000 species of plants. *Opuntia* is the largest genus of the cactus family. Members of the genus *Euphorbia* (Euphorbiaceae) differ from cacti by the absence of areoles at the base of the spines and by the presence of an irritant, white, milky sap. The cactus family is indigenous to the arid and semiarid regions of the western hemisphere. Cacti adapt easily to areas with low rainfall in the Mediterranean region, Africa, Europe, western and midwestern United States, and northern Mexico.

Common Name: Prickly Pear, Cholla

Scientific Name: *Opuntia* spp.

Botanical Family: Cactaceae (cactus)

Physical Description: The surfaces of leaves from cactus specimens have cushion-like structures (areoles, nipple) that contain medium-sized spines along with smaller spines (glochidia) at the base of the larger spines (See Figure 143.1). Prickly pears have flat joints, whereas chollas have cylindrical joints. The glochidia (glochids) arise from the base of the larger spines in a pin-cushion-like structure that contains hundreds of short (4–8 mm), barbed hairs. These glochidia appear as a soft, fluffy dot on the pad of the cactus. These tiny, profusely barbed hairs are translucent to yellow-white.

Distribution and Ecology: *Opuntia polyacantha* Haw. (prickly pear) is a perennial native of the western and midwestern United States.

Common Name: Barrel Cactus

Scientific Name: *Echinocactus* spp., *Ferocactus* spp., *Sclerocactus* spp.

Botanical Family: Cactaceae (cactus)

Physical Description: Long, sturdy spines up to 8–10 cm (~3–4 in.) arise from the central portion of the cactus. Although the end of the spine can be curved, the ends are not barbed. These spines do not easily break; therefore, foreign bodies are less common complications of contact with these cacti compared with other types of cactus spines. Radial spines of the barrel cactus are smaller than long spines in the central portion. These spines easily penetrate soft tissue and occasionally foreign bodies result from tangential pressure on the spine during contact.

Distribution and Ecology: The barrel cacti (*Ferocactus* spp.) are perennial native plants of the southwestern United States.

Common Name: Saguaro

Scientific Name: *Carnegiea gigantea* (Engelm.) Britt. & Rose

Botanical Family: Cactaceae (cactus)

Physical Description: Both central and radial spines of this cactus are long and sufficiently sturdy to limit dislodgement during contact.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

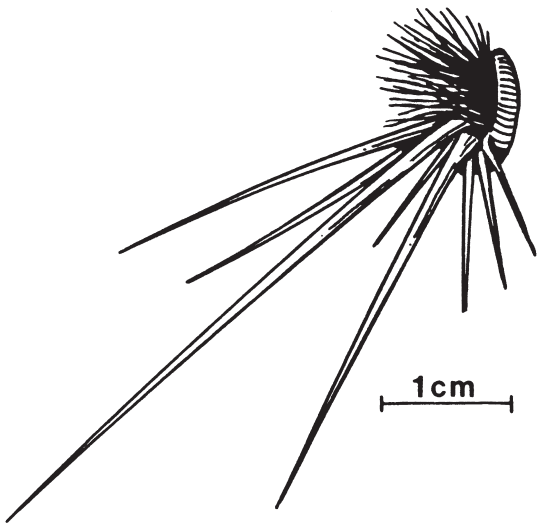

FIGURE 143.1. Glochidia. From Lindsey D, et al. Cactus spine injuries. Am J Emerg Med 1988;6:363. Reprinted from Elsevier with permission.

Distribution and Ecology: The saguaro cactus is a perennial native species of deserts in California and Arizona.

Common Name: Hedgehog

Scientific Name: *Echinocereus* spp., *Pediocactus* spp.

Botanical Family: Cactaceae (cactus)

Physical Description: These small to medium sized cacti have prominent ribs. The flowers are relatively large and produce edible fruit.

Distribution and Ecology: There are over 25 species of the hedgehog cactus in the western and southwestern United States, and Mexico.

EXPOSURE

The prickly pear fruit is a food source containing fructose and glucose.[1] In Mexico, the prickly pear cactus (nopal) has been an important food source since pre-Hispanic times. The leaves of prickly pear cacti are used by the Mexican population for medicinal purposes (e.g., diabetes, scurvy) and food.[2] The young stems (napalitos) are a vegetable in a variety of recipes. When ingested 5 hours prior to ethanol consumption, a double-blind, placebo-controlled, cross-over trial of 64 volunteers suggested that an extract of *Opuntia ficus-indica* (L.) P. Mill. (prickly pear) reduces the severity of a hangover (i.e., dry mouth, nausea, anorexia).[3] A concomitant reduction in C-reactive protein concentrations suggested that the mechanism of action was a decrease in the inflammatory state induced by alcohol impurities and metabolic byproducts of alcohol metabolism.

PRINCIPAL TOXINS

Physiochemical Properties

Calcium oxalate is the most common mineral in higher plants, occurring in two hydration states as monohydrate (whewellite) or as dihydrate (weddellite).[4] Crystalline forms of calcium oxalate in plants include druses, crystal sand, prisms, raphides, and styloids. Specimens from the cactus family contain highly pure and well-crystallized calcium oxalate crystals that form druses in both hydration states.[5] These druses appear as aggregates of thousands of individual crystallites in the shape of tetragons.

Mechanism of Toxicity

The adverse effect associated with exposure to cactus primarily involves mechanical trauma. Although infections can develop as a result of multiple puncture wounds, bacteria and acid-fast organisms do not usually colonize most cactus spines; therefore, infections are an uncommon complication of contact with cactus spines.[6] However, these spines often contain fungi (e.g., *Alternaria, Aspergillus*). The transfer of glochidia to human skin results from direct contact with surfaces (e.g., clothing or pets) containing glochidia, and contact of unprotected skin with glochidia produces an irritant contact dermatitis.[7] Wetting the prickly pear fruit and the use of protective clothing during windy days limits contact with the glochidia. Retention of *Opuntia* bristle fragments in the dermis can produce granulomas consisting of epithelioid cells, Langhans type and foreign body type giant cells, and retained bristles that react strongly with periodic acid-Schiff's (PAS) stain.[8] The fragments have angulated microscopic barbs, which remain in the skin after removal of the bristles.

CLINICAL RESPONSE

The initial sign of embedded cactus spines is the development of small (2–5 mm), asymptomatic, glistening papules within 24–72 hours after penetration of the spines.[8,9] Occasionally, the development of the lesions is delayed 7–10 days. Typically, the granulomas persist 2–8 months before resolving spontaneously.[10] Secondary infections following contact with cactus spines are relatively rare. Complications associated with foreign bodies secondary to cactus spines include chronic synovitis (afebrile, negative joint aspirate),[11] acute aseptic monoarticular arthritis,[12] chronic granulomas,[13] and postinflammatory hyperpigmentation. An occupational dermatitis (sabra dermatitis) results from contact with glochidia during the picking of prickly pear fruit char-

acterized by a pruritic papular eruption primarily in the intertriginous web space of the fingers.[14,15] Retention of these spines can produce a delayed hypersensitivity reaction that persists several months and simulates scabies.[16] A pruritic rash can also develop on unprotected areas of the skin when the glochidia become airborne. Occasionally, portions of retained glochidia produce a keratotic plug that requires scraping or a miniature cutaneous horn that requires excision. Bezoars in the stomach and rectum can develop following the chronic consumption of seeds from the prickly pear fruit.[17] Symptoms include dyspepsia, malaise, bloating, anorexia, early satiety, weight loss, and fullness in the epigastrium.

DIAGNOSTIC TESTING

Although xerography occasionally identifies cactus spines, these foreign bodies are not usually seen with conventional radiography. A case report suggests that magnetic resonance imaging (MRI) can detect subcutaneous cactus spines embedded in an inflammatory nodule.[18]

TREATMENT

Foreign Bodies

Successful removal of cactus spines depends on identification of the location of the spine, particularly in relation to important subcutaneous structures.[19] Axial traction should be applied to the portion of the spine protruding above the surface of the skin. The use of tangential lighting and splinter forceps held flat along the surface of the skin aids removal of the spines. The initial approach for spines, which cannot be seen on the surface of the skin, is an incision that intercepts the spine similar to the approach for the removal of subcutaneous needles. The spines of a few cacti (e.g., *Opuntia fulgida* Engelm., *Opuntia bigelovii* Engelm.) are sufficiently tenacious that a portion of the stem breaks off the plant with the spines. Because the spines are directed in multiple planes, direct pressure on the stem embeds more spines. The spiney stem should be inverted over a bucket and spines cut next to the surface of the stem. Then the embedded spines are removed with axial pressure. Removal of spines from *Opuntia* species involves initial removal of the larger spines by forceps under direct visualization, followed by the techniques to peel off the numerous minute spines. These techniques include warm wax, glue, cellophane tape and water soluble, commercial facial gels. Rubber cement is applied with an applicator, covered with gauze, and allowed to dry.[20] Although somewhat difficult, the edge is peeled upward by a fingernail to remove the cement and small spines. Hospital cement (e.g., ostomy cement) or Super Glue® (Super Glue Corp., Rancho Cucamonga, CA) should be avoided because of the adherence of these compounds to the skin. The removal of cactus spines in the cornea may require the use of a fiberoptic illuminator in the operating room.[21]

Chronic Granulomata

Unroofing a granulomatous papule with the aid of a dissecting microscope helps identify and remove the embedded cactus spine. The glochidia of *Opuntia* species contain microscopic, posterior-angulated barbs that break off and form granulomatous inflammation in the skin. Treatment of chronic granulomatous lesions involves the use of topical corticosteroids (0.05% fluocinonide) several times a day for up to 1 month.

Chapter 144

CAROLINA JESSAMINE

[*Gelsemium sempervirens* (L.) St. Hil.]

HISTORY

Extracts of *Gelsemium sempervirens* were used as herbal medications during the 19th century for neuralgias, fever, and nervousness. In 1862, a Detroit physician was indicted for administering this extract to a servant, who died about 2 hours after ingestion the extract. In 1885, a historical case series associated gelsemium poisoning with muscular weakness, staggering gait, mydriasis, respiratory depression, seizures, and death.[1] Animal experimentation at that time indicated that the extract of *Gelsemium sempervirens* was toxic, but there were no laboratory analyses of the toxic ingredients.

BOTANICAL DESCRIPTION

Common Name: Carolina Jessamine, Yellow Jessamine, Evening Trumpetflower

Scientific Name: *Gelsemium sempervirens* (L.) St. Hill.

Botanical Family: Loganiaceae (logania)

Physical Description: This woody, perennial, evergreen climbing vine has paired lance-shaped leaves and clusters of bright yellow, funnel-shaped flowers. Yellow jessamine should not be confused with day jessamine (*Cestrum diurnum* L.) or night jasmine (*Cestrum nocturnum* L.) from the Solanaceae family.

Distribution and Ecology: Carolina jessamine is found throughout the southeastern coastal plain from Virginia to Texas as a native vine. *G. sempervirens* is the state flower of South Carolina. This plant is cultivated as a climbing vine in California.

EXPOSURE

The Carolina jessamine is not commonly used as a medicinal herb. This plant is an ornamental plant in temperate climates.

PRINCIPAL TOXINS

Physiochemical Properties

All parts of *G. sempervirens* contain a mixture of 17-indole alkaloids including gelsemine, gelsevirine, gelsedine, 21-oxoglesemine, 14-β-hydroxygelsedine, gelsenicine, humantenidine, humantenirine, koumine, koumidine, kumantenine, and rankinidine.[2,3] Gelsemine (CAS RN:509-15-9, $C_{20}H_{22}N_2O_2$) is complex hexacyclic compound with an azatricyclodecane ring system that can be synthesized from 1-triisopropylsiloxy-3-methyl-1,3-cyclohexadiene via 26 intermediates.[4] Figure 144.1 displays the chemical structure of gelsemine.

Poisonous Parts

All parts of the plant contain alkaloids including gelsemine, gelseminine, and gelsemoidin. However, the blossoms and roots contain primarily high concentrations of gelsemine.[5] Honey made from the flowers is potentially poisonous, but there are no well-documented cases of

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

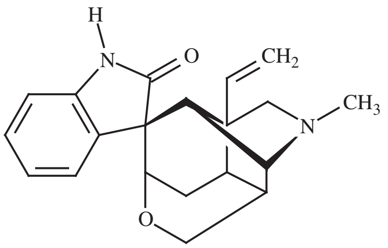

FIGURE 144.1. Chemical structure of gelsemine.

human intoxication from the ingestion of gelsemine-contaminated honey.

Mechanism of Toxicity

Gelsemine is a potent antagonist of central and peripheral muscarinic and nicotinic acetylcholine receptors.[5] This toxin interferes with cholinergic transmission at the neuromuscular junction and central nervous system by binding to the acetylcholine receptor.[5]

DOSE RESPONSE

There are inadequate data to determine the dose response of toxic constituents in this plant.

TOXICOKINETICS

The toxic constituents in this plant have not been identified.

CLINICAL RESPONSE

Most clinical reports on the toxicity of Carolina jessamine were published before 1900 when *G. sempervirens* extracts were used by herbalists to induce abortions. Patients developed profound muscle weakness, nausea, vomiting, diaphoresis, and respiratory depression leading to asphyxia.[6] A case report on a 3½-year-old girl associated the development of wide-based gait, bilateral ptosis, mydriasis, brisk deep tendon reflexes, generalized weakness and obtundation with the ingestion of five blossoms from *G. sempervirens*.[5] Additional symptoms included headache, dry mouth, dysphagia, blurred vision, and lightheadedness. Symptoms resolved within 10 hours after ingestion. Increased muscle tone and hyperactive deep tendon reflexes were reported in cases of *G. sempervirens* intoxication prior to 1900, but the etiology of these clinical findings is unclear.[1]

DIAGNOSTIC TESTING

Experimental studies use nuclear magnetic resonance (NMR) spectrometry to identify hexacyclic compounds in this plant.[7]

TREATMENT

Management is supportive. Decontamination measures are not usually recommended. The administration of activated charcoal to alert children who ingest more than one blossom or several leaves less than 1 hour prior to presentation is a therapeutic option, but there are no clinical data to confirm the clinical efficacy of decontamination measures following the ingestion of Carolina jessamine.

Chapter 145

DAPHNE
(*Daphne mezereum* L.)

BOTANICAL DESCRIPTION

Common Name: Daphne, February Daphne, Paradise Plant, Spurge Laurel, Mezereon, Dwarf Bay

Scientific Name: *Daphne mezereum* L.

Botanical Family: Thymelaeaceae (mezereum)

Physical Description: This small deciduous shrub grows 1–4 ft (~0.3–1 m) in height. Small lilac-purple, fragrant flowers develop before the simple alternate leaves appear.

Distribution and Ecology: *D. mezereum* is an ornamental shrub throughout the United States, and this perennial shrub has naturalized in the northeastern United States from Europe and Western Asia.

EXPOSURE

The compound, mezerein, isolated from seed extracts of *D. mezereum* demonstrates some activity against lymphocytic leukemia in mice, but there are limited clinical data on effects in humans.[1,2] Traditional herbal uses of this plant include the treatment of cancer since the time of Aphrodisias around 200 AD.[3]

PRINCIPAL TOXIN

Active constituents of *Daphne mezereum* include mezerein (CAS RN: 34807-41-5, $C_{38}H_{38}O_{10}$), the diterpenoid compound daphnetoxin (CAS RN: 28164-88-7) and 12-hydroxydaphnetoxin.[4] Figure 145.1 displays the chemical structure of mezerein. All plant parts have glycosides (e.g., daphnin, daphnetin, esculin) that contain dihydroxycoumarin as the aglycone.[5] Mezerein is a second-stage tumor promoter and an experimental antileukemic agent that activates protein kinase C (PKC) both *in vitro* and *in vivo*.[6] *In vitro* studies indicate that daphnetoxin is also a PKC activator, but this compound is a more selective and less potent PKC activator than mezerein.[2]

DOSE RESPONSE

There inadequate data to determine a dose response for ingestion of *D. mezereum.*

TOXICOKINETICS

There are few data on the toxicokinetics of active constituents in *D. mezereum*.

CLINICAL RESPONSE

There are few data in the modern medical literature on the toxicity of *Daphne mezereum.* Most reports of exposure to *D. mezereum* in children are not associated with symptoms. Frequently mentioned symptoms following ingestion of parts of this plant from textbooks on plant poisonings include local irritation, nausea, vomiting, abdominal pain, weakness, diarrhea, and occasionally bloody diarrhea. A case report associated the exposure of a 1-year-old girl to *D. mezereum* with the

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

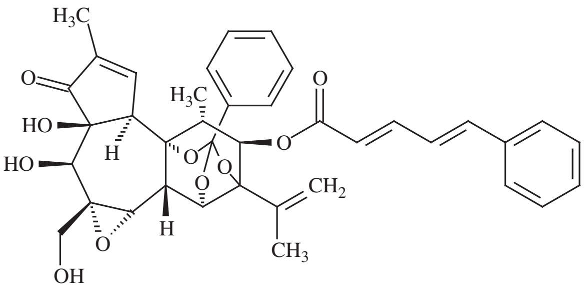

FIGURE 145.1. Chemical structure of mezerein.

development of increased salivation, hematuria, and diarrhea that resolved with conservative treatment.[7]

DIAGNOSTIC TESTING

There are few data on the detection of toxic constituents of laboratory abnormalities following ingestion of *Daphne mezereum*.

TREATMENT

Treatment is entirely supportive. Gastrointestinal decontamination measures are unnecessary. There are no clinical data to determine the efficacy of decontamination measures.

Chapter 146

DOG LAUREL
(*Leucothoe* Species)

BOTANICAL DESCRIPTION

There are about 40 species in the genus *Leucothoe*.

Common Name: Dog Laurel, Doghobble

Scientific Name: *Leucothoe* spp.

Botanical Family: Ericaceae

Physical Description: These shrubs or small trees have alternated leaves and white, fused petals. This evergreen shrub has green, slightly arching stems and pointed leaves. The fruit has a globular, five-lobed capsule with a slightly depressed apex.

Distribution and Ecology: *L. axillaris* (Lam.) D. Don forms dense thickets in moist woodlands of the coastal plain of the southeastern United States and in California.

EXPOSURE

Most serious exposures to this plant occur in grazing animals. There are few human data.

PRINCIPAL TOXINS

Older Japanese literature indicates that the main toxic ingredient in dog laurel is grayanotoxin I, which was structurally similar to andromedotoxin isolated from the *Rhododendron* species.[1] Leaves of *Leucothoe grayana* Maxim. contain isograyanotoxin II,[2] but the clinical significance of this tetracyclic diterpenoid is unclear.

DOSE RESPONSE

The toxic constituents in this plant have not been isolated.

TOXICOKINETICS

There are inadequate data on the principal toxins in dog laurel.

CLINICAL RESPONSE

Most casual exposures to *Leucothoe* plants do not produce toxicity in humans, and summaries of plant exposures reported to US poison centers do not indicate that this plant causes clinically significant toxicity.[3] Based on the presence of grayanotoxins in these plants, ingestions of these plants may cause gastrointestinal distress (nausea, vomiting, diarrhea, abdominal pain), lethargy, neuromuscular weakness, and cardiac depression. However, there are inadequate data to indicate that these toxins are present in sufficient quantities to cause serious toxicity. Grazing animals consuming large quantities of *Leucothoe* species can develop serious toxicity including vomiting, anemia, staggers, and focal hepatic necrosis.[4]

DIAGNOSTIC TESTING

The toxic constituents have not been well defined.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

TREATMENT

Most patients ingesting parts of dog laurel remain asymptomatic, and treatment is supportive. The most likely adverse effect is gastrointestinal irritation, and symptomatic patients should be evaluated and treated for any fluid or electrolyte imbalance. Decontamination measures are unnecessary.

Chapter 147

DOGBANE FAMILY and CARDENOLIDES

COMMON OLEANDER

HISTORY

Since antiquity, the Greeks, Romans, and Hindus recognized the medicinal properties of oleander as a cardiotonic and suicidal agent.[1] The early Greeks considered the oleander plant poisonous to "all four-footed beasts."[2] Preparations of oleander have been used as rodenticides and insecticides as well as remedies for indigestion, malaria, and venereal disease. The most commonly mentioned folk use was as an abortifacient. The Chinese used oleander extract for the treatment of mental disorders. Oleander extracts (Oleander Perpurat, Knoll) were treatments for heart failure and atrial fibrillation. African arrow poisons often contained cardenolides (ouabain, acolongifloroside K, acovenoside A) obtained from the wood and roots of other species of the dogbane (Apocynaceae) family including the genus *Carissa* (*Acokanthera*).[3,4]

BOTANICAL DESCRIPTION

Common Name: Common Oleander, Rose Laurel, Soland, Lorier Bol, Rosebay

Species Name: *Nerium oleander* L. [*Nerium indicum* (Mill.), *Nerium odorum* Aiton]

Botanical Family: Apocynaceae (dogbane)

Physical Description: The common oleander is a large ornamental evergreen shrub that may reach 20–25 ft (~6–8 m) in height with oblong, pointed leaves that contain a prominent midrib. During the summer, large clusters of white, pink, or red flowers appear at the ends of the branches. The fruit consists of two long, narrow pods.

Distribution and Ecology: Oleander plants occur throughout the temperate regions of the United States from California to Florida. The oleander plant is native to Asia and the Mediterranean regions, including India and China. In temperate climates of Africa, South America, and the southern United States, these plants are cultivated as flowering shrubs. A similar plant, called the yellow oleander [*Thevetia peruviana* (Pers.) K. Schum., *Thevetia thevetioides* (Kunth) Schumann], grows in Australia, Hawaii, and southern Florida.

EXPOSURE

Common oleander is an ornamental shrub that adapts well to dry areas along roadsides and in gardens. These shrubs are popular parts of gardens because of their prolific growth and decorative flowers. The root and the bark have been used in India for skin diseases and leprosy. Extracts of oleander have been used as insecticides, rodenticides, and as an abortifacient, as well as a cure for leprosy, malaria, ringworm, venereal disease, indigestion, fever, and alcoholism.[5] African arrow poisons typically contain toxic cardenolides (e.g., ouabain, acolongifloroside K) from *Carissa* (*Acokanthera*) species.[3]

In European folk medicine, herbal preparations from *Adonis* species are used as diuretics and cardiac stimulants.[6] Experimental studies in the 1950s suggested that

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

alcohol extracts of star of Bethlehem (*Ornithogalum umbellatum* L.) caused positive inotropic actions similar to digitoxin.[7] Preliminary studies investigated the efficacy of these extracts for the treatment of congestive heart failure, but the use of these preparations did not demonstrate a clear superiority over the administration of digitalis preparations (digitoxin).[8,9]

PRINCIPAL TOXINS

Physiochemical Properties

The two major classes of cardiac glycosides are 1) the bufadienolides from the poisonous glands in the skin of the cane toad (*Bufo marinus* L.), and 2) the cardenolides in plant tissues.[10] The major toxins in oleander are cardiac glycosides that contain a five-membered steroid nucleus with a lactone ring in contrast to the six-membered lactone ring in bufadienolides. Digitalis is the prototypical cardenolide, and oleander-derived cardenolides share similar physiological and structural characteristics with digitalis.

The three structural subunits of cardenolides are 1) steroid backbone, 2) lactone ring, and 3) sugar or carbohydrate moiety in glycosidic linkage.[1] The steroid component and the lactone ring represent the "aglycone" or "genin" component of the cardenolide compound. These plant cardenolides have the carbohydrate or sugar moiety attached to the three-carbon of the "A" ring of the five-membered steroid nucleus. The sugar moieties of cardenolides are specific, and this portion of the compound defines the name of the cardenolide (e.g., digitoxose, digitoxin, oleandrose, oleandrin). Figure 147.1 compares the chemical structures of common cardiac glycosides present in oleander.

Common oleander contains several cardiac glycosides (oleandrin, digitoxigenin, neriantin, rosagenin) that produce a digitoxin-like effect by inhibiting the sodium-potassium adenosine triphosphatase enzyme system. These cardiac glycosides bind to an extracellular portion of the Na^+/K^+ ATPases and cause increased intracellular calcium concentrations. Minor glycosides in oleander with limited cardiac activity include adynerigenin, adigoside, digitalin, and uzarigenin.[11] Because of the lack of toxicokinetics data, the identities of the toxic glycosides or toxic metabolites remain unclear.

Poisonous Parts

Of over 400 cardiac glycosides isolated from the plant kingdom, most of the cardiac glycosides occur in extracts from the milkweed (Asclepiadaceae), figwort (Scrophulariaceae), lily (Liliaceae), and dogbane (Apocynaceae) families. The highest concentrations of cardiac

FIGURE 147.1. Structural similarities between the prominent cardiac glycosides present in oleander and secretions from the cane toad (*Bufo marinus*). Adapted from Cheung K, et al. Detection of poisoning by plant-origin cardiac glycoside with the Abbott TDx Analyzer. Clin Chem 1989;35:297.

glycosides are found in seed, stems, and roots, followed by the fruit and leaves. However, the leaves contain the greatest oleandrin concentrations. The concentration of oleandrin varies widely between various strains and species of oleander. The estimated oleandrin content of leaves from common oleander ranges from approximately 0.02–0.4%.[11] In a study of 20 *Nerium oleander* L. from various countries, the oleandrin content of fresh, dried leaves ranged from 0.007–0.42%.[12] Using a radioimmunoassay that measured apparent digoxin concentrations as a surrogate for cardiac glycoside content, the value for stems from *Nerium oleander* was 620 µg/g compared with 52 µg/g for leaves from *Thevetia peruviana*.[10] Differences in the apparent digoxin concentration exist between plant species as measured by different immunoassays. The apparent digoxin concentration of leaves from the *Nerium oleander* was 2.21 µg/L as measured by Abbott TDx Analyzer (Abbott Diagnostics, Abbott Park, IL) and 2.86 µg/L as measured by in-house radioimmunoassay, whereas the apparent digoxin concentrations of the leaves from *Thevetia peruviana* were similar (3.51 µg/L and 3.56 µg/L, respectively).[13]

The highest concentrations of total cardiac glycosides occur during the flowering stage in April to May with red flowers possessing the highest glycoside content.[14] The roots contain larger concentrations of total cardenolides and smaller concentrations of oleandrin compared with the leaves, flowers, and stems. By unconfirmed historical accounts, 7 of 12 French soldiers died in 1809 when they roasted meat on oleander stems from which the bark had been stripped.[15] However, there are no well documented reports to indicate that sufficient amounts of oleandrin are transferred from oleander stems to food during the cooking process. *Thevetia* fruit and *Nerium* leaves were the most common parts of the oleander ingested in an Australian study of children with oleander exposure.[16] The children, who ate parts of whole plants, remained relatively asymptomatic compared with adults, who develop serious cardiac toxicity after intentional ingestions of teas made from oleander.

DOSE RESPONSE

Animals

There is substantial variation in the sensitivity to oleander poisoning between animal species. Dogs, cats, goats, monkeys, and humans are relatively sensitive to the effects of oleander-derived cardenolides, whereas rodents and avian species are relatively insensitive. The intravenous administration of oleander tincture in dogs produces a digitalis-like poisoning during experimental studies manifest by a combination of delayed conduction and increased automaticity terminating in intractable ventricular fibrillation.[17] In a study of monkeys receiving 30 mg dried oleander leaves per kg body weight, vomiting developed within 2 hours and bradycardia within 1–6 hours.[18] All the monkeys died, and postmortem examination revealed necrosis in the heart, kidneys, adrenals, liver, and pancreas.

Humans

Although one leaf has been considered potentially lethal, ingestion of larger amounts is probably necessary to produce serious toxicity. Using calculations on the digoxin pharmacokinetic in the antemortem serum from a 96-year-old woman who died after ingesting oleander tea, Osterloh et al estimated that the apparent digoxin concentration of 5.8 ng/mL was equivalent to the absorption of cardiac glycosides from 5–15 *Nerium* leaves.[19] The postmortem examination did not demonstrate any evidence of coronary artery disease. Using a crude oleander extract prepared by ethanol extraction, lead acetate purification, and solvent partition, the group estimated that 100 ng/mL of crude extract produced a 1 ng/mL false elevation of the digoxin concentration. Assuming the V_d of digitoxin was 1 L/kg, the estimated absorbed dose of cardiac glycosides was approximately 4 grams, which was equivalent to 5–15 oleander leaves.

In a study of children hospitalized for oleander ingestions in Australia from 1972–1978, the reported ingestion of three leaves by a 7-year-old resulted in a partial right bundle branch block.[16] The patient remained asymptomatic. Three other toddlers remained asymptomatic after ingesting leaves, flowers, or seed husks.

TOXICOKINETICS

There are few data on the kinetics of cardenolides during oleander intoxication. The apparent half-life of cardiac glycosides as calculated from the apparent digoxin concentration was 44 hours in the serum from a 17-year-old girl with oleander poisoning. She developed mild conduction abnormalities after ingesting five oleander leaves that were crushed and boiled.[20]

CLINICAL RESPONSE

Oleander poisoning resembles digitoxin poisoning with the predominant symptoms involving the gastrointestinal and cardiac systems. Serious oleander intoxication usually occurs following the ingestion of teas prepared from oleander leaves rather than from the ingestion of plant parts.[21–23] The bitter taste of the oleander leaves limits the ingestion of oleander leaves in children. Characteristic features of serious oleander poisoning include confusion, marked hyperkalemia, conduction

abnormalities, and ventricular arrhythmias. Nausea and vomiting usually occur within several hours, and gastrointestinal symptoms are more prominent following oleander poisoning than following digoxin toxicity. Increased salivation, dry mouth, burning of the mouth, and paraesthesias of the tongue may develop as a result of the local effects of oleander extracts.[22] Case reports indicate that the astringent properties of oleander sap produce mucosal irritation.[24]

The most common serious complication of oleander poisoning is disruption of cardiac conduction.[25] Cardiogenic shock, ventricular fibrillation, and cardiovascular collapse may occur following severe oleander toxicity. Conduction delays may persist 3–6 days, and these cardiac effects resemble classical digitalis toxicity (e.g., conduction abnormalities with ectopy, such as supraventricular tachycardia with atrioventricular block).[23,26] Following the intentional ingestion of oleander tea, a 96-year-old woman developed cardiovascular collapse 15 minutes after arrival in the emergency department.[19] Cardiac monitoring demonstrated a variety of rhythms including ventricular tachycardia, ventricular fibrillation, and asystole that failed to respond to the standard protocols outlined in the American Heart Association's Advanced Cardiac Life Support guidelines. Her admission potassium level was 8.6 mEq/L. A 30-year-old woman presented in cardiogenic shock with an idioventricular rhythm 10 hours after ingesting an oleander tea.[21] She died despite 1 hour of resuscitation that included fluids, endotracheal intubation, sodium bicarbonate, atropine, and a transthoracic pacemaker. A 33-year-old woman developed complete heart block and hyperkalemia (6.7 mEq K^+/L) after the ingestion of oleander tea as an abortifacient.[27] Within 24 hours, the complete heart block reverted to bradycardia that persisted for 6 days along with diarrhea and dizziness. She recovered completely with only supportive care.

Ornithogalum species contain calcium oxalate crystals arranged in bundles. An irritant dermatitis was associated with the direct contact of mucilaginous juice from *Ornithogalum caudatum* Aiton.[28] Erythema developed within 5 minutes at the site of contact along with pruritus and a sensation of burning that persisted 2 days. These symptoms were related to raphides in the mucilage rather than the presence of cardenolide compounds.

DIAGNOSTIC TESTING

Analytical Methods

Chromatography

The only cardiac glycoside in *Nerium oleander* available as a pure standard is oleandrin. The use of thin layer chromatography (TLC) and fluorescence spectrophotometry for the identification of oleandrin provides verification of oleander poisoning for forensic purposes. Oleandrin is the cardiac glycoside identified as the *o*-arabinoside of the 16-β-(acetyloxy)-14-hydroxy-card-20-(22)-enolide. Similar cardenolides include the glycoside, neriantin, and several odoroside glycoside derivatives of the aglycone oleandrigenin.[29] Because of the structural similarities of these cardenolides, the fluorometric assays for oleandrin also measure other cardiac glycosides. The thermolability and poor volatility of the cardiac glycosides present in oleander complicate the quantitation of these substances by gas chromatography/mass spectrometry. A more sensitive method for the detection of oleander poisoning is the use of high pressure liquid chromatography/mass spectrometry (HPLC/MS) to identify oleandrin and the aglycone metabolite, oleandrigenin.[30,31] The limit of quantitation for oleandrin in whole blood was 0.4 ng/mL.

Immunoassays

The presence of a positive digoxin immunoassay is consistent with the ingestion of oleander, but the apparent digoxin concentrations vary between assays depending on the assay. The relationship between the measured apparent digoxin concentration and the actual concentration of cardiac glycosides in serum depends on the specificity and heterogeneity of the antibody in each immunoassay as well as the type of cardenolide present in the ingested material. Consequently, the apparent digoxin concentration does not correlate to the usual therapeutic and toxic concentration of digoxin in serum. In a variety of plant genera, cardiac glycosides cross-react with digoxin immunoassays to a variable degree.[32] Table 147.1 lists plants and animals that contain cardiac glycosides capable of cross-reacting with digoxin assays.

The cardiac glycosides present in oleander cross-react with digoxin radioimmunoassays and commercial immunoassays. However, the identity of these cardiac glycosides and the extent of these cross-reactions are not well defined. Furthermore, these tests are not sensitive for all cardioactive glycosides, and sensitivity to a specific cardiac glycoside varies with the specific antigen used. For example, antidigoxin antiserum cross-reacts well with glycosides of digoxigenin that share the aglycone portion of digoxin, but this antiserum is less sensitive to digitoxin-like cardiac glycosides.[33,34] Radford et al demonstrated the variable sensitivity of immunoassays to cardiac glycoside concentrations present in samples of various cardenolide-containing plants including oleander by using four different antibodies (12-acetyl-3-succinyl digoxigenin, 3,12-disuccinyl

TABLE 147.1. Plants and Animals Containing Cardiac Glycosides that Potentially Interact with Digoxin Immunoassays

Scientific Name	Common Name	Principal Cardenolides
Plants

digoxigenin, digoxin, and an unknown commercial assay; see Table 147.2).[10] An *in vitro* study on the cross-reactivity of five common digoxin immunoassays for oleandrin indicated that fluorescence polarization immunoassay (FPIA) was the most sensitive for oleandrin, whereas the chemiluminescent assay (Bayer Diagnostics, Tarrytown, NY) was insensitive.[35] The Beckman digoxin assay on the Synchron LX and the turbidimetric assay on the ADVIA analyzer (Bayer) demonstrated intermediate sensitivity for oleandrin. Although the measurement of serum oleandrin concentrations with the digitoxin fluorescence polarization immunoassay is linear, the result does not correlate to toxicity.[11] Consequently, immunoassays for digoxin and digitoxin confirm exposure to cardiac glycosides present in oleander, but the results do not correlate linearly to the actual concentration of cardiac glycosides in these plants.

Biomarkers

Chromatography

A 45-year-old woman presented to the emergency department with nausea, vomiting, abdominal pain, sinus bradycardia, and cardiovascular shock.[31] The oleandrin concentration in a plasma sample drawn at the time of admission was 1.1 ng/mL, as measured by HPLC/MS. The patient survived and the following day the concentration of oleandrin in a blood sample was not detectable. Eighteen hours after ingesting a bowl of *Nerium oleander* blooms, a 47-year-old woman presented to the emergency department with bradycardia, intermittent third-degree AV block, and hyperkalemia.[36] The serum oleandrin concentration on admission was 1.6 ng/mL, as measured by HPLC/MS/MS. Sixteen hours later the serum oleandrin concentration was below the limit of quantitation (<1.0 ng/mL). The postmortem oleandrin concentration in heart blood from a 49-year-old woman, who died 1 day after ingesting an aqueous extract of oleander, was 9.8 ng/mL, as measured by liquid chromatography/three-dimensional quadrupole mass spectrometry with sonic spray ionization.[37] The limit of detection was 3 ng/mL.

Immunoassays

The apparent digoxin concentration in a serum sample from an asymptomatic 17-year-old boy with suspected ingestion of oleander leaves was 0.45 µg/L as measured by radioimmunoassay and 0.19 µg/L, as measured by the Abbott TDx Analyzer. The apparent digoxin concentration in the serum of a patient with asymptomatic bradycardia and a normal potassium level following the ingestion of several oleander leaves was 1.2 ng/mL, as measured by radioimmunoassay.[38] A 37-year-old woman ingested seven *Nerium oleander* leaves 8 hours prior to arrival at the hospital.[39] A blood sample drawn at admission contained an apparent digoxin concentration of 4.4 ng/mL, as measured by radioimmunoassay. The clinical course of this patient was unremarkable. Case reports have documented similar apparent digoxin concentrations following the ingestion of oleander tea, which

[a]Antibody A (goat) 12-acetyl-3-succinyl digoxigenin; antibody B (goat) 3,12-disuccinyl digoxigenin; antibody C (cow) digoxin. All three cardiac glycoside assays demonstrate 100% cross-reactivity to digoxin, whereas the cross-reactivity to digitoxin was 350%, 100%, and 23%, respectively.

caused severe toxicity (third degree heart block, serum potassium 8.8 mEq/L).[40] Following the ingestion of oleander extract the night before, the serum from an 83-year-old lady contained an apparent digoxin concentration of 7.1 ng/mL, as measured by radioimmunoassay.[22] The serum potassium concentration was 6.1 mEq/L. Using a digoxin radioimmunoassay from Abbott Diagnostics, Osterloh et al detected an apparent digoxin level of 5.8 ng/mL in the serum sample from a 96-year-old woman, who developed cardiac arrest within 15 minutes of arrival at the emergency department.[19] The serum potassium concentration was 8.6 mEq/L. The digoxin concentration was 6.4 ng/mL in postmortem blood from a 30-year-old woman, who died about 10–11 hours after ingesting oleander tea, as measured by radioimmunoassay (RIA).[21] There was some evidence of postmortem redistribution because the apparent digoxin concentration (method not specified) in serum drawn during resuscitation and analyzed 6 days later was 1.2 ng/mL.

Abnormalities

Classic electrolyte disturbances include hyponatremia and hyperkalemia as a result of the blockade of the Na^+-K^+ ATPase pump. Severe oleander toxicity is associated with hyperkalemia, but not with hypermagnesemia. Electrocardiographic changes include a wide range of conduction abnormalities and dysrhythmias. These changes range from bundle branch block to complete heart block and from ventricular premature beats and junctional escape rhythms to atrial and ventricular fibrillation.

TREATMENT

Stabilization

Serious oleander toxicity usually results from the ingestion of oleander teas rather than the ingestion of plant parts. These patients require careful evaluation for adequacy of ventilation, conduction abnormalities, ventricular ectopy, and hyperkalemia with cardiac monitoring and pulse oximetry. Lidocaine is the antiarrhythmic of choice for the treatment of digitalis-induced tachyarrhythmias. Quinidine, procainamide, and beta-blockers should be avoided because of adverse effects on cardiac conduction and contractility. There are few data on the use of amiodarone during digitalis intoxication. Symptomatic bradycardias should be treated first with atropine, and then a cardiac pacemaker. Patients who do not respond to supportive care are candidates for the administration of digoxin-specific Fab fragments, although the efficacy for this treatment has not been established.

Decontamination

Casual contact with common oleander leaves and flowers by children does not usually result in serious morbidity. If the child is alert and the parents are absolutely convinced that the child ingested less than a leaf or flower, then the child may be observed at home. The administration of activated charcoal to alert children who ingest more than one leaf within 1 hour prior to presentation is a therapeutic option, but there are no clinical data to confirm the clinical efficacy of decontamination measures on outcome following the ingestion of common oleander leaves. These patients should be monitored for evidence of conduction abnormalities and dysrhythmias.

Antidote

Although potentially useful, the role of digoxin-specific Fab fragments in the treatment of serious oleander poisoning remains undefined as a result of the pharmacokinetic differences between cardenolides and the lack of good quality controlled clinical trials.[41] Several case reports document the use of Fab fragments following oleander toxicity, but the efficacy of the Fab fragments in these cases is unclear. Currently, the use of digoxin-specific fragments is a reasonable therapeutic option in oleander-intoxicated patients with serious cardiac toxicity (e.g., complete heart block, hypotension, ventricular tachyarrhythmias) who do not respond to supportive care. The use of these fragments in dogs administered fatal doses of cardiac glycosides from *Nerium oleander* successfully reversed the digoxin toxicity, but the dose administered was equivalent to the use of 105 vials in a 70-kg (~154-lb) person.[42] Consequently, large quantities of Fab fragments may be necessary to reverse the digoxin-like effects of oleander poisoning.

A Haitian woman died at a hospital after failing to respond to supportive care including the use of 20 vials of Digibind® (digoxin-specific Fab fragments; GlaxoSmithKline Pharmaceuticals, Mississauga, Ontario, Canada). A 37-year-old man developed asymptomatic sinoatrial nodal arrest, a junctional escape rhythm, and a serum potassium concentration of 4.3 mEq/L after ingesting a few oleander leaves.[38] Thirty minutes after the intravenous administration of 5 vials (200 mg) of Digibind®, the heart rate and conduction improved, but a mild sinus bradycardia persisted for 4 days. No atropine was given. A 24-year-old man presented to the emergency department 10 hours after ingesting a mixture of orange juice and six ground *Nerium oleander* leaves.[43] He had marked miosis, bilateral ptosis, diaphoresis, and glossal fasciculations. The apparent digoxin concentration was 0.8 ng/mL, as measured by digoxin

radioimmunoassay. Hypotension, coma, and hyperkalemia (potassium 6.8 meq/L) developed despite the use of supportive care (atropine, pacemaker, insulin-glucose therapy, bicarbonate). The patient received 480 mg digoxin-specific Fab antibody fragments intravenously 18 hours after admission, and reversal of the coma, hyperkalemia, diplopia, and complete A-V block occurred within 1 hour of administration. The first-degree A-V block and the diffuse ST depression persisted for 6 days. Recovery from serious oleander poisoning has occurred without the use of digoxin-specific Fab fragments. Following the ingestion of oleander tea the previous night, an 83-year-old woman presented to the emergency department with a bradycardia, conduction delay (QRS = 138 milliseconds), blood pressure of 102/50 mmHg, and an apparent digoxin concentration of 7.1 ng/mL.[22] The administration of atropine converted her bradycardia to atrial fibrillation with a normal ventricular response. The hyponatremia (121 meq/L) and hyperkalemia (6.1 meq/L) resolved without the use of Digibind®.

Supplemental Care

Symptomatic patients should be evaluated and treated for fluid and electrolyte imbalance. Serial serum potassium and creatinine concentrations should be monitored until a downward trend develops. Hyperkalemia may not respond to sodium bicarbonate or insulin-glucose therapy because the inhibition of the Na^+/K^+ ATPase pump by cardiac glycosides in oleander prevents the movement of potassium into the cell.[21] Hemodialysis is an option if the hyperkalemia contributes to cardiac instability. However, the use of hemoperfusion and hemodialysis in a 17-year-old girl, who developed mild conduction abnormalities after ingesting five oleander leaves, did not alter the apparent serum digoxin concentration.[20] Cardiac monitoring may be discontinued after normal sinus rhythm returns.

YELLOW OLEANDER

HISTORY

Ingestion of yellow oleander seeds is a relatively common cause of accidental poisoning among children worldwide.[16] Currently, the ingestion of yellow oleander seeds is a common method of attempted suicide in northern Sri Lanka where the case fatality rate is about 10% for the thousands of cases reported every year there.[44] Thevetin was a cardiac glycoside tested in the 1930s for cardiotonic effects.[45] Although this extract of yellow oleander was efficacious in the treatment of heart failure and atrial fibrillation, the frequency of gastrointestinal side effects limited the use of this agent.

BOTANICAL DESCRIPTION

Common Name: Yellow Oleander, Be-Still Tree

Scientific Name: *Thevetia peruviana* (Pers.) K. Schum., *Thevetia thevetioides* (Kunth) K. Schum.

Botanical Family: Apocynaceae (dogbane)

Physical Description: This large ornamental evergreen shrub grows up to 20 ft (~6 m) in height and has narrow, oblong leaves with a prominent midrib similar to common oleander. Clusters of dull orange to bright yellow tubular flowers appear in the summer followed by the appearance of fleshy, triangular, globular black fruit. The fruit contains an outer flesh and a hard stone center.

Distribution and Ecology: The yellow oleander grows in Australia, South America, Hawaii, and southern Florida, whereas the common oleander (*Nerium oleander*) appears more frequently in the dry, temperate regions of the United States.

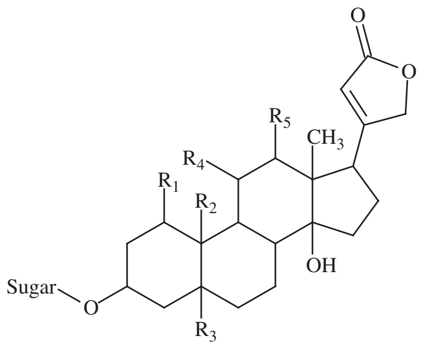
EXPOSURE

At one time, peruvoside, an extract of the seed, underwent clinical trials as a substitute for ouabain in India.[46] Past uses for extracts of yellow oleander include suicidal and homicidal agents, abortifacients and herbal remedies, as well as an experimental drug for heart failure and atrial fibrillation.[1]

PRINCIPAL TOXINS

Physiochemical Properties

The yellow oleander contains at least eight cardiac glycosides that are cardenolides with a chemical structure similar to digitoxin.[16] Cardenolides contain a five-membered, steroid nucleus with a lactone ring in contrast to the six-membered steroid nucleus present in bufadienolides (see Figure 147.1). These cardiac glycosides have a carbohydrate or sugar moiety attached to the three-carbon on the "A" ring of the steroid by an oxygen bridge. The cardiac glycosides in extracts from yellow oleander include thevetin A, thevetin B (cerberoside), thevetoxin, peruvoside, ruvoside, and neriifolin. Figure 147.2 displays the chemical structures of some *Thevetia* cardenolides, digoxin, digitoxin, and ouabain. The



Cardenolide	Sugar	R_1	R_2	R_3	R_4	R_5	MW	Log P	Bio-availability (%)	PO Onset	$t_{1/2}$	V_D (L/kg)	Protein Binding (%)

Pharmacokinetics of digoxin cross-reacting substances in patients with acute yellow oleander (*Thevetia peruviana*) poisoning, including the effect of activated charcoal. Ther Drug Monit 2006;28:785.

estimated potency of thevetin is about one-eighth the potency of ouabain on a weight for weight basis.[47]

Poisonous Parts

There are few data regarding the concentration of cardiac glycosides in yellow oleander. In a study of Australian children sent to medical care following exposure to oleander, *Thevetia* fruit and *Nerium* leaves were the most common plant parts associated with oleander exposure.[34] These children remained relatively asymptomatic and none of these children developed serious toxicity. Based on radioimmunoassay of digoxin-equivalents, Ansford and Morris demonstrated higher concentrations of digoxin-equivalents (i.e., cardiac glycosides) in *Thevetia* leaves than in mature fruit.[54] Although one leaf is considered potentially lethal, the ingestion of larger amounts is probably necessary to cause serious toxic effects. The kernel of the yellow oleander seed reportedly contains the highest concentration of cardiac glycosides in the seed.[57] The estimated percentage by weight of cardiac glycosides in different parts of *Thevetia peruviana* was as follows: sap, 0.036%; fruit, 0.045%; leaf, 0.07%; and kernel of seed, 4.8%.[47]

Mechanism of Toxicity

Similar to common oleander, the cardiac glycosides in yellow oleander inhibit the transmembrane Na^+/K^+ ATPase pump, and this action produces increased intracellular concentrations of Ca^{++} and Na^+. Subendocardial and perivascular hemorrhage along with focal myocardial edema are the common pathological findings during postmortem examination of fatal cases of yellow oleander poisoning.[48]

DOSE RESPONSE

Predicting outcome based on the number of seeds ingested is problematic because of the lack of reliable historical data. Based on radioimmunoassay of a broad cardiac glycoside-specific antibody, and assuming that *Thevetia* glycosides are concentrated 20 times more in heart muscle than in blood, Ansford and Morris estimated that the absorption of cardiac glycosides from two *Thevetia* leaves resulted in the death of a 12.5-kg (~28-lb) child.[54] However, there are inadequate human data to confirm this estimation. Based on historical estimates of the amount of yellow oleander seed ingested,

Saraswat et al estimated that the ingestion of one to two yellow oleander seeds caused mild gastrointestinal symptoms and the ingestion of three to four seeds produced moderate gastrointestinal and cardiac toxicity.[49] They estimated that the lethal dose of yellow oleander seeds was 8 to 10 seeds. However, the number of seeds reportedly ingested by 6 patients who died ranged from 1 to 10, and only 2 of 7 patients ingesting >10 seeds died.[44] In a 65-year-old patient with hypertension treated with metoprolol, the ingestion of two *Thevetia* seeds produced mild bradycardia, peak serum potassium concentration of 5.6 meq/L, non-specific ST-T wave changes, and atrioventricular conduction block, which resolved over 2 days.[50]

TOXICOKINETICS

There are limited data on the toxicokinetics of *Thevetia* cardenolides in intoxicated humans. Toxicokinetic data from a clinical study of 104 patients with *Thevetia* intoxication indicated that the absorption of *Thevetia* cardenolides is highly variable and prolonged with the time to maximum concentration exceeding 24 hours in some patients.[51] The apparent terminal half-life of *Thevetia* cardenolides as estimated by a digoxin immunoassay in patients receiving supportive care and no activated charcoal was also highly variable with a median time of 42.9 hours (range: 13.27–94.24 hours). Figure 147.2 displays some pharmacokinetic parameters for individual *Thevetia* and *Digitalis* cardenolides.

CLINICAL RESPONSE

Although the bitter taste of the leaves usually limits the quantity of oleander *leaves* consumed by children, the ingestion of yellow oleander *seeds* may produce serious toxicity in children. Like common oleander poisoning, yellow oleander intoxication closely resembles digitoxin poisoning as manifest by gastrointestinal and cardiac effects. Nausea, vomiting, abdominal pain, burning and dryness of the throat, and mucosal erythema may develop within several hours of the ingestion of yellow oleander. The most common symptoms in a series of 79 patients with yellow oleander poisoning were vomiting and abdominal pain.[44] Other symptoms (e.g., paresthesias, weakness, hypotension, hypertonia, excessive salivation) may occur depending on the severity of the poisoning.[46,52,53] Serious toxicity usually develops within 12 hours of ingestion, and fatalities usually occur within about 24 hours after ingestion.

Most abnormal electrocardiograms demonstrate bradycardia, and serious toxic effects usually result from cardiac complications, such as delayed conduction in sinoatrial and AV nodes.[54,55] Although serious ventricular dysthymias (ventricular tachycardia, ventricular fibrillation) occur in severe yellow oleander toxicity, ventricular ectopy is more common during digoxin poisoning than during oleander poisoning.[54] In a series of 168 patients admitted to a secondary care hospital in Sri Lanka with yellow oleander poisoning, about 15% of the patients developed serious conduction disturbances (e.g., nodal bradycardia, type II second degree AV block, third degree AV block).[56] Conduction block and sinus bradycardia may persist as long as 4–5 days after ingestion in seriously toxic patients.[46,57] These disturbances usually resolve without sequelae unless complete heart block or cardiogenic shock develops.[50]

DIAGNOSTIC TESTING

As with common oleander, digoxin radioimmunoassays in yellow oleander poisoning confirm the presence of cardiac glycosides, which cross-react with digoxin.[54] The apparent concentration of digoxin does not correlate to the usual toxic and therapeutic concentrations of digoxin. Although apparent digoxin concentrations exceeding 1.5 ng/mL suggests serious intoxication, variability in the cross-reactivity between these assays and the cardenolide compounds in yellow oleander limit the correlations to clinical outcome.[35] The extent of the rise in serum potassium is probably the most practical biochemical measure of the severity of yellow oleander poisoning. A $2^1/_2$-year-old child died of complete atrioventricular block and cardiogenic shock approximately 18 hours after the ingestion of a large quantity of yellow oleander seeds.[58] The apparent digoxin and digitoxin concentrations in a sample of blood drawn in the emergency department were 11 μg/L and 170 μg/L, respectively. The serum potassium concentration was 9.0 meq/L. The cardiac (conduction blocks, dysrhythmias) and electrolyte (hyperkalemia) abnormalities following yellow oleander poisoning are similar to the abnormalities that follow common oleander poisoning. Magnesium concentrations are usually within the normal range during yellow oleander poisoning.

TREATMENT

The management of yellow oleander poisoning is similar to the medical treatment for common oleander (*Nerium oleander*) ingestions. The efficacy of digoxin-specific Fab fragments for yellow oleander poisoning is variable, with improvement of the cardiac abnormalities in some, but not all patients with serious yellow oleander poisoning. The administration of 190 mg digoxin-specific Fab antibody fragments (5 ampules Digibind®) to a 7-year-old girl with sinus bradycardia and variable second- and third-degree AV block after the ingestion of yellow ole-

ander seeds resulted in conversion of the rhythm to sinus tachycardia with first-degree AV block.[59] Her rhythm did not revert to normal sinus rhythm until 16 hours after ingestion despite the administration of an additional 190 mg digoxin-specific Fab antibody fragments. The administration of 1,200 mg digoxin-specific Fab fragments to 34 patients with serious yellow oleander toxicity resulted in the resolution of the dysrhythmias in 15 of the treated patients.[60] About 23% of the patients in the trial developed adverse reactions primarily involving urticarial rashes and a few cases of bronchospasm and angioedema. The administration of serial-activated charcoal is an alternative treatment of oleander intoxication,[61] when digoxin-specific Fab fragments are not available. Although the administration of multiple dose-activated charcoal (50 g every 6 hours for 3 days) usually causes minimal adverse reactions, there are no unequivocal clinical data to confirm the efficacy of this treatment. Given the high tissue binding of digoxin-like compounds, more clinical data are necessary to prove the efficacy of serial-activated charcoal.[51]

ODOLLAM TREE

The odollam tree (*Cerbera odollam* Gaertn., Apocynaceae) is a native tree in coastal salt swamps and creeks in south India and along river banks in Vietnam, Cambodia, Myanmar, and Sri Lanka.[62] *Cerbera manghas* L. (sea mango) is a closely related species that is very similar in appearance to the odollam tree. The odollam tree grows to 6–15 m (~20–49 ft) in height and possesses dark green, lanceolate leaves that produce large white flowers with a jasmine-like scent. The fruit has a green fibrous shell surrounding an ovoid kernel. On exposure to air, the color of the white kernel changes to violet and then to brown-black. *C. odollam* and *C. manghas* are differentiated by the color of the corolla, the shape of the fruit, and the color of the ripe fruit. *C. odollam* possesses a yellow-eyed, white corolla with a spherical to ovoid-shaped fruit that is green when ripe. *C. manghas* (sea mango) has a red-eyed, white corolla with oblong to ellipsoid-shaped fruit that is red when ripe. Traditional uses for extracts from oil extracts of the seed from the odollam tree include lighting oil, cosmetic, insect repellant, insecticide, rubefacient, antipruritic agent, and ordeal poison. The seeds of odollam tree (yellow-eyed cerbera, pink-eyed cerbera) and *Cerbera manghas* (sea mango) from the Apocynaceae family contain cardenolide compounds, such as cerberin (monoacetylneriifolin), 17β-neriifolin, deacetyltanghinin, tanghinin, 2′-*O*-acetyl-cerleaside A, cerberoside, and odollin.[63,64] The use of *Cerbera odollam* seeds is a common means of suicidal poisoning in India; The ingestion of these seeds produces cardiotoxicity similar to oleander poisoning manifest by hyperkalemia, bradycardia, and AV nodal conduction block.[65,66] The leaves from this tree are substantially less toxic than the seeds. Treatment is supportive and similar to common oleander poisoning.

URGINEA SANGUINEA SCHINZ

This Southern African plant from the Liliaceae family is a notorious livestock poison and a well-known herbal medicine. Common names include Burke's slangkop, red slangkop, and Transvaal slangkop. Traditional uses for this herb include the treatment of venereal disease, hypertension, abdominal pain, backache, impotence, menstrual disorders, asthma, bronchitis, and blood poisoning.[67] Extracts from this plant are also used as an arrow poison and an abortifacient. Poisoning of grazing animals (e.g., sheep, cattle, goats) by *Urginea sanguinea* are characteristic of cardiac glycoside intoxication.[68] *Urginea* species are bulbous plants with a large flower stalk, which emerges before the leaves in spring. The large, reddish brown pear-shape bulb is about 15 cm (~6 in.) in diameter. This onion-like bulb is perennial with the leaves dying back in the winter. The red bulb extrudes a reddish material when cut, and hence the name sanguinea. *U. sanguinea* is a highly invasive pant that inhabits southern Africa, particularly in hilly areas. All parts of the plant are poisonous, particularly the flowers and bulb. The main toxin in *U. sanguinea* is the bufadienolide, scillaren A (transvaalin), which occurs in concentration of approximately 0.01–0.05%.[69] Scillaren A (CAS RN: 124-99-2) has a molecular formula of $C_{36}H_{52}O_{13}$. Figure 147.3 displays the chemical structure of scillaren A. Spectrographic analysis of fresh bulbs of *Urginea sanguinea* yielded stigmasterol, phloroglucinol, phloroglucinol 1-β-D-glucopyranoside (phlorin), scillaren A, 5-α-4,5-dihydroscillaren A, salicylic acid, and 3-hydroxy-4-methylbenzoic acid with scillaren A and 5-α-4,5-dihydroscillaren A being the major compounds.[70]

Scillaren A is Na^+-K^+ pump poison that alters membrane depolarization and elevates extracellular potassium concentrations. There are few clinical data on *U. sanguinea* poisoning in humans. Ingestion of herbal remedies containing *U. sanguinea* extracts was associated with gastrointestinal distress, dehydration, weakness, abdominal pain, hematuria, tachycardia, and renal failure, but the classic signs and symptoms (hyperkale-

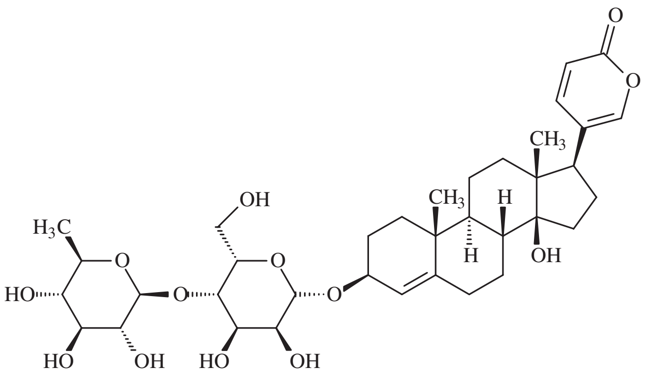

FIGURE 147.3. Chemical structure of scillaren A.

mia, bradycardia, conduction block) of digoxin poisoning were not documented.[67] Treatment is supportive and similar to the treatment of oleander poisoning if signs of digoxin poisoning are present. There are no clinical data on the affinity of digoxin-specific Fab fragments for scillaren A.

Chapter 148

HOLLY
(*Ilex* Species)

BOTANICAL DESCRIPTION

Common Name: English Holly (*Ilex aquifolium* L.), American Holly (*Ilex opaca* Ait.)

Scientific Name: *Ilex* species

Botanical Family: Aquifoliaceae (holly)

Physical Description: These plants grow as deciduous and evergreen shrubs and trees. They have bright green leaves, often with hard teeth on the leaf margins, which discourage leaf consumption.

Distribution and Ecology: The genus *Ilex* contains 300 to 350 species found throughout regions with temperate and tropical climates.

EXPOSURE

These plants typically are grown as ornamental plants. The red or black berries (Christmas holly) are attractive decorations, especially to curious children.

PRINCIPAL TOXINS

Polyphenols, saponins, triterpenes, steroids, and alkaloids have been extracted from *I. opaca*.[1] In animal experiments, ethanol leaf extracts of holly were lethal when injected into mice, whereas *in vitro* studies indicated that these extracts were hemolytic to human erythrocytes. Fruit extracts did not produce toxic reactions in mice. Although saponins are present in both fruit and leaf extracts, the limited oral bioavailability of saponins makes systemic toxicity by the oral route unlikely.

DOSE RESPONSE

There are inadequate data to determine the dose response between the ingestion of holly berries or active constituents and clinical effects.

TOXICOKINETICS

The gastrointestinal toxin in holly berries has not been identified.

CLINICAL RESPONSE

Ilex species produce gastrointestinal distress in some, but not all ingestions. In fact, early settlers of the Southeast enjoyed a very mild brew from *Ilex vomitoria* Ait. leaves called "yaupon tea."[2] Case studies of toxic effects from the ingestion of *Ilex* species in humans are rare. A set of identical twins ingested a "handful of holly berries" after which 15 mL of ipecac was given. Over the next 6 hours, the twins vomited 40 and 50 times. The following day, several loose stools were passed and mild vomiting continued, but symptoms resolved completely by 30 hours after ingestion.[3] Although one twin was lethargic, his neurological symptoms could not be differentiated from a side effect of ipecac administration.

DIAGNOSTIC TESTING

There are few data on the detection of toxic constituents of *Ilex* species.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

TREATMENT

Treatment is supportive. Decontamination measures are unnecessary. Casual ingestions (e.g., a few berries) require no decontamination measures.

Chapter 149

HONEYSUCKLE
(*Lonicera* Species)

BOTANICAL DESCRIPTION

There are over 150 species of the genus *Lonicera* distributed over the northern hemisphere with approximately 35 native and introduced species in the United States.[1] *Lonicera sempervirens* L. is a native species common throughout the southeastern United States, whereas the native species, *L. involucrata* Banks ex Spreng. inhabits moist areas of Canada and the western United States.

Common Name: Chinese Honeysuckle, Japanese Honeysuckle

Scientific Name: *Lonicera japonica* Thunb.

Botanical Family: Caprifoliaceae (honeysuckle)

Physical Description: These shrubs or vines have showy, pleasantly scented flowers that form red to blue-black berries. The flowers are red to yellow or white, and the leaves are simple.

Distribution and Ecology: Japanese honeysuckle is a native species of eastern Asia. This plant is an introduced species in the United States that has naturalized to the roadsides, abandoned fields, and margins of mature woodlands in the eastern, southern, and western United States.

EXPOSURE

Jinyinhua is the Chinese herbal medicine containing extracts of the honeysuckle plant. Medicinal uses for this herb include the treatment of fever, pneumonia, diuresis, dysentery, furuncles, and other skin infections.

PRINCIPAL TOXINS

Extracts of the buds and flowers from *Lonicera japonicum* contains saponin (lupine-triterpene glycosides, iridoid glycosides, loniceroside C), flavones, and phenolic compounds.[2–4] The major compounds detected in a traditional Chinese medicinal herb (Caulis Lonicerae Japonicae) derived from the caulis of *Lonicera japonica* were chlorogenic acid, caffeic acid, loganin, sweroside, secoxyloganin, rutin, and luteolin 7-*O*-glucoside.[5] Some phenolic compounds (methyl caffeate, 3,4-di-*O*-caffeolquinic acid, methyl 3,4-di-*O*-caffeolyquinate) inhibit ADP-induced platelet aggregation in *in vitro* studies.[6]

DOSE RESPONSE

There are inadequate data to determine the dose response associated with exposure to this plant or its extracts.

TOXICOKINETICS

A case report of a 61-year-old man receiving warfarin associated the development of easy bruising, epistaxis, bleeding gums, and elevated international normalized ratio (INR) with the ingestion of an herbal product containing extracts of *Lonicera japonica*.[7] However, the herbal product contained many herbs and the contribution of jinyinhua to the apparent drug interaction between warfarin and the herbal product remains unclear.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

CLINICAL RESPONSE

There are few case reports of toxicity following exposure to the honeysuckle despite the reporting of over 1,000 annual exposures to US national data collection system for poison control centers.[8] Several case reports document the development of a pruritic, maculopapular rash following exposure to the sap of *Lonicera japonica*.[9] Although casual contact with *Lonicera* berries frequently does not produce adverse effects, ingestion of the berries can cause mydriasis, myalgias, and mild gastrointestinal irritation manifest by nausea, vomiting, and diarrhea.[10]

DIAGNOSTIC TESTING

There are few data on the detection of toxic constituents in honeysuckle or its extracts. Methods for detecting bioactive constituents in *Lonicera* species include high performance liquid chromatography (HPLC).[5]

TREATMENT

Treatment is supportive. The contact dermatitis associated with honeysuckle usually responds to topical steroids (0.05% fluocinonide) and antihistamines as necessary. Decontamination measures are unnecessary.

Chapter 150

IVY and FALCARINOL

English or common ivy (*Hedera helix* L.) and Algerian ivy (*H. canariensis* Willd., canary ivy) are popular ground covers and indoor plants that have been recognized causes of contact dermatitis since approximately 1900.[1] *H. helix* contains sterols, saponosides, bidesmosides (bayogenin, hederagenin, oleanolic acid), and flavonoids, as well as emetine alkaloids.[2] The major saponins in English ivy include kalopanax saponin B (hederacoside C), hederagenin, and α-hederin. Other saponins include helixoside A and B.[3] Saponins from the leaves of *Hedera helix* are used by herbalists for anti-infective and antitussive properties. The role of these saponins in causing human toxicity is unsubstantiated. *H. helix* contains falcarinol (heptadeca-1,9-diene-4,6-diyne-3-ol, CAS RN: 21852-80-2), didehydrofalcarinol (heptadeca-1,9,11,16-tetraene-4,6-diyne-3-ol, CAS RN: 110927-49-6), and the ketone falcarinone. Extraction of powdered, dry leaves from a specimen of *H. helix* yielded 21.83 mg hederacoside C/g, 0.41 mg α-hederin/g, and 0.02 mg hederagenin/g as measured by liquid chromatography coupled to electrospray ionization/tandem mass spectrometry.[4] Falcarinol and didehydrofalcarinol are direct irritants and moderate sensitizers, particularly falcarinol. In adult volunteers, the application of a nonirritating 5% solution of falcarinol produced sensitization in 10 of the 20 subjects.[5] Falcarinol also occurs in members of the carrot family (Apiaceae) including carrots, celery, and parsnips, as well as ginseng (*Panax ginseng* C.A.Mey.) and *Schefflera arboricola* (Hayata) Merr. Some shampoos and therapeutic creams also contain this sensitizer.[1] *Hedera* dermatitis is a contact dermatitis characterized by linear and vesicular eczema on the forearms and hands, usually in the spring time following the pruning of actively growing ivy.[6,7] The stems and roots also contain high concentrations of the main allergen, falcarinol. Contact dermatitis following exposure to *Hedera helix* is uncommon in children.[8]

Older European medical literature suggests that children develop significant toxicity including vomiting, diarrhea, respiratory depression, and coma after ingestion of berries or leaves from *H. helix*. However, most exposures reported to poison control centers are not associated with clinically significant toxicity. The most common symptoms reported to the American Association of Poison Control Centers Toxic Exposure Surveillance System after undocumented exposure to *Hedera helix* included vomiting, cough, and oral irritation.[9] There were no reports of serious systemic complaints. Children exposed to *Hedera* species usually require only observation, and decontamination measures are unnecessary.

Chapter 151

LANTANA
(*Lantana camara* L.)

BOTANICAL DESCRIPTION

Varieties of *Lantana* species (e.g., *L. canescens* Kunth, *L. involucrata* L., *L. montevidensis* (Spreng.) Briq., *L. trifolia* L.) inhabit areas throughout the world, but *L. camara* is probably the most widespread and toxic to grazing animals (cattle, sheep, goats, buffalo).[1]

Common Name: Lantana, Red or Yellow Sage, Wild Saga, Bunchberry, West Indian Lantana

Scientific Name: *Lantana camara* L. (*Lantana aculeata* L.)

Botanical Family: Verbenaceae (vervain)

Physical Description: This sprawling, perennial shrub has simple, serrated leaves and heads of multicolored red, white, yellow, pink, and violet flowers. Flowering starts in April/May, and the fruiting continues until November with the development of green-blue to dark blue berries.[2]

Distribution and Ecology: Lantana is a hardy shrub in subtropical, tropical, and temperate climates at elevations up to about 1,500 ft (~450 m) elevation. This plant occurs in parts of California, southern United States, tropical Central and South America, West Indies, Australia, New Zealand, South Africa, East Indies, and India. In many warm climates, this plant became naturalized weed, particularly near fences and water.

EXPOSURE

Hepatotoxicity and photosensitization following the ingestion of lantana by grazing animals is common, but human poisoning is rare.[3] Medicinal uses of lantana include the treatment of gastrointestinal diseases (antispasmodic, carminative), fever, malaria, and infection.[4,5]

PRINCIPAL TOXINS

Physiochemical Properties

Lantana contains a number of pentacyclic triterpenoid compounds that probably produce hepatotoxicity in animal studies, particularly lantadene A and lantadene C (dihydrolantadene A).[6,7] The major triterpenoid compounds in *L. camara* are lantadene A (22-β-angeloxy-3-oxoolean-12-en-28-oic acid), lantadene B (22-β-dimethylacryloyloxy-3-oxoolean-12-en-28-oic acid), lantadene C (dihydrolantadene A) lantadene D, reduced lantadene A and B, and 22-β-hydroxyoleanonic acid.[8] Lantadene A (rehmannic acid, CAS RN:467-81-2) is the most abundant triterpenoid compound.[9] Figure 151.1 displays the chemical structure of lantadene A. Lantadene B is structurally similar to lantadene A, but lantadene B is not apparently pharmacologically active.[10]

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

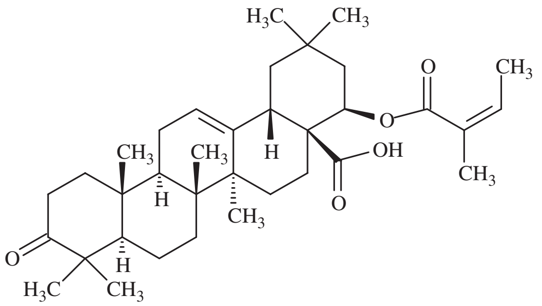

FIGURE 151.1. Chemical structure of lantadene A.

Poisonous Parts

Lantadene A content varies between plant parts and season with the lantadene content increasing with maturity of the leaves.[11] Total lantadene content varied from 0.2% in spring to 1.4%–1.7% in late summer and early fall. In a study of *L. camara* in July and August, the flowers, fruits, and shoots contained no detectable amounts of lantadene A, whereas the plant leaves contained 0.6% by dry weight lantadene A.[12]

Mechanism of Toxicity

The exact mechanism of toxicity is unknown. Lantana poisoning in animals causes widespread changes in mitochondrial, microsomal, and membrane enzymes resulting in cholestasis, hepatotoxicity, and photosensitization.[13]

DOSE RESPONSE

Lantana consumption by grazing animals causes widespread livestock loss in South Africa, Australia, India, Mexico, and the United States. In children, the ingestion of green, but not ripe, berries has been associated with serious toxicity including a fatality.[14]

TOXICOKINETICS

There are few data on the toxicokinetics of lantadene compounds in humans.

CLINICAL RESPONSE

Animals

In animals grazing on lantana, an acute cholestatic jaundice develops characterized by weakness, vomiting, anorexia, jaundice, conjunctivitis, blindness, mucosal ulcerations, and photosensitization. Death occurs within 7–10 days. The chronic form is associated with dehydration and renal failure.[15,16]

Humans

There are few data on the toxicity of lantana in humans despite the abundance of this plant. In a series of 17 children presenting to a Florida poison control center after ingesting an unknown quantity of lantana berries, four children became symptomatic with nausea, vomiting, lethargy, depressed respiration, decreased deep tendon reflexes, and dilated pupils.[14] Symptoms begin within 2–3 hours after ingesting *green* berries, and one patient died. The postmortem examination demonstrated marked congestion of the lungs and green *Lantana* berries in the small intestine. In this series, 13 of 17 patients ingesting *Lantana* berry ingestions remained asymptomatic.

DIAGNOTIC TESTING

Methods to quantitate lantadene A and related compounds include high performance liquid chromatography (HPLC).[8]

TREATMENT

The management of patients with exposure to *Lantana* species is supportive. Decontamination measures are usually unnecessary. The administration of activated charcoal to alert children, who ingest more than several *Lantana* berries less than 1 hour prior to presentation, is a therapeutic option, but there are no clinical data to confirm the clinical efficacy of these measures on outcome of *Lantana* ingestions. Children should be observed closely for 4–6 hours after ingestion, and symptomatic children should be evaluated by a physician. Most symptoms resolve within 6–8 hours.

Chapter 152

RHODODENDRONS and GRAYANOTOXINS

HISTORY

The toxicity of honey collected from bees frequenting rhododendron leaves has been recognized since ancient times. The ancient Greek soldier, Xenophon, reported in the *Anabasis* the poisoning of his troops by the honey of *Rhododendron ponticum* flowers. While disabled after honey ingestion, Pompey's army was massacred by King Pontius's army in northern Asia Minor.[1] The disease was characterized by nausea, vomiting, lethargy, weakness, and paresthesias that lasted several days.

BOTANICAL DESCRIPTION

Azaleas and rhododendrons belong to the same genus, *Rhododendron*, which contains over 800 species. Toxic *Rhododendron* species in grazing animals include the following plants: *Kalmia angustifolia* L. (lambkill, sheep-kill, dwarf laurel), *Kalmia latifolia* L. (sheepkill laurel, mountain laurel, ivy bush, mountain ivy),[2,3] *Kalmia microphylla* (Hook.) Heller (pale laurel, alpine bog laurel), *Ledum glandulosum* Nutt. (Western labrador tea), *Ledum columbianum* Piper (Pacific or coast Labrador tea), *Leucothoe davisiae* Torr. ex Gray (Sierra laurel, black laurel), *Menziesia ferruginea* Sm. (mock azalea, rustyleaf), *Pieris japonica* (Thunb.) D. Don ex G. Don (Japanese pieris), *Rhododendron albiflorum* Hook. (white-flowered rhododendron), *Rhododendron occidentale* (Torr. & Gray ex Torr.) Gray (Western azalea), *Rhododendron macrophyllum* D. Don ex G. Don (California rosebay), and *Rhododendron maximum* L. (rhododendron, great laurel, rose bay).[4] The latter two *Rhododendron* species are the state flowers of Washington and West Virginia, respectively. There are few data to indicate which of these *Rhododendron* species causes human toxicity.

Common Name: Rhododendron, Azalea, Rosebay

Scientific Name: *Rhododendron* spp.

Botanical Family: Ericaceae (Heath)

Physical Description: These evergreen, semi-evergreen, and deciduous shrubs have flowers of various colors. Commercial hybridization produces new rhododendron plants that are difficult to identify.

Distribution and Ecology: *Rhododendron* species grow in the mountainous areas of Turkey near the eastern Black Sea, Japan, Brazil, Nepal, and parts of North America and Europe.

EXPOSURE

Rhododendron dauricum L. and *Rhododendron latoucheae* Franchet are medicinal herbs used in China as expectorants for chronic tracheitis.[5,6] In Turkey, honey from rhododendron plants is a traditional treatment for diabetes mellitus, bowel disorders, hypertension, abdominal pain, and sexual dysfunction.[7]

PRINCIPAL TOXINS

Physiochemical Properties

Grayanotoxins are unique tetracyclic diterpenes that occur only in the Ericaceae family. There are over 30

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

diterpenic polyalcohols in this family that possess an tetracyclic A-*nor*-B-*homo*-*ent*-kaurane skeleton including the most prominent toxins, grayanotoxin I (andromedotoxin, acetylandromedol, rhodotoxin) and grayanotoxin III (andromedol). Other structurally similar Ericaceae compounds include asebotoxins, rhodojaponins, and lyoniatoxins (lyoniols).[8] Volatile constituents of solvent extracts of 15 different organs (leaves, flowers, fruits) of five *Rhododendron* species grown in Turkey demonstrated 200 volatile compounds as analyzed by gas chromatography/mass spectrometry (GC/MS).[9] About 34 volatile compounds were identified in an organic solvent extract of *R. luteum* (L.) Sweet. (Honeysuckle azalea) flowers with the major compounds being benzyl alcohol (16.6%), limonene (14.6%), and *p*-cymene (8.4%).

Poisonous Parts

Grayanotoxins are present in nectar, flowers, stems, and the leaves of plants in the family Ericaceae. The grayanotoxin I (andromedotoxin) content of a fresh *Rhododendron ponticum* L. leaf is about 0.024%.[10] Grayanotoxins in honey produced by bees that feed on *Rhododendron* species are responsible for toxicity associated with mad honey poisoning, particularly in Turkey.[11]

Mechanism of Toxicity

Grayanotoxin, batrachotoxin, veratridine, and aconitine have similar structural groups that modulate the sodium gate.[12] These toxins bind the sodium channel in the open state, modify the sodium channel to prevent activation, and shift the sodium channel in the direction of hyperpolarization.[13] In animal models, the intravenous administration of grayanotoxins produces dose-dependent bradycardia, hypotension, respiratory depression, conduction delay, ventricular tachycardia and fibrillation, emesis, and central nervous system depression similar to the effects of veratrum poisoning.[14] These animal studies suggest that grayanotoxin may bind to the M_2-muscarinic receptors.[15] Grayanotoxin I is a potent parenteral hypotensive agent in experimental animal studies.[16] Animal studies suggest that the bradycardia association with grayanotoxin results from peripheral vagal stimulation.[17]

DOSE RESPONSE

Animals

In animal studies, grayanotoxins I, II, and VI are the most toxic grayanotoxin compounds following parenteral administration.[18] There is substantial variation in toxicity depending on the route of exposure. The minimum *parenteral* dose necessary to produce hypotension and bradycardia was 1–2 µg/kg, whereas more than 35 µg/kg was required to induce ventricular dysrhythmias. In contrast, the LD_{50} for grayanotoxin I in mice *per os* was 5.1 mg/kg.[18] Prediction of toxicity to humans based on a history of ingestion is limited by the lack of knowledge of diterpenoid pharmacokinetics and human toxicity data.

Humans

Although rhododendron plants cause significant animal toxicity, exposure of humans to these plants do not usually result in serious toxicity except under unusual circumstances (e.g., ingestion of teas and extracts).[19] The ingestion of 75 mL of Turkish honey containing grayanotoxin produced coma, convulsions, bradycardia, and atrioventricular block in a 17-year-old woman.[20] Not all *Rhododendron* species produce toxic nectar, and predicting which hybrids will secrete toxic nectar is difficult.[21] Hypotension, bradycardia and syncope were associated with the ingestion 10–15 g contaminated honey.[22] There are few data on the dose-response relationship between parts of the rhododendron and toxicity.

TOXICOKINETICS

There are few data on the toxicokinetics of grayanotoxins in humans. The elimination of grayanotoxin is relatively rapid with symptoms usually resolving within 24 hours.[8,15]

CLINICAL RESPONSE

Most casual exposures to rhododendron plants do not produce toxicity in humans. In a series of 152 exposures to azalea plants reported to a regional poison control center, only one patient became symptomatic (protracted vomiting, transient hypertension).[23] Consumption of an unknown amount of rhododendron leaves and flowers by a 4-year-old child resulted in vomiting and abdominal pain about 2½ hours after ingestion, followed by apnea and perioral cyanosis for 30 seconds.[24] Subsequent cardiac monitoring revealed a sinus bradycardia. No neuromuscular weakness, ventricular dysrhythmias, or hypotension occurred. The child recovered without sequelae. Toxic effects associated with the ingestion of mad honey derived from *Rhododendron* species include nausea, vomiting, salivation, blurred vision, dyspnea, generalized weakness, circumoral paresthesias, syncope, bradycardia, hypotension, seizures, supraven-

tricular tachycardia, and conduction disturbances including complete heart block responsive to atropine.[11,25,26] Cardiac abnormalities in serious poisonings generally resolve within 1 to 2 days.[15,27] However, symptoms from minor intoxications usually resolve within 2 to 6 hours.[28] Fatalities are rare following the ingestion of grayanotoxin-contaminated honey.

DIAGNOSTIC TESTING

Analytical methods for the detection of grayanotoxin I include thin-layer chromatography,[10] GS/MS,[29] and liquid chromatography/mass spectrometry.[30] The low vapor pressure and heat instability of grayanotoxins necessitates derivatization prior to analysis when using gas chromatography.

TREATMENT

Most children who sample rhododendron plants remain asymptomatic. Decontamination measures are usually unnecessary. The administration of activated charcoal to alert children, who ingest more than a whole leaf or flower less than 1 hour prior to presentation, is a therapeutic option; however, there are no clinical data to confirm the clinical efficacy of activated charcoal on outcome of *Rhododendron* ingestions. Symptomatic patients should be observed by a physician for 4–6 hours with monitoring of cardiac rhythm and vital signs. Hypotension usually responds to fluid administration.[22] The administration of atropine for bradycardia is appropriate if the dysrhythmia is associated with a reduction in cardiac output.[15,26]

Chapter 153

SNOWBERRY
[*Symphoricarpos albus* (L.) Blake]

BOTANICAL DESCRIPTION

Common Name: Snowberry, Common Snowberry

Scientific Name: *Symphoricarpos albus* (L.) Blake (*Symphoricarpos racemosus*)

Botanical Family: Caprifoliaceae (honeysuckle)

Physical Description: Snowberry is a low deciduous shrub that reaches about 3–6 ft (~1–2 m) in height and produces waxy, white berries in late summer and fall. These berries usually remain on the shrub until the leaves drop in the winter.

Distribution and Ecology: This deciduous shrub grows in woodlands and open areas of the northern United States and Canada. In Europe, this plant species is cultivated as an ornamental hedge.

EXPOSURE

The bark of *S. albus* is used by Pacific Northwest Indians as a compress for pruritus.[1]

PRINCIPAL TOXINS

The alkaloid chelidonine occurs in extracts from *S. albus*, but this alkaloid does not cause the toxicity associated with snowberry ingestion.[2] Additional compounds contained in *S. albus* include secologanin, aesculin, sitosterol saponins, tannins, terpenes, triglycerides, sugars, coumarins, and flavonoids. However, the compounds associated with toxicity remain unknown.

DOSE RESPONSE

There are inadequate data to determine the dose response of snowberry and related parts following consumption by humans.

TOXICOKINETICS

The toxic constituents in snowberry have not been identified.

CLINICAL RESPONSE

The ingestion of snowberries by children does not usually produce symptoms. Occasionally, nausea and vomiting occur after the ingestion of snowberries.[3] Although the older medical literature associates gastrointestinal distress, delirium, and altered mental status with the consumption of large amounts of snowberries,[4] there are no well-documented serious complications or fatalities in the modern medical literature. The ingestion of snowberries by a 4-year-old girl was associated with somnolence, mydriasis, difficulty urinating, and coma.[5] The patient was treated supportively with an intravenous infusion, and she recovered without sequelae within 24 hours.

DIAGNOSTIC TESTING

There are few data on the detection of toxic constituents in snowberry.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

TREATMENT

Treatment is supportive. Decontamination measures are unnecessary.

Chapter 154

SQUIRTING CUCUMBER
[*Ecballium elaterium* (L.) A. Richard]

HISTORY

The use of the juice from the squirting cucumber for the treatment of chronic sinusitis dates back to the writings of Dioscorides (20–79 AD) in the *Materia Medica*. The Greek philosopher Theophrastus mentioned this plant in his history of plants.

BOTANICAL DESCRIPTION

Common Name: Squirting Cucumber, Jumping Cucumber, Donkey's Green

Scientific Name: *Ecballium elaterium* (L.) A. Richard

Botanical Family: Cucurbitaceae (citrouilles, gourdes, gourds, squashes)

Physical Description: This hairy vine has palmately lobed, bristly leaves. The funnel-shaped, yellow flowers produce hairy, blue-green seed pods, which eject dark seeds and juice after maturity in response to light pressure. Both male and female flowers appear on the same plant.

Distribution and Ecology: This perennial vine grows in hot, dry areas on disturbed ground and roadsides in the Mediterranean region and Micronesia. It is cultivated in central Europe and England.

EXPOSURE

The diluted (i.e., up to 30:1) aqueous extract from the fruit of *Ecballium elaterium* is a traditional anti-inflammatory and analgesic for chronic sinusitis by nasal aspiration.[1,2] Other traditional uses include the treatment of fever, cancer, liver cirrhosis, constipation, hypertension, dropsy, and rheumatic diseases.[3]

PRINCIPAL TOXINS

Physiochemical Properties

Cucurbitacin compounds (CAS RN: 60137-06-6, $C_{30}H_{42}O_6$) are a group of colorless, bitter, highly oxygenated triterpenoid substances characterized by the tetracyclic cucurbitane nucleus [19-(10→9β)-abeo-10α-lanost-5-ene].[4,5] These compounds are present in several other plant species including *Citrullus colocynthis* (L.) Schrad. (colocynth, bitter apple). Figure 154.1 displays the chemical structure of cucurbitacin B (RN: 6199-67-3, $C_{32}H_{46}O_8$), which is the principal anti-inflammatory compound in the squirting cucumber.[6,7]

Poisonous Parts

All parts of the squirting cucumber are toxic, particularly the ovoid green fruits. The juice of the fruit produces dermal erythema, inflammation, and edema.

Mechanism of Toxicity

Although cucurbitacin B has been identified as the active anti-inflammatory compound in the squirting cucumber, the ingredient or ingredients causing severe irritation to mucus membranes are unknown. The mechanism of toxicity (i.e., direct toxic effect, hypersensitivity response) is also not well defined, but the clinical

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

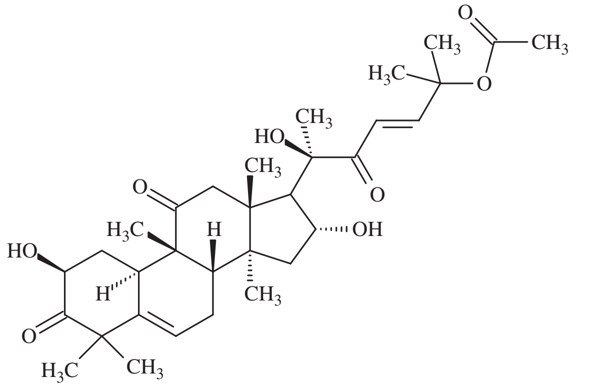

FIGURE 154.1. Chemical structure of cucurbitacin B.

effects often do not respond to antihistamines or epinephrine.[8]

DOSE RESPONSE

Cases of severe mucus membrane swelling typically involve the use of undiluted juice from the squirting cucumber. Traditionally, the juice is diluted 3–30 times before nasal aspiration for the treatment of chronic sinusitis.

TOXICOKINETICS

The toxic ingredient in squirting cucumber has not been identified, and there are no human data on the toxicokinetics of constituents (e.g., cucurbitacins) in the juice of squirting cucumber.

CLINICAL RESPONSE

The undiluted juice from the squirting cucumber causes marked inflammation of mucous membranes and localized edema following ingestion, instillation in the nasal cavities, or ocular exposure. Most patients with adverse responses to this juice have multiple allergies, and previously may have used the juice without complications.[9] Symptoms begin within 10–20 minutes of exposure and persist for 24–48 hours.[10] Progression of the inflammation can cause conjunctival irritation, corneal edema and erosions, sore throat, dysphagia, drooling, dyspnea, or respiratory distress secondary to upper airway edema (soft palate, uvula).[11] Obstruction of the upper airway is a potentially fatal complication of the nasal installation of undiluted juice from the squirting cucumber.[12] A case report associated the development of progressive facial and pharyngeal edema, fever, respiratory distress, renal insufficiency, and cardiac failure over 5 days with the use of four to five nasal aspirations of diluted juice from the squirting cucumber.[13] The patient died on the sixth day after exposure to the juice, but the role of the exposure to this juice is unclear because of the lack of medical details (blood cultures, oxygen saturations, imaging studies) and the failure to exclude other causes (sepsis, cardiovascular/renal disease).

DIAGNOSTIC TESTING

Laboratory measurements of hepatorenal function and serum electrolytes typically are normal after exposure to the undiluted juice of the squirting cucumber with the exception of laboratory evidence of airway obstruction.[14]

TREATMENT

Patients should be evaluated carefully for the presence of upper airway obstruction (stridor, drooling, dyspnea, tachypnea, reduced oxygen saturation). The respiratory effects associated with exposure to the squirting cucumber usually occur within minutes to a few hours after exposure. Although the exact mechanism of toxicity is unclear, treatment of the severe upper airway edema following exposure to undiluted juice from the squirting cucumber typically involves medicines to treat anaphylactic responses including the use of epinephrine (0.3–0.5 mL 1:1000 solution SQ), intravenous H_1- (diphenhydramine) and H_2- (ranitidine or cimetidine) histamine blockers, and intravenous methylprednisolone. However, the swelling may not respond to these agents, and prophylactic intubation may be necessary in severe cases. Ocular exposure to the undiluted juice should be treated with copious irrigation followed by slit lamp examination to detect corneal erosions.

Chapter 155

WISTERIA

BOTANICAL DESCRIPTION

Japanese wisteria [*Wisteria floribunda* (Willd.) DC.] is similar to Chinese wisteria with the exception that the white-barked Japanese wisteria vines twine clockwise around the host plant and Chinese wisteria twines counter-clockwise. Additionally, the Chinese species has 7–13 compound leaves compared with 13–19 for the Japanese species. The American wisteria [*Wisteria frutescens* (L.) Poir.], which is native to the southeastern United States, flowers June through August and produces a nonhairy seed pod 2–4 in. (~5–10 cm) long.

Common Name: Wisteria, Chinese Wisteria, Kidney Bean Tree

Scientific Name: *Wisteria sinensis* (Sims) DC.

Botanical Family: Fabaceae (pea)

Physical Description: This climbing vine has sweet-scented, lavender, pea-like flowers that produce pods 12.5–15 cm (~5–6 in.) in length. The flat, brown seeds are slightly oblong, and velvety seed pods forcefully eject the seeds up to 2–3 m (~7–10 ft) when ripe in late summer and early autumn.

EXPOSURE

Wisteria is a native plant of China, Japan, and the southeastern United States. This plant is grown as an ornamental vine covering balconies, walls, and trellises in temperate climates of Europe and the United States. There are no well-recognized medicinal uses for wisteria. In Japan, the gall from *Wisteria brachybotrys* Siebold & Zucc. is a folk remedy for gastric cancer.[1]

PRINCIPAL TOXINS

Tendrils are slender, coiled extension of a modified leaf or stem that functions as a means of support for climbing vines. Some species of wisteria (*Wisteria sinensis*, Chinese wisteria) have pointed, transparent hairs on their tendrils that produce an irritant contact dermatitis following direct exposure of the skin to these tendrils.[2] *Wisteria* species contain a variety of triterpenoid saponins (wisteria saponins) and isoflavonoids.[3] There are few data on toxic constituents in wisteria seeds or other parts of the plant.

DOSE RESPONSE

The ingestion of 10 raw seeds by a 50-year-old woman produced headache, vomiting, vertigo, and syncope.[4] The patient was released from the emergency department after symptomatic treatment and administration of activated charcoal. Similar gastrointestinal symptoms and drowsiness developed in two young teenagers after the ingestion of at least 5–6 seeds from a wisteria plant.[5]

TOXICOKINETICS

The toxic constituents in *Wisteria* species have not been identified.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

CLINICAL RESPONSE

The primary target organ after ingestion of *Wisteria* seeds is the gastrointestinal tract manifest by nausea, vomiting, and abdominal pain.[5] The vomitus can become bloody or bile-stained. Diarrhea is less common than other gastrointestinal symptoms. Symptoms develop with several hours of ingestion, and these symptoms usually resolve within 6–24 hours.[6]

DIAGNOSTIC TESTING

The ingestion of wisteria seeds has been associated with leucocytosis and some abnormalities of the prothrombin times, but no clinically significant abnormalities of serum hepatic aminotransferases or serum creatinine.[5]

TREATMENT

Treatment is supportive, primarily involving correcting any fluid or electrolyte imbalance resulting from the gastrointestinal irritant properties of *Wisteria* seeds. Decontamination measures are unnecessary because of the presence of profuse vomiting. Patients can be discharged from the emergency department after control of the vomiting and replacement of fluid and/or electrolyte deficits.

VI Trees

Chapter 156

BLACK LOCUST
(*Robinia pseudoacacia* L.)

BOTANICAL DESCRIPTION

Common Name: Black Locust, False Acacia

Scientific Name: *Robinia pseudoacacia* L.

Botanical Family: Fabaceae (pea)

Physical Description: This large, fast-growing tree that grows to 75 ft (~23 m) in height with alternate, compound leaves and unbranched spines resembling rose thorns. Showy white flowers mature into straight, flat pods. The fragrant, drooping, pea-like flowers occur in clusters that appear in May and June. The smooth fruit pods (legumes) contain four to eight seeds and reach about 10 cm (~4 in.) in length.

Distribution and Ecology: This native tree of the southeastern United States prefers dry woodlands and occurs throughout the United States, particularly in the eastern and central United States and on the Pacific Coast from Washington to central California. The black locust is widely cultivated as a source of nectar, and this tree has become naturalized in forests, prairies, and savannas in temperate climates of Europe and Asia, as well as North America.

EXPOSURE

This large tree is a popular ornamental plant along streets and in parks. The black locust is also a source of honey, such as the French acacia monofloral honey. This durable wood is a source of firewood, fence posts, and wooden crafts.

PRINCIPAL TOXINS

The toxic constituents in *R. pseudoacacia* are not well defined, but at least some of the adverse effects probably result from toxic glycoproteins (lectins). Compounds isolated from this species include lectins (robin, robitin, phasin), robinlin (C_{11}-homomonoterpene)[1] and triterpene glycosides (robiniosides A-J, sophoraflavoside II).[2,3] Analysis of an ethanolic extract of *R. pseudoacacia* indicated that the major constituent was robinetin (CAS RN:490-31-3, $C_{15}H_{10}O_7$) with smaller amounts of myricetin and quercetin as measured by nuclear magnetic resonance and mass spectroscopy.[4] The toxic constituents probably contain heat-labile proteins. In animal models, extracts of bark from *R. pseudoacacia* produce gastrointestinal (GI) distress and lethargy.[5] *In vitro* studies in rats indicate that water-soluble extracts of *R. pseudoacacia* increase the frequency of smooth muscle contraction in uterine tissue, but not in intestinal or vascular tissues.[6] Several high-molecular-weight lectins are nonspecific agglutinators of the human erythrocyte.[7] Lectins from the black locust stimulate *in vitro* blast transformation by binding to specific receptors on the cell surface and activating T-cells.[8] Studies of patients with seasonal allergies suggest that substantial cross-reactivity occurs between *R. pseudoacacia* pollen and common testing pan allergens; consequently, *R. pseudoacacia* pollen may not produce potent allergic responses.[9]

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

DOSE RESPONSE

There are inadequate data to determine the dose-response relationship between ingestion of plant parts of black locust and clinical effects. These effects are primarily gastrointestinal.

TOXICOKINETICS

The GI toxin in black locust has not been well defined.

CLINICAL RESPONSE

Reports of toxicity from exposure to the black locust are rare in the modern medical literature. GI symptoms and lethargy are the most common clinical features of *Robinia pseudoacacia* intoxication.[10] In an orphanage where 32 children ate bark from the black locust, the clinical presentation included vomiting, mild hematemesis, pallor, peripheral cyanosis, dilated pupils, and stupor.[11] This case series did not report any laboratory values or vital signs. There were no fatalities. In another case series of seven boys, the chewing of bark from the black locust tree was associated with the development of nausea, vomiting, diarrhea, abdominal pain, dry throat, mydriasis, headache, dizziness, and muscle weakness in a group of children.[12] There were no sequelae. A case report during modern times associated the development of vomiting with the chewing of bark from the black locust.[13] The vomiting began about $2^1/_2$ hours after chewing the bark, and the vomiting responded to anti-emetic medication. There were no other symptoms.

DIAGNOSTIC TESTING

Abnormalities associated with ingestion of plant parts from *R. pseudoacacia* include hematuria, mild elevation of serum hepatic aminotransferases, and electrolyte imbalance.

TREATMENT

There are limited data on the treatment of intoxication from *R. pseudoacacia,* and management is supportive. Substantial ingestions of plant parts from the black locust are usually associated with vomiting and therefore GI decontamination is unnecessary. Casual contacts require no treatment. The main aspect of supportive care is the maintenance of fluid and electrolyte balance. Asymptomatic patients may be discharged after 3–4 hours after ingestion.

Chapter 157

BUCKEYE
(*Aesculus* Species)

BOTANICAL DESCRIPTION

The genus *Aesculus* includes *Aesculus hippocastanum* L. (horse chestnut), *Aesculus glabra* Willd. (Ohio buckeye), and *Aesculus flava* Ait. (yellow buckeye, *Aesculus octandra* Marsh.).

Common Name: Buckeye, Horse Chestnut

Scientific Name: *Aesculus* spp.

Botanical Family: Hippocastanaceae (buckeye)

Physical Description: These deciduous trees and shrubs contain opposite leaves palmately divided into five to seven leaflets (toothed margins) on a long stalk. Yellow, red, and white flowers produce a characteristic three-compartment fruit surrounded by a leathery husk that encloses brown, round, glossy seeds.

Distribution and Ecology: Seven native species appear throughout the United States. *Aesculus hippocastanum* L. (horse chestnut) is widely planted as an ornamental shade tree in the United States, Europe, and the United Kingdom. Other species include *Aesculus californica* (Spach) Nutt. (California buckeye), *Aesculus sylvatica* Bartr. (painted buckeye), *Aesculus parviflora* Walt. (bottlebrush buckeye), *Aesculus pavia* L. (red buckeye), *Aesculus glabra* Willd. (Ohio buckeye), and *Aesculus flava* Ait. (yellow buckeye). The horse chestnut (*A. hippocastanum*) is indigenous to southeastern Europe, and the horse chestnut is also present in Iran, Northern India, and Asia Minor.

EXPOSURE

Traditional herbal uses for horse chestnut are as an antipyretic and a hemorrhoidal cream. Randomized clinical trials suggest that the use of horse chestnut seed extract is an efficacious, short-term treatment for chronic venous insufficiency based on reduction in leg size and leg pain, when compared with placebo.[1] However, the US Food and Drug Administration (FDA) has not approved the use of horse chestnut seed extract containing aescin for the treatment of chronic venous insufficiency; compression therapy (e.g., pumps, bandaging, and/or graded compression stockings) remains the primary treatment for this disease.[2] Horse chestnut contains saponins that have been tested in experimental animals for cholesterol lowering effects.[3]

PRINCIPAL TOXINS

This genus contains the bioactive saponins, such as escins (Ia, Ib, IIa, IIb, IIIa, IIIb, IV, V, VI) and isoescins (I, II, V), aesculin, bioflavonoids (quercetin, kaempferol), coumarin compounds (esculin), and antioxidants (proanthocyanidin A_2).[4,5] The bioactive saponins (escin) are derived from the seed extracts of the horse chestnut. Escin (aescin, CAS RN:6805-41-0) is a complex mixture of chemically related compounds called triterpenoid saponins. β-escin (β-aescin, CAS RN:11072-93-8) is a fraction of escin that contains about 30 constituents, and this relatively nontoxic extract is administered as a treatment for chronic venous insufficiency.[6] In experimental animals, the administration of extracts from

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Aesculus produces muscle weakness, twitching, lethargy, ataxia, paralysis, respiratory depression, coma, and death.[7]

DOSE RESPONSE

The recommended dose of β-escin for the treatment of varicose veins is 100 mg as a sustain-release preparation, which corresponds to about 500–600 mg of the extract.[8]

TOXICOKINETICS

The bioavailability of β-escin is relatively high with peak plasma concentrations occurring about 2–3 hours after dosing.[9] However, there are large inter- and intra-individual variations in the absorption of β-escin following the administration of single doses to volunteers.[10] Animal studies suggest that the elimination of escin is relatively slow with only 1–2.5% of the dose excreted in the urine during the first 24 hours after ingestion.[11] Unchanged escin accounts for about 50% of the renal elimination with various metabolites accounting for the remainder including the main metabolite, escinol.

CLINICAL RESPONSE

Most ingestions of horse chestnut by children produce no significant symptoms other than mild gastrointestinal distress. In grazing animals, the ingestion of parts of plants from the *Aesculus* genus produces ataxia, gait disturbances, muscle stiffness, and seizures.[12] The pollen of *Aesculus hippocastanum* (horse chestnut) is highly allergenic and sensitization to the pollen may cause allergic rhinitis as well as contact dermatitis and anaphylactic shock.[13,14] Rare case reports associate occupational exposure to escin with the development of occupational asthma.[15] Clinical trials using horse chestnut seed extract suggest that the doses associated with these trials produce minimal side effects.[16]

DIAGNOSTIC TESTING

A thin layer chromatographic (TLC) method is available to determine the total escin (saponin) content of herbal products containing horse chestnut that lacks the interference associated with colorimetric methods.[17] The use of high pressure liquid chromatography (HPLC) method with UV detection is limited by the poor UV absorbance of triterpene glycosides.[18] Other analytical methods for the quantitation of saponins (e.g., escins) include accelerated solvent extraction followed by HPLC/diode array detector and positive ion electrospray/time-of-flight/mass spectrometry.[19] Using this method, the limits of detection of escin Ia, escin Ib, isoescin Ia and isoescin Ib ranged from 0.40–0.75 µg/mL. Radioimmunoassay (RIA) methods can detect aescin concentrations in extracts of *Aesculus hippocastanum* in the range of 100 pg.[20] This method does not separate escin from the main metabolite, escinol.

TREATMENT

Treatment is supportive. Decontamination measures are unnecessary.

Chapter 158

CHINABERRY
(*Melia azedarach* L.)

BOTANICAL DESCRIPTION

There are about 5–10 species of the genus *Melia* with the common US species being *Melia azedarach*. This deciduous tree should not be confused with the margosa or neem tree (*Azadirachta indica* Adr. Juss.). Previously this latter tree was named *Melia azedarach*, but now the evergreen neem tree belongs to its own genus.

Common Name: Chinaberry, China Tree, White Cedar, Cape Lilac, Pride-of-India

Scientific Name: *Melia azedarach* L.

Botanical Family: Meliaceae (mahogany)

Physical Description: A rapidly growing, deciduous tree that grows to 50 ft (~15 m) with a stout trunk and finely furrowed, brown-gray bark. The leaves are large, pinnate, and compound. The small, numerous purple flowers produce a round, yellow berry about 1 cm (~0.4 in.) in diameter inside drupes (berry-like seedpods).

Distribution and Ecology: This plant is native to northern Australia, eastern Africa, and southwestern Asia. In warm regions, chinaberry is also a popular ornamental plant. The chinaberry is naturalized in the southeastern United States, California, Hawaii, and other warm climates around the world.

EXPOSURE

The medicinal use of *Melia indica* (neem or margosa oil) is much more common than the use of *Melia azedarach*. Uses of the latter include the treatment of parasitic and bacterial infections, leprosy, skin lesions (eczema), asthma, and fever. Meliatoxins A and B demonstrate some insect repellant properties *in vitro* and *in vivo*.[1,2] The chinaberry tree is an ornamental shade tree.

PRINCIPAL TOXINS

The toxins in *Melia azedarach* are not well defined. The chinaberry fruit contains several tetranortriterpene limonoid compounds, such as meliatoxin A_1 (Figure 158.1), A_2 (Figure 158.2), B_1, and B_2. The latter two compounds are probably isomers of the two former compounds, respectively, that lack an epoxide group. Experimental studies suggest that meliatoxins A_1 and A_2 are the primary toxins, whereas meliatoxins B_1 and B_2 are probably artifacts of the analytical process. Other limonoid compounds present in the seeds, fruit, and bark of this plant include salannin, meldenin, meliacarpinins, and meliantriol.[3,4] In experimental animal studies, the administration of these compounds produced muscle contractions, weakness, ataxia, paresis, abdominal distress, seizures, emaciation, and death.[5,6] The leaves of the chinaberry also contain the tetracyclic diterpenoid compound, grayanotoxin III, which produces salivation, dyspnea, ataxia, hind leg paralysis, and death following intraperitoneal doses to animals.[7] This compound increases sodium permeability in various excitable tissues.[8] The oil extracted from the fruit of *Melia azedarach* contains linoleic and oleic fatty acids along with lesser amounts of palmitic, stearic, and palmitoleic fatty acids. In an analysis of a chloroform extract of green berries from chinaberry, the concentration of mystic

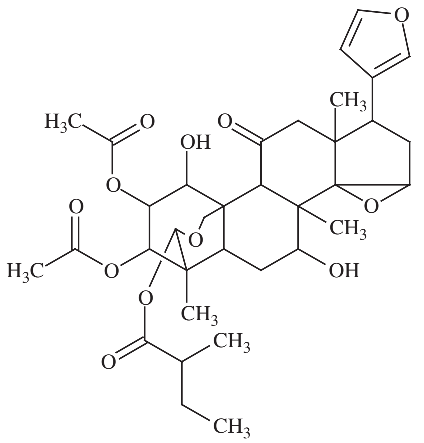

FIGURE 158.1. Meliatoxin A_1 (CAS RN: 87725-70-0).

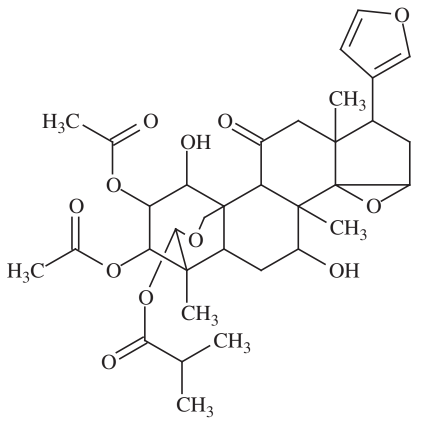

FIGURE 158.2. Meliatoxin A_2 (CAS RN: 87617-82-1).

acid was <0.1%.[9] Although most cases of exposure involve ingestion of the fruits, the bark and flowers also contain meliatoxins. There is considerable variability in toxicity following the consumption of the fruits and foliage of the chinaberry plant, probably as a result of differences in toxin content between location and stage of growth. The yield of meliatoxins in one sample of fruit ranged up to 0.5% by wet weight.[6]

DOSE RESPONSE

The toxicity of the chinaberry varies substantially as a result of several factors including location and the part of the plant. The LD_{50} of pigs administered an ethanol extract of the meliatoxins was 6.4 mg/kg, whereas the LD_{50} following intraperitoneal injection of mice was 16 mg/kg.[6] Animal feeding studies suggest that the lethal dose of chinaberry fruit is approximately 0.5% of body weight.[10]

TOXICOKINETICS

There are inadequate data to determine the toxicokinetics of meliatoxins.

CLINICAL RESPONSE

There are few case reports of toxicity following exposure to the chinaberry despite the reporting of over 1,400 exposures to the data collection system for state poison control centers in the United States.[11] Case reports of the older medical literature associate the development of respiratory insufficiency, cardiac depression, coma, and death with ingestion of fruit[12] and aqueous extracts of the bark[13] from chinaberry. Case reports in the veterinary literature indicate that the ingestion of fruit from the chinaberry causes ataxia, diarrhea, trembling, respiratory distress, bradycardia, and death in grazing animals.[14,15] Pathological examination demonstrated hemorrhagic enteritis and coagulation necrosis in the liver, kidney, and myocardium.

DIAGNOSTIC TESTING

There are few data on the use of analytical methods to detect the presence of meliatoxins in the clinical setting.

TREATMENT

Treatment is supportive.

Chapter 159

GOLDEN CHAIN TREE
(*Laburnum anagyroides* Medikus)

HISTORY

The toxicity of *Laburnum* seeds was recognized during the 19th century.[1] During this period, case reports associated convulsions and death with the ingestion of *Laburnum* seeds, but the validity of this association is unclear because of the lack of adequate data (e.g., postmortem examination) to exclude other causes of death.[2] Studies during the early 1900s indicated that cytisine was the principal toxin in *Laburnum* species.[3] Ing identified the chemical structure of cytisine in 1931.[4] *Laburnum* ingestion was a common occurrence in England during the late 1970s, primarily due to the attraction of children to the beautiful seeds and pods. During this period, the ingestion of parts from the golden chain tree accounted for an estimated 3,000 admissions to hospitals in England and Wales, but serious toxicity was not well documented.[5]

BOTANICAL DESCRIPTION

British species of *Laburnum* include *L. alpinum* (Mill.)Bercht. & J.Presl (Scottish laburnum) and *L. anagyroides.*

Common Name: Golden Chain Tree

Scientific Name: *Laburnum anagyroides* Medikus

Botanical Family: Fabaceae (pea)

Physical Description: This deciduous tree reaches up to 12–30 ft (~4–9 m) and has alternate leaves on a long stalk with three leaflets. The golden, pea-like flowers appear in long drooping clusters during May and June. The green fruit is a long, flattened pod that contains two to seven kidney-shaped seeds.

Distribution and Ecology: This beautiful flowering tree is a native species in southern and central Europe that was introduced in the northern United States and southern Canada as an ornamental tree.

EXPOSURE

In the United States, Native Americans used *Laburnum* seeds as emetics and purgatives during rituals. Uses for alcoholic extracts of *Laburnum* species in traditional European medicine included the treatment of cough, constipation, respiratory depression, neuralgias, headache, asthma, and insomnia. In Europe during World War II, the leaves of *Laburnum anagyroides* were a substitute for tobacco.[6] In Eastern European countries, cytisine is currently an aid for smoking cessation.[7] However, the evidence for the efficacy of cytisine for smoking cessation is inconclusive.[8] Most poisonings occur in children between July and September when the attractive pods and seeds appear.[9]

PRINCIPAL TOXINS

Laburnum contains the toxic quinolizidine alkaloid, cytisine, which is structurally and pharmacologically similar to nicotine and lobeline.[3] The pK_a of cytisine is 7.92. *Laburnum* seeds contain approximately 1%

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

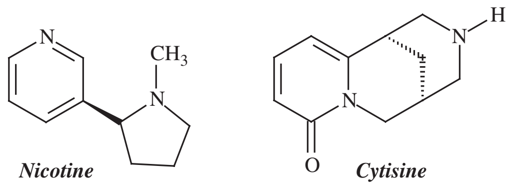

FIGURE 159.1. Chemical structures of cytisine and nicotine.

cytisine by weight; the estimated lethal dose is approximately 0.5 mg/kg.[10] Animal studies indicate that cytisine produces toxic effects similar to nicotine.[11] Figure 159.1 compares the chemical structures of cytisine and nicotine. Cytisine is a nicotine agonist that binds to nicotinic receptors (e.g., $\alpha_4\beta_2$),[12] but the physiological and behavioral effects are complex, and cytisine is probably not active at all nicotine receptor subtypes.[13]

DOSE RESPONSE

In a retrospective review of 49 children exposed to *Laburnum* seeds, the estimated ingestion of 1–10 seeds from *L. anagyroides* was not associated with serious toxicity.[14] Of the 49 children, 34 children remained asymptomatic. There are inadequate data to correlate the ingestion of a specific number of *Laburnum* seeds to toxic effects.

TOXICOKINETICS

In rodent studies, the average bioavailability of cytisine following a dose of 2 mg/kg body weight was 42% with peak blood concentrations occurring about 2 hours after ingestion.[15] About 18% of an oral dose of cytisine was excreted in the urine during the first 24 hours after oral administration. The bile contained approximately 11% of the oral dose during the first 6 hours. In animal studies, the plasma elimination of cytisine is relatively rapid (i.e., 1–3 hours), and limited biotransformation of cytisine occurs.[6]

CLINICAL RESPONSE

Despite frequent exposures to *Laburnum*, particularly in children, there are few data on the clinical features of *Laburnum* (cytisine) intoxication.[16] Symptoms classically associated with cytisine intoxication are similar to mild nicotine toxicity and the onset of symptoms usually begins about $^1/_2$–4 hours after ingestion with nausea, vomiting, abdominal pain, pallor, lightheadedness, drowsiness, and ataxia.[17] Other clinical features include dilated pupils, tachycardia, delirium, paralysis, and respiratory depression. Symptoms resolve within 12–24 hours. An adult paranoid schizophrenic died suddenly at an inpatient facility without any obvious signs or symptoms of toxicity.[10] The death was associated with *Laburnum* toxicity because the autopsy demonstrated 23 *Laburnum* seedpods in the stomach. A comprehensive analysis of postmortem blood for drugs was not done. He had appeared in his usual state of health 10 minutes prior to death, and he did not display symptoms of cytisine toxicity immediately prior to death.

DIAGNOSTIC TESTING

Analytical methods for determination of cytisine in *Laburnum* extracts include reversed-phase high performance liquid chromatography,[18] gas chromatography/mass spectrometry,[19] liquid chromatography/atmospheric pressure chemical ionization/mass spectrometry, and liquid chromatography/electrospray ionization/tandem mass spectrometry.[20]

TREATMENT

Management is supportive. Gut decontamination measures are usually unnecessary, and there are no clinical data to determine the efficacy of activated charcoal following the *Laburnum* ingestion. Most children can be safely discharged after 4–6 hours of observation, providing the child is asymptomatic and the vital signs are normal. There are no antidotes to cytisine toxicity.

Chapter 160

KARAKA NUT
(*Corynocarpus laevigatus* J.R. & G. Forst.)

BOTANICAL DESCRIPTION

Common Name: New Zealand Laurel, Karaka Nut

Scientific Name: *Corynocarpus laevigatus* J.R. & G. Forst.

Botanical Family: Corynocarpaceae (karaka)

Physical Description: This evergreen tree reaches up to 12 m (~40 ft) in height and 8 m (~25 ft) in width. The alternate, obovate leaves have a smooth edge over the entire leaf margin and they reach 12–20 cm (~5–8 in.) in length. The bark is brownish to grayish fibrous tissues with patches of reddish-brown cork cells. The pistil develops into a club-shaped drupe containing one seed.

Distribution and Ecology: This tree is a native species of New Zealand that inhabits moist woodlands and is an invasive species in Hawaii.

EXPOSURE

Karaka nuts are one of the staple vegetables of the Maori people of New Zealand. They prepare this food by baking the fruit in earthen ovens for several hours and then washing the baked fruit for 1–2 days to remove the covering of the fruits.[1] The kernels are then dried in the sun.

PRINCIPAL TOXINS

Karakin is the bitter principle isolated from raw portions of the karaka berry.[2] The primary compound in karakin probably is a 1,4,6-triester compound (1,4,6-tris-(β-nitropropionyl)-D-glucopyranose) structurally similar to endecaphyllin B [1,4,6-tri-*O*-(3-nitropropanoyl)-β-D-glucopyranose] isolated from *Indigofera spicata* Forssk. (trailing indigo, Fabaceae).[3,4] Karakin (CAS RN:1400-11-9) has a molecular formula of $C_{15}H_{21}N_3O_{15}$, and Figure 160.1 displays the chemical structure of this compound. Hydrolysis of the glycoside karakin produces three molecules of β-nitropropionic acid (CAS RN:504-88-1, hiptagenic acid). When administered to laboratory animals, both karakin and β-nitropropionic acid cause convulsions and death.[5] Other nitropropanoyl glucopyranose compounds are present in the seeds of *C. laevigatus* including cibarian [1,6-di-(3-nitropropanoyl)-β-D-glucopyranose], coronarian [2,6-di-(3-nitropropanoyl)-α-D-glucopyranose, CAS RN: 63505-68-0], and 2,3,6-tri-(3-nitropropanoyl)-α-D-glucopyranose.[6]

DOSE RESPONSE

In a study involving experimental animals, the lethal dose of β-nitropropionic acid was about 100 mg/kg with a range of 65-120 mg/kg.[5]

TOXICOKINETICS

There are inadequate data to determine the toxicokinetics of karakin or other potentially toxic principals in the karaka nut.

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

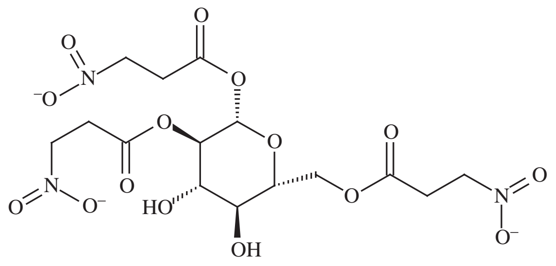

FIGURE 160.1. Chemical structure of karakin.

CLINICAL RESPONSE

Consumption of raw karaka nuts has been associated with the development of convulsions.[1] However, there are few data in humans to determine the toxicity of karaka nuts.

DIAGNOSTIC TESTING

There are few data on analytical data for the determination of karakin concentrations in biological samples.

TREATMENT

Treatment is supportive. Although the older medical literature suggests the potential of seizures following ingestion of karaka nuts, there are inadequate clinical data to guide management. Decontamination measures are unnecessary.

Chapter 161

OAKS
(*Quercus* Species)

BOTANICAL DESCRIPTION

Oak species involved in poisonings of grazing animals include the following: United States, *Q. havardii* Rydb. (Harvard oak), *Q. gambelii* Nutt. (Gambel oak); Europe, *Q. robur* L. (English oak), *Q. sinuata* Walter (bastard oak); Israel, *Q. coccifera* L. (Palestine oak); and Himalayas, *Q. incana* Bartram (bluejack oak).[1]

Common Name: Oaks, Live Oaks (evergreens)

Scientific Name: *Quercus* speciesThere are over 200 species of oaks with about 60 species of evergreen oaks in the United States and Canada.

Botanical Family: Fagaceae (beech)

Physical Description: The *Quercus* species range from bushes to trees and are characterized by their fruit, called the acorn. Small, yellowish-green flowers (catkins) typically produce a single seed that matures slowly. This fruit has a detachable cap covering a hard oval body.

Distribution and Ecology: This genus contains both evergreen and deciduous species native to the northern hemisphere. Oaks are widely distributed from cold latitudes to tropical areas of North America, South America, Europe, and Asia.

EXPOSURE

Ethanolic extracts of *Quercus* species have been used in Jordanian folk medicine for the treatment of digestive disorders, including ulcers.[2] Tannic acid was introduced as a cleansing agent in barium enemas for the delineation of mucosal lesions.[3] The origin of commercial tannic acid used in barium enemas in the middle 1900s was Turkish nutgalls gathered from young twigs of *Quercus infectoria* Oliver (aleppo oak).[4] The use of tannic acid continued into the 1960s, when case reports and animal studies indicated that high doses of tannic acid produce coagulative necrosis of the colon and hepatotoxicity.

PRINCIPAL TOXINS

Physiochemical Properties

The primary toxic agents in acorns are polyhydroxyphenolic compounds, which are commonly called tannins. This complex mixture consists of polyhydroxyphenolic compounds that vary in molecular weight between 500 and 3,000 Da. Tannins include hydrolyzable tannins (e.g., gallotannins, ellagitannins) and condensed or nonhydrolyzable tannins (proanthocyanidins).[5] The most important toxins in tannins include tannic acid, pyrogallol, and gallic acid.[6] The extraction of powdered galls with ether, alcohol, and water produces a complex mixture of substances including about 50–70% tannic acid. Hydrolysis of commercial tannic acid forms primarily glucose and gallic acid. Tannic acids oxidize easily in air or light to create dark substances.

Poisonous Parts

The concentration of total phenolics in acorns varies between different species of oaks. The concentrations of these chemicals are higher in green acorns than in

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

mature ones.[7] Mature acorns are edible after processing removes the tannins. For example, the mean concentration of total phenolics by weight in acorns of *Q. velutina* Lam. (black oak) was 4.51% (range: 3.29–6.13%) compared with 1.09% (range: 0.41–2.54%) for acorns from *Q. alba* L. (white oak).[8] Mature oak leaves contain a small amount of tannins, and the consumption of mature oak leaves by grazing animals does not usually produce toxicity.[9]

DOSE RESPONSE

Animals

Rodent studies indicate that enemas containing concentrations of tannic acid >2% cause edema and inflammation of the colon as well as coagulative necrosis and hemorrhage at concentrations of 16%.[10]

Humans

Several case reports associated the use of tannic acid with fatal hepatotoxicity. A case report associated the deaths of three children with the administration of two or three enemas containing 0.75% tannic acid during the same morning.[11] Five fatalities also occurred in a group of patients receiving barium enemas containing 2% tannic acid.[12] The use of enemas containing <0.25–0.5% were not associated with hepatotoxicity in a study of human volunteers.[13]

TOXICOKINETICS

There are few data on the pharmacokinetics of tannins in humans. Volunteer studies suggest that ellagitannins (e.g., ellagic acid, castalagin, vescalagin) are metabolized (e.g., urolithin B) and conjugated with glucuronic acid before excretion in the urine.[14] The kidneys excrete little unchanged ellagic acid in the urine.

CLINICAL RESPONSE

Chronic consumption of *Quercus* parts (immature leaves, buds, acorns) by grazing animals (e.g., cattle, sheep) produces gastrointestinal toxicity and renal damage, leading to numerous deaths.[1,15,16] In most human ingestions, toxic effects are not reported.[17] Loose stools were the most common adverse effect in calls to a poison control center concerning acorn consumption. The oak processionary moth (*Thaumetopoea processionea* L.) inhabit *Quercus* (oak) species, and the third to sixth larval instars possesses poisonous hairs (setae) that contain an urticating toxin (thaumetopoein, CAS RN: 99332-51-1) potentially harmful to humans.[18] An anaphylactic response (generalized urticaria, angioedema, vomiting, diarrhea, hypotension) occurred in a 45-year-old man about 15 minutes after ingesting three acorn nuts.[19]

DIAGNOSTIC TESTING

Analytical methods to analyze extractable tannins (e.g., gallic and ellagic acid esters) include liquid chromatography/electrospray ionization/mass spectrometry (LC/ESI/MS),[20] nuclear magnetic resonance,[21] and reversed-phase liquid chromatography/electrospray ionization/tandem mass spectrometry (LC/ESI/MS/MS).[22] Radioallergosorbent (RAST) testing revealed IgE-specific antibodies to acorn, peanut, grass pollen, and *Quercus ilex* pollen extracts.[19]

TREATMENT

Casual ingestions require only symptomatic care for gastrointestinal distress (e.g., clear liquid diet). Decontamination measures are unnecessary.

Chapter 162

PEPPER TREE
(*Schinus* Species)

BOTANICAL DESCRIPTION

Common Name: Peruvian Peppertree, California Peppertree, Molle

Scientific Name: *Schinus molle* L.

Botanical Family: Anacardiaceae (cashew)

Physical Description: This evergreen shrub or tree reaches 3–15 m (~10–50 ft) in height and has pinnately compound leaves that emit a malodorous smell when crushed similar to black pepper. The trunk is relatively short with deeply fissured, dark brown bark. Viscous, white latex extrudes from damaged bark. The branches have a graceful, weeping habit similar to a willow, and the small, white to yellow flowers have four to five petals. The flowers produce small, red berries. The appearance of this tree is similar to the mastic tree (*Pistacia lentiscus* L.)

Distribution and Ecology: A native tree of South America, the *Schinus* species is naturalized in Mexico, Florida, southern Arizona, and southern California.

Common Name: Brazilian Peppertree, Florida Holly, Christmas Berry

Scientific Name: *Schinus terebinthifolius* Raddi

Botanical Family: Anacardiaceae (cashew)

Physical Description: This tree is smaller (up to 30 ft/~9 m) and has a more erect habit than *S. molle* with fewer, but larger, leaflets. White flowers produce clusters of glossy, green berries, which turn red during maturity. The crushed leaves and fruits emit a less intense pepper-like odor compared with *S. molle*.

Distribution and Ecology: The Brazilian peppertree is a native species of South America that is cultivated in the temperate climates of California, Texas, Florida, New Zealand, Australia, Caribbean, and the South Pacific Islands.

EXPOSURE

In Brazil, medicinal uses for crushed, dried leaves of *S. terebinthifolius* include antiseptic poultices on ulcers, gouty joints, painful muscles, and strained tendons.[1] Leaf infusions are given to treat bronchitis and other respiratory ailments.

PRINCIPAL TOXINS

Extracts of crushed leaves of *S. terebinthifolius* contain triterpenes, such as ursolic, masticadienonic, and hydroxymasticadienoic acids.[2] The neutral, oily portion of crushed berries contains monoterpene hydrocarbons, such as α-pinene, β-pinene, δ3-carene, α-phellandrene, β-phellandrene, limonene, and *p*-cymene.[3] The triterpene compounds [e.g., masticadienonic acid, masticadienolic acid (schinol)] are specific inhibitors of phospholipase A_2. This latter substance affects a variety of inflammatory processes as a result of the mobilization of eicosanoids and the metabolism of phospholipids.[4]

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

DOSE RESPONSE

There are inadequate data to determine the dose response following exposure to *Schinus* species.

TOXICOKINETICS

There are few data on the pharmacokinetics of polyphenol compounds in *Schinus* species.

CLINICAL RESPONSE

The pepper tree (*Schinus* spp.) belongs to the cashew (Anacardiaceae) family that contains potent sensitizers. Contact with plant parts from the pepper tree may cause a mild allergenic dermatitis in sensitized individuals characterized by pruritus and a maculopapular rash, particularly in woodcutters involved with cutting branches of the Brazilian pepper tree. Ingestion of large amounts of berries produces gastrointestinal irritation characterized by nausea, vomiting, and diarrhea.

DIAGNOSTIC TESTING

Methods to identify polyphenol compounds in *Schinus* species include high performance liquid chromatography (HPLC).[5]

TREATMENT

Treatment is supportive. Skin lesions following contact with parts of the pepper tree should respond to topical steroids (0.05% fluocinonide) and antihistamines after the skin is cleaned. Decontamination measures are unnecessary.

Chapter 163

YEW
(*Taxus* Species)

HISTORY

The use of the yew predates Christian churches, and knowledge of the toxicity of this plant dates back to classical times. The Celts used yew as agent for ritual suicides and a poison on the tips of arrows during the Gaelic Wars.[1] The yew was a sacred tree and symbol of immortality for Druid priests. Julius Caesar documented the poisoning of the King of Eburones, Catibulus, by yew "juice in the 2nd century BC".[2] Yew trees were often planted on sacred sites, and Christians adopted this custom. The Third Witch in Macbeth mentions yew as a constituent of the caldron's brew.[3] Decoctions of yew leaf were abortifacients in Europe and India during the 18th and 19th centuries.[4] Lucas was the first scientist to recover a white, noncrystalline powder from European yew (*Taxus baccata*) in 1856; he called the residual powder taxine.[5] Twenty years later, the French scientist, Marmé, isolated a crystalline form of taxine using a similar extraction method as Lucas. By 1890, Hilger and Brande determined the basic molecular structure of taxine.[6]

The first description of yew toxicity appeared in the English medical literature in 1836 when Hurt reported the death of a 3-year-old child following the ingestion of yew berries.[7] In the 1800s, the mastication of yew seeds was associated with convulsions.[8] Taxanes (paclitaxel, docetaxel) are novel antitumor agents isolated from the Pacific yew tree and the European yew. During the US National Cancer Institute drug screening program of the 1960s, Wani et al discovered the chemical structure and cytotoxic properties of paclitaxel,[9] and by 1979 paclitaxel was a recognized spindle poison. Preclinical studies on the antitumor activity of paclitaxel began in the 1980s. Docetaxel, a semisynthetic derivative from the needles of the European yew, entered clinical trials as a chemotherapeutic agent for metastatic cancer in the early 1990s.[10] Currently, taxanes are widely administered for the medical treatment of cancer.[11]

BOTANICAL DESCRIPTION

Common (Scientific) Name: Western or Pacific Yew (*Taxus brevifolia* Nutt.), Canadian Yew (*Taxus canadensis* Marsh.), English Yew (*Taxus baccata* L.), Hicks Yew (*Taxus* x *media* Rehder), Japanese Yew (*Taxus cuspidata* Sieb. & Zucc.)

Botanical Family: Taxaceae (yew)

Physical Description: The Pacific yew is a conifer that grows up to 5–15 m (~15–50 ft) with drooping branches and alternate branchlets. The characteristic flattened, stiff, green, needlelike leaves are about 2–3 cm (~0.8–1 in.) long. The upper surface is dark green with a prominent midrib, and the undersurface is more pale yellow. The large, hard seeds are partially enclosed by a fleshy red cup called an aril. English yew (*Taxus baccata*) is an evergreen shrub several feet tall with linear spirally arranged dark green leaves. The bark is thin and red or red-brown with a scaly appearance. Figure 163.1 displays a specimen of the English yew (*T. baccata* L.).

Distribution and Ecology: Western or Pacific yew is a tall tree native to mountain gorges below 7,000 ft (~2,000 m) in mixed evergreen forests from

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

FIGURE 163.1. English yew (*Taxus baccata* L.). Photograph courtesy of Professor Sylvie Rapior. See color insert.

northern California to Alaska and Montana. *Taxus cuspidata* Sieb. & Zucc. (Japanese yew) and *Taxus baccata* L. (English yew) are cultivated as ornamental shrubs. *Taxus canadensis* Marsh. and *Taxus brevifolia* Nutt. are native species in the eastern and western United States, respectively. Most species of yew are dark green evergreen shrubs that flourish in many soil types.

EXPOSURE

Aqueous extracts of yew are an Indian folk medicine (i.e., Zarnab) used for their cardiotonic, expectorant, antispasmodic, diuretic, and antiseptic properties.[12] Extracts of *Taxus celebica* (Warb.) H. L. Li contain a flavonoid (sciadopitysin) used in traditional Chinese medicine for the treatment of diabetes mellitus. Paclitaxel (Taxol®, Bristol-Myers Squibb Company, Princeton, NJ) and docetaxel (Taxotere®, Sanofi-Aventis, Bridgewater, NJ) are semisynthetic derivatives of the bark of *T. brevifolia* (Pacific yew) and *T. baccata* (European yew), respectively. These compounds are spindle poisons that possess antitumor activities. Paclitaxel is also used as a starting skeleton for other chemotherapeutic agents and in paclitaxel-eluting stents in cardiovascular therapies.[13] Japanese and English yew plants are ornamental shrubs with red berries.

PRINCIPAL TOXINS

Physiochemical Properties

Taxus species contain more than 350 naturally occurring taxoids (taxane diterpenoids).[14] These diterpenoid compounds are a mixture of alkaloids formed from nitrogen-free polyhydroxyl diterpenes (taxicins) esterified with β-dimethylamino-β-phenylpropionic acid and acetic acid.[15] Most taxoids possess a pentamethyl tricyclopentadecane (taxane) skeleton, although some taxoids have bicyclic structures or rearranged skeletons (abeotaxoids). Isotaxine B, a structural isomer of taxine B, is the major constituent of the alkaloid fraction of *Taxus* species with minor constituents including taxine A, 2-deacetyltaxine A, deoxytaxine B, 1-deoxyisotaxine B, and taxine B pseudoalkaloids.[16] Taxanes are novel compounds that share a complex taxane ring (baccatin III). This class of compounds includes the chemotherapeutic agent, paclitaxel from *T. brevifolia* and docetaxel from *T. baccata*. The concentration of taxanes in the low trailing shrub, Canadian yew (*Taxus canadensis*) differs for other yews. This plant contains a variety of uncommon taxanes including 15-benzoyl-10-deacetyl-2-debenzoyl-10-dehydro-abeo-baccatin III; 15-benzoyl-2-debenzoyl-7, 9-dideacetyl-abeo-baccatinVI; *N*-acetyl-*N*-debenzoyltaxol; 7,9,13-trideacetylbaccatin VI; 10-deacetyl-10-glycolylbaccatin IV; 1-β-hydroxy-10-deacetyl-10-glycolylbaccatin I; and 7-deacetyltaxuspine L in addition to taxanes more commonly present in other yew species (e.g., 9-dihydro-13-acetylbaccatin III, taxacustin, taxagifine, 2-deacetyl-7,10-diacetyl-5-deaminoacyl taxine A).[17,18]

Poisonous Parts

Taxine alkaloids are present in all parts of the yew plant except the edible scarlet aril (berry).[4] The taxine content of yew plants varies with season and species. Maximal taxine concentrations occur in winter, and taxines are relatively abundant in English yew (*T. baccata*) and Japanese yew (*T. cuspidata*) compared with Pacific yews (*T. brevifolia*).[2]

Mechanism of Toxicity

Taxine B is the principal cardiotoxin in *Taxus* species. In isolated papillary muscle preparations, taxine B significantly reduces the maximum rate of depolarization of the action potential similar to class I antiarrhythmic drugs (flecainide, quinidine, procainamide).[19] The mechanism of toxicity is an alteration of calcium and sodium channel conductance that increases cytosolic calcium concentrations. The clinical consequence of these alterations is hypotension, bradycardia, and depressed myocardial contractility and conduction delay, similar to digitalis poisoning.[20] Taxanes (paclitaxel, docetaxel) are spindle poisons that possess antitumor activity as a result of the binding of these compounds to β-subunit of tubulin causing microtubule polymers, mitotic arrest, and cell death. Postmortem examination of patients dying of yew poisoning is usually nonspecific with gen-

eralized congestion of internal organs, dilation of the ventricles, and unremarkable microscopic findings. Histological evidence of taxine poisoning on postmortem examinations included alveolar hemorrhagic edema, focal pulmonary hemorrhages, and pronounced interstitial myocardial edema with early signs of ischemia (swollen nuclei, homogenization and eosinophilia of the sarcoplasm, perinuclear vacuolization).[21] Immunohistochemical staining for troponin C was positive with depletion of troponin C in many areas of the left ventricles.

DOSE RESPONSE

Most casual ingestions of berries result either in no symptoms or in mild gastrointestinal distress. After the ingestion of at least 5 whole leaves and 10 seeds, a 19-month-old toddler remained asymptomatic following the administration of syrup of ipecac.[22] The fatal dose of yew leaves is unknown, but the estimated lethal dose of chopped yew leaves is about 50–100 g. The ingestion of 150 yew leaves (*Taxus baccata*) by a 40-year-old woman[23] and four to five handfuls of yew leaves by a psychiatric patient produced ventricular tachycardia, refractory cardiogenic shock, and death.[20]

Paclitaxel (Taxol®, Bristol-Myers Squibb Company, Princeton, NJ) and the synthetic analogue docetaxel (Taxotere®, Sanofi-Aventis, Bridgewater, NJ) are novel chemotherapeutic drugs used in the treatment of advanced breast cancer. The dosages in phase II/III trials were an infusion of 135–200 mg/m^2 and 100 mg/m^2, respectively, once every 3 weeks.[24] During clinical trials, paclitaxel doses in the range of 200–250 mg/m^2 produced neutropenia and myelosuppression, whereas doses of 390 mg/m^2 caused severe mucositis.[25]

TOXICOKINETICS

Elimination of taxanes (paclitaxel, docetaxel) occurs primarily by hepatic metabolism and biliary excretion. Paclitaxel undergoes stereospecific hydroxylation by CYP2C8 to form the major metabolite, 6-α-OH-paclitaxel and by CYP3A4 to the minor metabolite, 3′-*p*-hydroxyphenyl-paclitaxel.[26]

CLINICAL RESPONSE

Most cases of yew berry ingestion result in no symptoms. Symptomatic patients typically develop gastrointestinal distress about 1–3 hours after ingestion. Serious cardiac toxicity may occur after large ingestions including ventricular dysrhythmias, intraventricular conduction delay, cardiogenic shock, and death.[27] Lightheadedness, nausea, and abdominal pain developed within 1 hour after the ingestion of four to five handfuls of yew leaves ingestion, followed by coma, wide complex ventricular tachycardia, QRS prolongation, and cardiopulmonary arrest.[20] Several case reports associate the administration of the flavonoid, sciadopitysin, from traditional Chinese extracts of *Taxus celebica* (Warburg) H. L. Li with acute interstitial nephritis, hemolysis, and acute tubular necrosis.[28] Allergic responses may develop following exposure to yew. Case reports associate chewing yew needles with the immediate onset of anaphylactic shock,[29] and cutting yew wood with a severe contact dermatitis.[30]

DIAGNOSTIC TESTING

Analytical methods to quantitate ingredients in *Taxus* species include high performance liquid chromatography with photodiode detection (HPLC/PDA),[31] immunoaffinity chromatography/HPLC,[32] liquid chromatography/mass spectrometry (LC/MS),[33] gas chromatography/mass spectrometry (GC/MS),[34] and liquid chromatography/tandem mass spectrometry (LC/MS/MS).[35] Other methods include competitive-inhibition enzyme immunoassay[36] and an enzyme-linked immunosorbent assay (ELISA) method. The latter method detects free, biologically active taxine compounds in patients receiving paclitaxel or docetaxel for advanced cancer.[37] The toxic alkaloid, taxine B, is unstable and difficult to detect in postmortem blood.

Gas chromatography/mass spectrometry analysis of postmortem blood samples from a 19-year-old man, who was found dead after ingesting both leaves and tea brewed from the yew leaves, did not detect taxine compounds.[38] However, the detection of 3,5-dimethoxyphenol in heart blood at a concentration of 320 μg/kg provided *indirect* evidence of yew ingestion. 3,5-Dimethoxyphenol is the aglycon of the *Taxus* ingredient, taxicatine, which results from the glucosidic cleavage of taxicatine. In a case series of five individuals found dead with evidence of yew poisoning, cardiac blood samples contained the following concentrations of 3,5-dimethoxyphenol: 31 ng/mL, 47 ng/mL, 97 ng/mL, 110 ng/mL, and 528 ng/mL.[39] Although analyses of samples from femoral blood suggested postmortem redistribution, there were insufficient samples to determine the extent of postmortem redistribution. Analysis of heart blood from a 43-year-old man found dead after ingesting tea brewed from *Taxus baccata* demonstrated the presence of total taxines (taxine B, isotaxine B) equivalent to 11 ng/g tissue as measure by high performance liquid chromatography/mass spectrometry.[21] Microscopic examination of contents from the gastrointestinal tract may reveal characteristic stomata on undigested yew leaves.[40]

TREATMENT

Most exposures to *Taxus* species require no decontamination because whole seeds are relatively nontoxic.[41] The administration of activated charcoal to alert children, who ingest more than several *Taxus* seeds less than 1 hour prior to presentation, is a therapeutic option, but there are no clinical data to confirm the clinical efficacy of activated charcoal following the ingestion of yew. Asymptomatic patients or those with only mild gastrointestinal distress may be released after 4 hours of observation. There are limited clinical data to guide management in serious ingestions involving the ingestion of large amounts of yew leaves or extracts of the yew plant. Serious ingestions require monitoring of oxygen saturation, an intravenous line, and cardiac monitoring in an intensive care setting. Cardiac pacing may be required for severe conduction disturbances. There is no clinical evidence to support the use of antidotes including digoxin-specific Fab antibody fragments.[42]

Chapter 164

MITES and TICKS
(Order: Acari)

Mites and ticks belong to the phylum Arthropoda, class Arachnida, and order Acari (Acarina). This taxon contains the following two separate lineages: Acariformes (mites) and the Parasitiformes (bird mites, soft-bodied and hard-bodied ticks).

MITES

Mites are ubiquitous creatures that are barely visible to the naked eye and cause significant pruritic dermatoses. These animals are easily distinguished from other arachnids by a distinctive gnathosoma (capitulum with the mouth parts) and the absence of a division between the abdomen and the cephalothorax.[1] Mites can infest cheese, flour, sugar, cereals, grains (*Pyemotes ventricosus* Newport), dried meats, vegetables, feathers, birds (*Dermanyssus gallinae* De Geer, *Dermanyssus avium* De Geer), rats, cats, dogs, and rabbits. With the exception of the human follicle mites (*Demodex folliculorum* Simon) and the scabies mite [*Sarcoptes scabiei* (L.)], most mites leave the human host soon after feeding rather than burrow into human skin. Mites do not possess any specialized venom apparatus, and they usually return to their natural hosts after feeding. The *Demodex* mites feed on sebum in hair follicles and sebaceous glands primarily on the nose, forehead, and cheeks. There is no definite association between the presence of these nonblood sucking mites and human disease.[2] Bites from a variety of these arachnids produce pruritic, excoriated lesions with and without central puncta as a result of the injection of reactive salivary proteins deposited during feeding on human blood.[3] Although only a small portion of people infested with these mites develop symptoms, extensive crusted lesions of the scalp may appear during an infestation.[4] Clinical characteristics of mite bites include unexplained pruritus, closely associated persons with similar lesions, absence of other insects (e.g., bedbugs, lice, mosquitoes, fleas, spiders), and the lack of burrows.[5] Human eruptions range from mild, pruritic, papular lesions to severe vesicles and pustules. Infestations of the eyelids may cause conjunctival inflammation, superficial corneal vascularization, marginal corneal infiltration, superficial corneal opacity, and nodular corneal scarring.[6] Lesions resulting from animal mites are typically symmetric in the area of greatest contact with the pet (i.e., inner forearms, chest, abdomen). Identification of mites requires a careful search of the environment because these mites do not remain on human skin for identification.[7] Infected cats and dogs may be asymptomatic.[8] Beside elimination of the mites, treatment of mite-induced lesions includes the use of topical antipruritic agents (e.g., menthol, camphor, pramoxine), and oral antihistamines.

Trombiculidae (Chiggers/Harvest Mites)

This family includes chiggers (harvest mites, red bugs). Chiggers are the parasitic larval form of harvest mites (e.g., *Trombicula alfreddugesi* Oudemans) in the

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Trombiculidae family. The larval stages produce crusted lesions similar to chicken pox. They possess a bright red, hairy body 0.5 mm × 0.25 mm. Contact usually occurs during periods of peak outdoor activity during late summer and fall when the larvae crawl along the ground and grass after emerging from eggs laid in the soil.[9] Small (1–2 mm) macules usually appear near belt lines, ankles, or moist intertriginous areas where the larva pierces the skin with its stylostome and releases proteolytic enzymes to liquefy epidermal cells. These mites feed on lymph and tissue dissolved by their proteolytic enzymes rather than blood. The initial bite is painless, but an intensely pruritic papule surrounded by a clear vesicle develops within 3–24 hours. The lesion may become ecchymotic. The mite typically leaves the human host after feeding and before the pruritus develops. A 0.5- to 2.0-cm (~0.2–0.8 in.) lesion persists for several weeks and eventually crusts, similar to chicken pox. Treatment is supportive with prevention of secondary infection. Anecdotal evidence suggests that application of an ointment containing 5–10% sulfur and 1% phenol may relieve pruritus and remove any remaining mites. Insect repellents (e.g., diethyltoluamide or *N,N*-diethyl-meta-toluamide [DEET]) effectively repel biting insects, such as biting flies, gnats, chiggers, and ticks.

Scabies

IDENTIFYING CHARACTERISTICS

Common Name: Scabies

Scientific Name: *Sarcoptes scabiei* L.

Physical Description: The scabies mite is barely visible to the unaided eye.

EXPOSURE

These mites remain on humans during their whole life cycle unless interrupted by an effective miticide. After mating on the skin, the female scabies mite burrows into the epidermis at a rate of several millimeters per day. The female mite lays up to 40 eggs over 1–2 months while leaving a trail of debris and feces in the burrow. The female then dies. Although the male scabies mite remains on the skin, the life span is shorter for the male than the female. Additionally, the male produces only shallow burrows. About 3 weeks after the eggs are laid, larvae emerge from tunnels, where impregnation occurs; the females burrow again, repeating the cycle. Infestation requires close personal contact because the mite lives only several days when not in direct human contact. These mites can neither jump nor fly, but these insects can crawl as fast as 2.5 cm (1 in.)/minute on warm human skin.[2] Therefore, the transmission of scabies between humans requires direct contact with infected persons. Norwegian scabies commonly occurs in immunocompromised or debilitated patients in institutional settings including patients with human immunodeficiency virus (HIV).[10,11]

PRINCIPAL TOXINS

The female mite has specialized jaws and cutting claws on the forelegs that allow easy entrance into the epidermis. Scabies mites subsist on dissolved human tissue rather than blood.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The lesions of scabies result from both mechanical irritation and hypersensitivity.

CLINICAL RESPONSE

These burrowing mites produce intensely pruritic lesions in sensitized individuals, primarily on the hands and feet. Often the pruritus is worse at night. These nodular lesions classically appear in skin folds, such as the fingers, wrists, elbows, umbilicus, lower abdomen, genitalia, gluteus, and breast. In infants, the plantar region of the foot is frequently affected with vesicles. The burrows resemble a wavy, gray-white papule several millimeters in length with a small vesicle at one end. The vesicle at the end of the gray threadlike trail covers the mite resting at the end of the channel. These lesions typically occur in the interdigital spaces of the hand, flexor surfaces of the wrists and elbows, areola of infected women, umbilicus, waist, and male genitalia.[12] Secondary lesions (papules, pustules, vesicles, excoriations) develop from hypersensitivity or bacterial infection; these secondary lesions do not correlate to the distribution of the adult mites. These secondary lesions are more numerous and prominent than the burrows when the infestation persists. The intensely pruritic lesions usually begin about 10–30 days after the onset of the infestation. Pruritic lesions on the head or neck are uncommon, except in immunocompromised patients. Norwegian or crusted scabies describes a heavy infestation of hundreds to thousands of the scabies mite with severe skin lesions, primarily in homeless AIDS patients.[2] Health workers are at risk for contracting scabies from direct contact with patients infested with Norwegian (crusted) scabies.[13]

TABLE 164.1. Method of Skin Scraping for Scabies

1. Obtain mineral oil or microscope immersion oil, microscope slide, and #15 scalpel blade.
2. Apply mineral oil or microscope immersion oil to suspicious skin lesions and to the scalpel blade.
3. After holding the skin taut around the lesion, scrape the noninflamed, nonexcoriated portions of the skin lesions vigorously until the stratum corneum is removed.
4. Apply skin scrapings from at least six different areas to a single slide.
5. After placing a slipcover over the scrapings on the slide, examine the slide under low (2×–4×) and high magnification (25×–50×).

DIAGNOSTIC TESTING

For laboratory confirmation of a scabies infestation, the burrows, vesicles, and nonexcoriated papules are scraped with a mineral-oil-coated Joseph knife or small curved blade from a scalpel. Scraping of linear burrows from nonexcoriated areas with a sterile scalpel may contain mites, mite parts, or black fecal material. Table 164.1 lists the steps required to scrape the skin for suspected scabies. Areas of highest yield include the nonexcoriated lesions in fingers, web space, wrists, or the ulnar aspect of the hand. Inspection of the scraping in oil under low power on the microscope reveals actively moving mites, eggs, and/or feces in a majority of patients with lesions highly suspicious of scabies.[14] Failure to identify mites in skin scraping samples does not eliminate the diagnosis of scabies.

TREATMENT

Options for the topical treatment of scabies infestations include 5% permethrin cream, 1% lindane (gamma benzene hexachloride) lotion, 6% precipitated sulfur in petrolatum, crotamiton, malathion, allethrin spray, and benzyl benzoate, as well as the only oral treatment, ivermectin.[15] The treatment of scabies varies between locations depending on the presence of resistant strains of *Sarcoptes scabiei*.[16] The usual treatment of choice for scabies in adults and children over the age of 2 months is 5% permethrin cream applied at bedtime. This cream contains 0.1% formaldehyde, which is a potential sensitizing agent. The patient should take a warm shower or tub bath using soap and then apply the lotion over the entire body including the scalp, face (except eyes, nose, mouth), postauricular area, nails, fingers, and toes. The lotion should remain on the skin overnight until washed off in the morning. The process is usually repeated in 1 week, but repeat applications are not always necessary. All family members should be treated for scabies regardless of the absence of symptoms. The clothing, bed linen, and towels in intimate contact with the patient should be washed and dried simultaneously with treatment, preferably on high heat settings. Papular and pustular skin lesions usually resolve within 1 week following treatment, although nodular lesions may persist for months. Pruritus may continue up to 6 weeks after treatment because of hypersensitivity to dead mite parts. The presence of new skin lesions 2 weeks after initial therapy suggests reinfestation or inadequate treatment.

Precipitated sulfur (6%) in petrolatum applied for three consecutive nights is the treatment of choice for patients under 2 months of age; this treatment is an alternative to permethrin cream in adults when permethrin is not available. Lindane is also a treatment option, but the potential of toxicity in pediatric patients limits the use of this compound as a scabicide.[17] The most frequent adverse effects associated with the use of lindane for *pediculosis* as reported to a poison control center were relative minor adverse effects including nausea, vomiting, and ocular irritation or pain.[18] Less common complications included lethargy, conjunctivitis, and seizures. Symptomatic treatment for pruritus includes pramoxine-containing lotions and oral antihistamines at night.

Treatment of Norwegian scabies is complicated by the presence of hyperkeratosis that prevents the adequate penetration of topical scabicides. Options to traditional treatment include the use of adjunctive keratolytic agents, repeated daily application of the scabicide, and the sequential use of several scabicides. Ivermectin in a single oral dose of 150–200 µg/kg may be useful for resistant cases of scabies in HIV patients, who do not respond to topical scabicides (e.g., 25% benzyl benzoate).[19,20]

TICKS

Ticks are specialized groups of mites that are classified into the following two families: *Ixodidae* (hard-bodied ticks) and *Argasidae* (soft-bodied ticks). Of the approximately 800 species of ticks, almost 100 tick species can transmit infectious diseases to humans.[2] These blood-sucking parasites are common inhabitants of rural areas worldwide. They possess an ovoid body (fused thorax and abdomen) and have prominent legs; they reach 1–1.5 cm (~0.4–0.6 in.) in size when engorged with blood. The adult tick has a mite-like body with tough skin and four pairs of clawed legs. After contact with animal hosts (cats, dogs) or with tall grass or brush containing hungry ticks, these insects (i.e., larva, nymph, or adult)

attack humans by painlessly attaching to the host with strong barbed mouth parts (chelicerae) reinforced by cement-like secretions. Attractants for ticks include the odor of sweat, body heat, and the color white.[21] The tick may spend up to 24 hours on the host searching for a protected site to feed (e.g., skinfold, hairline). The mouth parts consist of a paired anchoring organ (rostrum) covered with posterior-directed, curved hooks and a pair of sharp mandibles. Soft-bodied ticks primarily infest birds, and the mouth parts of these ticks reside underneath the body. These insects sense the presence of a host primarily by detecting increased carbon dioxide concentrations and movements. Tick bites commonly occur in the spring and early summer.[22] The tick typically feeds up to 1 week until engorged with blood, and then the tick leaves the human host.

Hard-bodied ticks are parasites primarily of mammals, and these tick species are disease vectors for typhus, viral encephalitis, ehrlichiosis, babesiosis, tularemia, Q fever, hemorrhagic fevers (e.g., Rocky Mountain spotted fever, Colorado tick fever), Lyme disease (deer tick—*Ixodes dammini*),[23] and a symmetrical ascending paralysis known as tick paralysis. The latter disease results from the secretion of a neurotoxin by certain species including *Dermacentor andersoni* Stiles and *Dermacentor variabilis* Say in North America, *Ixodes holocyclus* Neumann in Australia, and *Ixodes rubicundus* Neumann, *Rhipicephalus evertsi* Neumann *evertsi*, and *Argas walkerae* Kaiser & Hoogstraal in Africa. Ataxia and weakness in the cranial nerves occurs before the flaccid paralysis develops. Tick paralysis usually resolves within 24 hours of tick removal. Relapsing-fever results from the bite of a soft-bodied tick (*Ornithodoros turicata* Dugès). The European castor bean tick (*Ixodes ricinus* L.) is endemic to Europe, parts of Asia, and North Africa. This hard-bodied tick infests a variety of mammals (e.g., livestock, dogs, deer, humans), and this tick transmits a variety of diseases including tick-borne encephalitis, Lyme disease, babesiosis, and rickettsial illnesses. Figure 164.1 displays a specimen of the European castor bean tick.

Tick bites induce foreign body and hypersensitivity reactions, as well as delayed hypersensitivity reaction with fever, urticaria, and pruritus. The most common reaction to a tick bite is a red papule that resolves over 2–3 weeks. Local swelling and pruritus may occur, but necrosis and ulcerations are rare. Occasionally, a persistent nodule or granuloma may develop that requires months to resolve. Rarely, tick bites may produce severe allergic reactions manifest by hypotension and dyspnea.[24] Removal of the tick requires gentle traction on the mouth parts with care to avoid excretion of fluid from the body of the tick. Dislodgement of the chelicerae in the skin may produce a granuloma that necessitates surgical removal. Permethrin-based repellents kill ticks on contact, and these products can be safely applied to clothes, tents, and sleeping bags. The combination of permethrin-based repellents on clothes and DEET on the skin provides the best protection against ticks.[25]

Chapter 165

SCORPIONS
(Order: Scorpiones)

HISTORY

Scorpions are one of the oldest terrestrial animals in the order Arachnida based on fossil records dating back almost 400 million years.[1] Written medical accounts of painful scorpion stings date back to the 3rd century BC.[2] Although all species of scorpions cause painful stings, only a few are very toxic (e.g., Mexican *Centruroides suffusus* Pocock, Brazilian *Tityus serrulatus* Lutz & Mello, North African *Leiurus quinquestriatus* Ehrenberg, Indian *Hottentotta tamulus* Fabricius). The only dangerous species in the United States is *Centruroides exilicauda* Wood (*C. sculpturatus*, bark scorpion). Although numerous fatalities were associated with *C. exilicauda* Wood envenomations of young children during the 1950s, fatalities from scorpion envenomations in the United States have not been well documented since the late 1960s.[3]

IDENTIFYING CHARACTERISTICS

There are approximately 650–800 species of scorpions distributed throughout the tropical and subtropical regions of the world. Scorpions are arachnids that form one of the largest orders of Arthropoda. Medically important arachnids include species from the order Araneida (spiders) and order Acari (ticks, mites) as well as the order Scorpiones (scorpions). Arachnids are terrestrial, ambulatory creatures with two body segments, whereas insects have wings, antennae, and three body segments. Scorpions possess a hard exoskeleton, two anterior pinching claws, and a tail with a terminal bulbous enlargement. Most medically important scorpions belong to the family Buthidae that is characterized by a triangular sternal plate. The bark scorpion (*Centruroides exilicauda* Wood) is the only scorpion native to the United States that produces life-threatening envenomation, particularly in children.

Common Name: Bark Scorpion

Scientific Name: *Centruroides exilicauda* Wood (*C. sculpturatus*)

Physical Description: The body of the scorpion consists of a cephalothorax, an abdomen, and a six-segmented tail that terminates in a bulbous enlargement called the telson and contains the stinger. This scorpion is a small (13–75 mm/0.5–3 in. long), hairless creature that passes through four color phases ranging from the characteristic yellow-brown to striped.[4] Features distinguishing the bark scorpion from other scorpions include a rectangular proximal tail segment, a small spine or tubercle at the base of the stinger that requires magnification for identification, and long, slender pedipalps (pincers).

EXPOSURE

Geographic Distribution

The effect of scorpion envenomation varies among scorpion species and geographic location with the most severe clinical effects resulting from certain buthid species (Buthidae family). Highly toxic scorpions include

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Centruroides suffussus Pocock (Mexico), *Androctonus crassicauda* Oliver (Middle East, North Africa), *Androctonus australis* Hector *(Israel), Hottentotta tamulus* Fabricius (*Mesobuthus tamulus*, *Buthus tamulus*, India), *Tityus serrulatus* Lutz & Mello (Brazil), *Tityus trinitatis* Pocock (Trinidad), *Parabuthus granulatus* Ehrenberg (South Africa), and *Leiurus quinquestriatus* Ehrenberg (Middle East, North Africa). The geographic distribution of scorpion species is between the 45° latitudes. Occasionally, scorpion envenomations occur at locations distant to their native habitat as a result of inadvertent transport of the scorpion.[5,6]

Australia

In Australia, scorpion stings are not usually associated with severe clinical effects.[7] Most scorpion envenomations in Australia result from stings of species in the family Buthidae (e.g., *Lychas* spp., mostly mainland Australia), and to a lesser extent the family Bothriuridae (*Cercophonius* spp.) and the family Scorpionidae (*Urodacus* spp.). Usually stings from Australian buthid scorpions cause more severe effects than from the larger species in the families Scorpionidae (*Urodacus* spp.) and Hemiscorpiidae (*Liocheles* spp.).[8] Most of the scorpions that cause serious toxicity reside in North Africa and the tropics.

United States and Mexico

Medically important *Centruroides* species in the western United States and Mexico include *C. exilicauda* Wood (bark scorpion, *C. sculpturatus*) and *C. suffusus* Pocock (Durango scorpion). The bark scorpion inhabits areas throughout the dry, arid regions of Arizona and parts of Texas, New Mexico, Northern Mexico, small desert sections of southeastern California, and Lake Mead in Nevada. These scorpions tolerate some subfreezing temperatures by seeking warm shelter during the cold temperatures. Other US species of scorpions associated with less severe envenomations compared with *C. exilicauda* include *Isometrus maculatus* de Geer (California, Florida), *Diplocentrus* species (California, Texas, Florida), *Hadrurus hirsutus* Wood (southwestern United States), and *Vejovis* species (the Southwest). The most important venomous species of *Centruroides* in Mexico beside *C. suffusus* and *C. exilicauda* include *C. elegans* Thorell, *C. infamatus* C. L. Koch, *C. limpidus* Karsch, *C. noxius* Hoffman, and *C. pallidiceps* Pocock.

South America

Medically important species of scorpions in South America include species from the genus *Tityus* including *T. discrepans* Karsch, *T. serrulatus* Lutz & Mello, *T. trinitatis* Pocock, and *T. bahiensis* Perty.

Middle East and North Africa

The most dangerous scorpions in this region include *Androctonus crassicauda* Olivier (Black scorpion), *Androctonus amoreuxi* Audouin, *Androctonus bicolor* Ehrenberg, *Androctonus australis* L., *Leiurus quinquestriatus* Ehrenberg (Yellow scorpion), and *Buthus occitanus* Amoreux.

South Africa

Parabuthus granulatus Ehrenberg is one of the primary scorpions involved in serious scorpion envenomation in South America.

India

Serious scorpion envenomations in India typically involve *Hottentotta tamulus* Fabricius and *Palamneus swammerdami* Krishnan.[9] Evenomation by these scorpions may cause death despite the use of local antivenom, particularly in children and older adults.[10]

Behavior

Scorpions are nocturnal hunters that hide in rocks, leaf litter, and burrows during the day. These creatures grasp their prey (i.e., insects, spiders, small animals) with their pedipalpus, and they paralyze prey with the venom injected from their caudal stinger. Stings frequently occur indoors during the night; a scorpion will typically hide in bedding or clothing. Scorpions detect prey by air movements and vibrations rather than by their limited vision.[4]

Bark Scorpion

This scorpion is a climbing rather than burrowing scorpion species that prefers areas around trees. Climbing characteristics cause it to sting unsuspecting humans, who fail to look beneath objects hiding the scorpion. The bark scorpion often rests the telson on the ground rather than carry it arched overhead like most scorpions. This scorpion is a nocturnal feeder that eats small insects and spiders by clasping them in its claws and stinging them to death by inserting its stinger from the arched tail. Scorpions hibernate during winter and seek shelter during the day, preferring moist, cool areas under rocks, debris, houses, or household items (e.g., shoes, clothing, beds).

PRINCIPAL TOXINS

Venom Composition

Scorpion venom is a complex, species-specific mixture of low-molecular-weight neurotoxic proteins, phospholipase A_2, acetylcholinesterase, hyaluronidase, amino acids, protease inhibitors, histamine releasers, and serotonin.[11] In contrast to spider and snake venoms, most scorpion venoms lack clinically significant amounts of tissue-destructive enzymes with few exceptions (e.g., South Indian scorpion, *Heterometrus scaber* Kraepelin).[12] The most toxic portion of scorpion venom consists of small, neurotoxic peptides that recognize and bind to integral membrane proteins involved with the control of ion transport. To date, experimental studies suggest that most of these peptides bind to activated Na^+ and voltage-dependent K^+-channels[13] and, to a lesser extent, to Cl^-- and Ca^{++}-channels.[14] One class of scorpion neurotoxins induces slow, inward sodium currents that prolong the action potential so that a given stimulus causes greater sodium channel activation. Other neurotoxins are stabilizers that reduce sodium channel flow during depolarization. These effects on sodium gating occur at preterminal sites, resulting in the release of neurotransmitters at the neuromuscular junction and repetitive, enhanced axonal discharges.[3]

Venom Apparatus

Two venom glands are located within the telson with independent ducts leading to an opening near the stinger. The metasoma (tail) of the scorpion contains five segments. Distal to the metasoma is the round, terminal segment (telson) that contains the venom glands and the stinger as demonstrated in Figure 165.1. Scorpions catch prey in their two anterior pincers, and they inject their venom by raising their caudal stinger over their head and inserting the stinger into the prey.

Dose Response

The severity of scorpion envenomation depends on the potency of the venom (species-specific) and volume of venom injected (i.e., amount of venom and number of stings). Most scorpion envenomations produce mild effects.

TOXICOKINETICS

The absorption, peak concentration, and elimination half-life of scorpion venom is variable and species-specific.[15] Animal studies suggest that substantial amounts of venom are absorbed within 15 minutes of the sting, and distribution is complete within 1–4 hours.[16,17] These animal studies indicate that the absorption and distribution phases are relatively rapid while the elimination half-life is relative long (i.e., about 4–24 hours).[17,18]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

The principal targets of scorpion venom are the voltage-dependent ion channels involved with nerve impulse conduction. The clinical features of scorpion envenomation result from a complex interaction of parasympathetic and sympathetic stimulation along with the release of a variety of endogenous compounds including catecholamines, angiotensin II, glucagon, corticosteroids, bradykinins, prostaglandins, and cytokines (e.g., interleukin-8). Scorpion venom increases sodium influx into the cell, resulting in prolonged duration and increased amplitude of the action potential. The subsequent increase in calcium permeability at presynaptic and postsynaptic nerve fibers increases the release of acetylcholine. Scorpion venom also causes excess catecholamine release resulting in autonomic stimulation, the accumulation of endothelin, and generalized vasoconstriction. Symptoms generally reflect sympathetic, parasympathomimetic, and neuromuscular excitation followed by exhaustion. Scorpion venom contains a mixture of short, neurotoxic proteins that open sodium channels at presynaptic nerve terminals and inhibit Ca^{++}-dependent potassium channels leading to excess autonomic stimulation. During severe envenomation, these actions cause transitory myocardial ischemia that manifests as depression of the left ventricular ejection

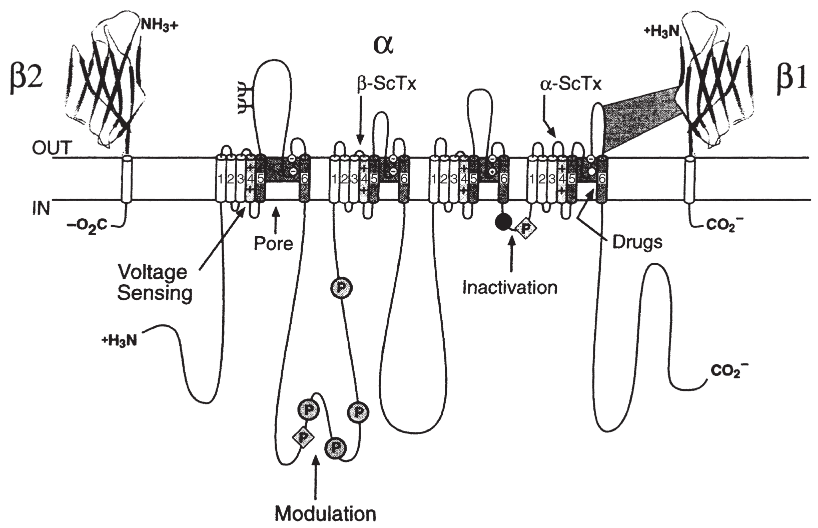

FIGURE 165.2. Structure of voltage-gated Na^+-channels in mammalian brains. The extracellular domains, β1 and β2, are folds of α-helical segments. Bold lines represent polypeptide chains. ψ is the probable site of *N*-linked glycosylation and P represents areas of protein phosphorylation. The lightly shaded S4 segment is the voltage sensor and the dark circle represents the inactivation particle in the inactivation gate loop. The sites of binding of β- and α-scorpion toxins are domains II and IV, respectively. From Catterall WA. Molecular mechanisms of gating and drug block of sodium channels. Novartis Found Symp 2002;241:207. Reproduced with permission from John Wiley & Sons Limited.

fraction and acute pulmonary edema.[19] These perfusion defects normalize as the effects of the venom cease.

Sodium ion channels from mammalian brain are complexes of α-, β_1-, and β_2-subunits as demonstrated in Figure 165.2.[20] The molecular weights of these subunits are 260 kDa, 36 kDa, and 33 kDa, respectively. Each of the four homologous domains (I–IV) of the sodium channels consist of six α helical transmembrane segments (S1–S6) as well as a re-entrant loop that dips into the transmembrane region of the protein between transmembrane segments S5 and S6. Domain II is involved with activation of the membrane, whereas domain IV is involved with the coupling of activation to inactivation. The β_1- and β_2-subunits modulate channel gating and cell-cell interaction. Membrane depolarization causes a voltage-dependent conformational change of the channel that induces an increase in Na^+ permeability. Voltage sensors (gating charges) in the S4 transmembrane segments initiate the voltage-dependent activation of the sodium channel by a conformational change that moves the S4 segments outward along a spiral path causing the opening of the pore.[21] Voltage-dependent coupling of channel activation to inactivation results from voltage-dependent multiple transitions during the activation phase including the translocation of the S4 segment outward. This conformational change initiates the closure of inactivation gates formed by the short intracellular loop connecting domains III and IV of the α-subunit of the sodium channel as demonstrated in Figure 165.2. Inactivation produces closure of the pore and the restoration of pre-excitation sodium ion concentrations.

Scorpion venoms contain two different toxins (α- and β-toxins) that produce voltage sensor-trapping. β-Scorpion toxins bind to a receptor site (neurotoxin receptor site 4) in the S3–S4 extracellular loop in domain II of the α-subunit of the sodium channel as demonstrated in Figure 165.2.[22] These β-scorpion toxins modify the activation process of voltage-gated sodium channels by trapping the IIS4 segment in an activated position, and thereby enhance activation by shifting the voltage dependence to more negative membrane potentials.[23] Normally, Na^+-channels inactivate within a few milliseconds of opening. Once the membrane is activated, the presence of β-scorpion toxins slows deactivation of the channel and creates large tail currents.

α-Scorpion toxins bind to a receptor site (neurotoxin receptor site 3) in the S3–S4 extracellular loop in domain IV of the α-subunit of the sodium channel. The α-scorpion toxin-binding site is the same site bound by sea anemone[24] and funnel web spider toxins.[25] These α-scorpion toxins (e.g., makatoxin I, bukatoxin) slow inactivation of the Na^+ channel and prolong the action potentials. Voltage-sensor trapping results from the effects of α-scorpion toxins on Na^+-channel inactivation. These toxins prevent the outward translocation or movement of the S4 segment in domain II during repolarization and trap the IVS4 segment in an inward, partially activated position. The physiological effect is the slow or delayed closure of the inactivation gate.[20]

Potassium channels are divided into voltage-gated K^+-channels and ligand-gated-K^+-channels. These channels are composed of two main subunits: α and β. The α-subunit is involved with the conduction of the potassium ion across the membrane, whereas the β-subunit modulates the properties of the channel.[23] Scorpion venom contains toxins that bind to the outer vestibule of potassium channels and block ion conduction by physical occlusion of the K^+ channel pore without altering the gating kinetics of the K^+ channel.[22] Voltage-gated and

calcium-dependent K^+-channels are tetrameric molecules that contain four α-subunits. These potassium channels control a variety of physiological processes involved with cell excitation including processes that regulate neuronal and cardiac electrical patterns, muscle contraction, neurotransmitter release, hormone secretion, and cell secretions.[26] A variety of scorpion toxins [e.g., noxiustoxin (CAS RN: 85205-49-8), maurotoxin, tamapin] alter conductance through potassium channels[27–29] as well as through T-type Ca^{2+} channels (e.g., kurtoxin).[30,31] The venom from the Israeli scorpion, *Leiurus quinquestriatus hebraeus* Ehrenberg, contains the 37-amino acid neurotoxin, charybdotoxin (CAS RN: 115422-61-2). This polypeptide inhibits potassium channels on nerve cell membranes by a pore-blocking mechanism.[32]

Target Organs

Local histological changes at the site of scorpion stings include superficial and deep mixed inflammatory cell infiltrate with a few eosinophils dispersed among collagen bundles in an edematous dermis.[33] Most scorpion envenomations do not cause clinically significant changes in the tissue surrounding the envenomation. In rats, the injection of purified venom from *Tityus serrulatus* causes acute and chronic pancreatitis characterized by necrosis, interstitial fibrosis, lymphocyte infiltration, ductal and ductular dilation, acinar cell atrophy, periductal ductular hyperplasia, and hyperplasia of the islets of Langerhans.[34]

Cardiovascular

Stimulation of the autonomic nervous system with the release of catecholamines causes a predominance of sympathetic stimulation and cardiorespiratory dysfunction. In experimental animals and in children, scorpion venom causes marked, prolonged hypertension and vasoconstriction.[35] Severe scorpion envenomation produces predominant left ventricular dysfunction with normal systemic vascular resistance that manifests as pulmonary edema or severe hypotension depending on the fluid balance.[36] These cardiovascular effects may progress to myocardial damage and multisystem organ failure secondary to biventricular dysfunction and vasodilation.[37,38] Pathological changes associated with severe scorpion envenomation include degeneration of the muscle fibers, local necrosis, hemorrhage, coagulative myocytolysis (contraction bands), and interstitial edema.[39] Electromicroscopy of the heart demonstrates intracellular edema, scattered destruction of the I-band, contraction band necrosis with ruptured and hypercontracted sarcomeres, dilation of the tubular system, and lipid deposition along with preservation of the mitochondria, nucleus and sarcolemma.[40] These abnormalities are qualitatively different from the histopathological changes associated with massive catecholamine release.[35]

Central Nervous System

Neurological complications associated with scorpion envenomation include dysarthria, dysphagia, tongue fasciculations, paresthesias, hemiplegia, muscular weakness, abnormal eye movements, blurred vision, and seizures.[41] Case reports document central nervous system (CNS) changes in fatal cases of scorpion envenomation, including cerebral edema, diffuse punctate hemorrhages, cerebral infarction, and cerebrovascular thrombosis.[42,43] Because scorpion venom diffuses poorly across the blood–brain barrier, these CNS changes probably are secondary to the cardiorespiratory effects (e.g., hypertension, pulmonary edema, shock) associated with severe scorpion envenomation.

CLINICAL RESPONSE

Stings from most scorpion species produce only mild pain, even following envenomation by dangerous species (e.g., *Centruroides suffussus, Androctonus crassicauda, Androctonus amoreuxi*, *Parabuthus liosoma* Ehrenberg, *Nebo hierichonticus* Simon, *Leiurus quinquestriatus, Hottentotta tamulus*, *Tityus serrulatus*).[44–46] The severity of a scorpion envenomation depends on the presence of neurological and cardiorespiratory dysfunction, and the development of this type of dysfunction varies with the species, age, and size of the scorpion as well as the age of the victim and the amount of injected venom.[47] Severity of envenomation by dangerous scorpion species ranges from local pain and paresthesias to encephalopathy and fatal cardiotoxicity depending on the above factors. Local pain develops almost immediately (i.e., seconds to minutes) after scorpion envenomation. Although many envenomations in healthy adults and older children result only in local pain, significant respiratory distress can develop, particularly in young children (i.e., <6 years of age).[48,49] Scorpion envenomations are not usually associated with clinically significant edema or erythema with the exception of stings by *Androctonus crassicauda*.[18] Systemic symptoms of envenomation typically begin within about 45–60 minutes after envenomation with common signs including diaphoresis, hypertension, tachycardia, and salivation.[50]

Local

Most scorpion stings produce local pain and paraesthesias, but swelling, erythema, and ecchymosis do not

usually develop.[51] Patients with *Centruroides exilicauda* envenomations almost always demonstrate moderately severe local pain following mild palpation of the site of envenomation (i.e., positive "tap" test). Local symptoms typically resolve within 10 hours after *C. exilicauda* envenomation. Even envenomations by other dangerous scorpion species (e.g., *Leiurus quinquestriatus*) frequently produce only local pain and paresthesias.[52]

Systemic

Nervous System

Mild envenomations produce agitation, diaphoresis, and anxiety. Neurotoxic effects following serious scorpion envenomation include excitability, exaggerated startle response, roving eye movements, ptosis, hyperreflexia, ataxia, hemiplegia, seizures, and visual disturbances. The most common initial symptoms are irritability, motor restlessness and anxiety.[44] Envenomations by some scorpion species (e.g., *Parabuthus transvaalicus* Purcell, *Centruroides exilicauda*) cause more prominent neuromuscular than cardiac symptoms.[53] Children, especially infants, typically develop more severe CNS symptoms compared with adults, and these symptoms are usually occur soon (i.e., 15 minutes) after envenomation.[54,55] The typical sequence of severe envenomation by neurotoxic scorpion species is initial intense pain followed within a few minutes to several hours by hyperexcitability, increased salivation, tachypnea, muscle fasciculations, muscle spasm, opisthotonus, erratic/wandering eye movements, disconjugate gaze, nystagmus, convulsions, paralysis, and respiratory failure. Sympathetic effects include tachycardia, diaphoresis, mydriasis, piloerection, priapism, hyperthermia, and hyperactivity.[56] Parasympathomimetic signs are salivation, lacrimation, urination, defecation, vomiting, and gastric distension.

Cardiorespiratory System

Tachycardia and hypertension are common toxic effects of scorpion envenomation, but these effects usually respond to conservative therapy.[57] Patients with moderate to severe cardiotoxicity following scorpion envenomations usually present to medical facilities within 3 hours, and almost always within 6 hours of the sting.[58] During severe scorpion envenomations by cardiotoxic scorpion species (e.g., *L. quinquestriatus*), severe hypertension, pulmonary edema, myocardial infarction, and cardiogenic shock may develop along with serious dysrhythmias (AV dissociation, ventricular tachycardia) and sudden cardiac arrest (i.e., ventricular fibrillation).[59] Toxic myocardial effects (i.e., acute pulmonary edema secondary to congestive heart failure) are more common than neurotoxic effects following envenomation by some Indian (*Hottentotta tamulus*)[60,61] and Middle East/North African (*Androctonus crassicauda, Leiurus quinquestriatus*)[56] scorpion species. Respiratory effects in patients with severe envenomation, particularly in young children, include stridor, cyanosis, dyspnea, Cheyne-Stokes breathing, respiratory depression, and the development of pulmonary edema.[62] The presence of tachypnea (respiratory rate >30), diaphoresis, agitation, and dyspnea suggests the development of pulmonary edema.[63]

Clinical Severity

Curry et al. graded the severity of envenomation by the native US species, *Centruroides exilicauda*, based on the presence of pain, paresthesias, and cranial nerve or somatic/neuromuscular dysfunction.[49] Other species of scorpions (e.g., *Centruroides suffussus, Androctonus crassicauda, Androctonus australis, Hottentotta tamulus, Tityus serrulatus, Tityus trinitatis, Leiurus quinquestriatus*) produce more cardiovascular dysfunction compared to *C. exilicauda* and *Parabuthus transvaalicus* Purcell. Table 165.1 displays the four grades of severity modified to include cardiovascular dysfunction. Cranial nerve dysfunction may include blurred vision, disconjugate gaze, hypersalivation, dysphagia, slurred speech, tongue fasciculations, or upper airway obstruction, whereas somatic/neuromuscular dysfunction includes increased involuntary activity (e.g., myoclonic jerks, tremors), restlessness, and hemiballismus.

TABLE 165.1. Clinical Grades of Scorpion Envenomation

Grade	Clinical Features
I	Local pain and/or paresthesias limited to site of envenomation.
II	Local signs plus pain and/or paresthesias remote from site of envenomation.
III	Presence of cranial nerve dysfunction (blurred vision, dysconjugate gaze, hypersalivation, dysphagia, slurred speech, fasciculations) **or** somatic signs (muscle jerking, restlessness, involuntary shaking) **or** cardiovascular dysfunction (moderate to severe hypertension, cardiac dysrhythmias, myocardial ischemia, pulmonary edema).
IV	Presence of any combination of cranial nerve, cardiac, or somatic/neuromuscular dysfunction.

Source: Adapted from Ref 49.

DIAGNOSTIC TESTING

Analytical Methods

Enzyme-linked immunosorbent assays (ELISA) have been developed from polyclonal Fab fragments for the detection of envenomation by North African (*Androctonus australis garzonii* Goyffon & Lamy, *Buthus occitanus* Amoreux, *Androctonus mauritanicus* Pocock),[64,65] and Brazilian (*Tityus serrulatus*) scorpions.[66] In general, the degree of envenomation is proportional to the amount of venom present in the serum of the victim. These tests can detect moderate to severe envenomations, but the sensitivity of some of these assays for mild envenomation is relatively low.[66]

Abnormalities

A variety of cardiac arrhythmias are associated with scorpion envenomation ranging from premature atrial and ventricular contractions to AV nodal block and ventricular tachycardia. In a case series of 17 patients admitted to a Turkish emergency department for scorpion envenomation, the most common electrocardiographic abnormalities in order of frequency were as follows: sinus tachycardia, premature ventricular contractions, premature atrial contractions, and paroxysmal supraventricular tachycardia.[67] Less common electrocardiographic abnormalities were sinus bradycardia, first-degree and second degree atrioventricular block, and atrial fibrillation. Occasionally, during severe envenomations by cardiotoxic scorpion species, electrocardiographic abnormalities may resemble a myocardial infarction with inverted or peaked T-waves, ST elevation or depression, and Q waves, particularly following envenomation by dangerous Middle Eastern and Indian scorpion species.[68] A case series of severe envenomation by *Buthus occitanus* and *Leiurus quinquestriatus* scorpions indicated that serum concentrations of cardiac troponin I are a specific marker of myocardial injury during envenomation by these species.[69] Echocardiographic abnormalities involve segmental hypokinesis and left ventricular dysfunction (ejection fraction <0.55, increased left ventricular end-systolic dimensions, interventricular septal thickening).[70] Myocardial perfusion scans by thallium-201 scintigraphy during severe scorpion envenomation by cardiotoxic scorpion species demonstrates evidence of myocardial hypoperfusion consistent with echocardiographic abnormalities that may persist for at least 2 weeks.[71]

Common laboratory abnormalities include leukocytosis and hyperglycemia.[37] Hyponatremia, hypocalcemia, and a relative hyperkalemia occasionally develop following scorpion envenomation. Rarely, complications of severe scorpion envenomation include acute pancreatitis (hyperamylasemia) after *Tityus trinitatis* evenomation and rhabdomyolysis (elevated creatine kinase).[72,73]

TREATMENT

With the exception of species-specific antivenom, the treatment of scorpion envenomations is supportive including the maintenance of fluid and electrolyte balance, analgesics, and sedatives. During the hypertensive phase of severe scorpion envenomation, the use of cardiovascular agents (vasodilators, adrenergic antagonists, calcium channel blockers) may be necessary depending on the severity of the clinical response. The administration of corticosteroids probably does not alter the course of scorpion envenomation.[74]

Stabilization

Most US envenomations (grade I or II) produce no serious side effects and may be treated with local ice application, local anesthetics or regional nerve block, analgesics (e.g., codeine), antiemetics (metoclopramide, chlorpromazine), and occasionally sedation (benzodiazepines). The immediate, life-threatening complications associated with scorpion envenomation include upper airway obstruction, respiratory depression, pulmonary edema, and cardiogenic shock. Patients should be evaluated carefully for the adequacy of the airway, ventilation, and perfusion. Those patients with signs of systemic toxicity require cardiorespiratory monitoring, intravenous access, and supplemental oxygen, continuous positive airway pressure (CPAP), or intubation as indicated by pulse oximetry and the clinical presentation. These patients should be observed for deterioration of respiratory function secondary to respiratory paralysis, upper airway obstruction, and pulmonary edema.

There are limited data on the efficacy of specific cardiac drugs during scorpion envenomation. In the absence of hypovolemia, intravenous diuretics are appropriate for the treatment of pulmonary edema. The use of a Swan-Ganz catheter may be necessary to optimize fluid replacement and hemodynamic parameters. Vasodilators for the treatment of hypertension include nitroprusside, angiotensin-converting enzyme (ACE) inhibitors (e.g., captopril), and calcium channel blockers (nifedipine).[37] Prazosin is a α_1-blocker that reduces preload and left ventricular impedance without raising heart rate or renin secretion. Case series suggest that prazosin (250 mg, children; 500 mg, adults) orally every 6 hours reduces morbidity and shortens recovery time following scorpion envenomations by the Indian red scorpion (*Hottentotta tamulus*), which is associated with

severe cardiotoxicity.[75,76] Afterload reduction with vasodilators (e.g., nitroglycerin, nitroprusside) is the treatment of choice for scorpion envenomations that develop hypertensive encephalopathy or pulmonary edema.[77] A case series suggests that dobutamine in dosages of 7–20 μg/kg/min titrated to achieve the best compromise between hemodynamic and tissue oxygenation improves left and right ventricular dysfunction following scorpion envenomation associated with cardiogenic shock and pulmonary edema.[78]

Both benzodiazepines (diazepam, lorazepam) and phenobarbital enhance GABA-induced increases in chloride conductance and augment the anticonvulsant effects of GABA neurons in the CNS. Benzodiazepines are the drug of choice to treat seizures associated with scorpion envenomation because of relatively less respiratory depression compared with phenobarbital. The administration of phenobarbital (5–10 mg/kg intravenously) is an option when seizures do not respond to benzodiazepines. Large phenobarbital doses may depress respirations and patients receiving phenobarbital should be monitored closed for respiratory failure, particularly when the patient also receives benzodiazepines.[48]

First Aid

First aid primarily involves rest, reassurance, and transport to a health care facility, particularly if any systemic symptoms develop. There are few data on the efficacy of restrictive bands to retard the distribution of scorpion toxins. Young children should be transported immediately for a medical evaluation when envenomated by dangerous species from scorpion genera (e.g., *Centruroides, Leiurus, Androctonus, Tityus, Hottentotta*) because of the vulnerability of young children to scorpion toxins.

Antidotes

The use of antivenom following scorpion envenomation is controversial, and there are limited data to support the use of scorpion antivenom in addition to supportive care (systemic and local analgesics, ice, cardiorespiratory support), particularly in adults.[50,64] Case series from various parts of the world suggest the scorpion-specific antivenom from animal species (goat, horse, donkey) improves clinical outcome following *severe* scorpion envenomation (e.g., grades III and IV for US bark scorpion) including studies from Arizona (*Centruroides exilicauda*),[79] Brazil (*Tityus serrulatus*),[80] Mexico (*Centruroides* spp. including *C. suffusus suffusus*),[81] Morocco (*Androctonus mauritanicus, Buthus occitanus*),[64] and Saudi Arabia (*L. quinquestriatus, A. crassicauda*).[82,83] However, other studies did not confirm the efficacy of scorpion-specific antivenom for the treatment of cardiovascular and neurological complications of scorpion envenomations, particularly in adults.[84] Variables that affect the efficacy of antivenom include specificity of the antivenom, the potency of the scorpion venom, dose of antivenom administered, the severity of the envenomation, and the delay between envenomation and antivenom administration. Some of these antivenoms are genus-specific. The polyclonal equine antivenom raised against *Tityus discrepans* Karsch is highly cross-reactive with venoms from other *Tityus* species, but not other genera of scorpions (e.g., *Centruroides, Chactas, Brotheas, Rhopalurus, Diplocentrus*).[85] Adverse effects associated with scorpion antivenom include urticaria, diffuse maculopapular rash, and bronchial hyperreactivity.[82] Anaphylaxis is relatively rare following the administration of scorpion antivenom.

In the United States, *Centruroides exilicauda*-specific antivenom has been developed in goats by the Antivenom Product Laboratory, Department of Botany and Microbiology, Arizona State University, Tempe, Arizona. However, this product was never approved by the US Food and Drug Administration (FDA) for transportation across state lines. Current supplies of this whole immunoglobulin G scorpion-specific goat antivenom are limited because of curtailment of production. A case series of 151 bark scorpion envenomations indicated that the administration of one to two vials of antivenom relieved symptoms in 71% of the patients within 30 minutes.[79,86] Adverse effects included immediate hypersensitivity reactions occurring in 8% of the patients receiving antivenom, but these acute reactions were relatively mild. Typically, one vial of antivenom is diluted in 50 mL normal saline, and the infusion is titrated slowly for the first 10 minutes to observe for adverse reaction. If no reaction occurs the remainder is infused over 30–45 minutes. Delayed reactions (serum sickness, rash) are relatively common following the administration of this antivenom. In a retrospective chart review with follow-up contact, 7 of 12 (58%) children receiving *Centruroides* scorpion antivenom had rash, hives, or serum sickness within 2 weeks of the administration of the antivenom.[87] These symptoms usually resolved with a few days after the initiation of oral steroid and antihistamine therapy. Anascorp® (Rare Disease Therapeutics, Inc, Nashville, TN) is an equine $F(ab)_2$ antivenom currently undergoing clinical trials for the treatment of *Centruroides* envenomation in the United States and Mexico.

Supplemental Care

Atropine is not recommended for the treatment of most scorpion envenomations (i.e., scorpions associated with

cardiovascular toxicity) because of the potential to exacerbate adrenergic toxicity. There are inadequate data to support the use of antihistamines, corticosteroids, or calcium during scorpion envenomation without evidence of an allergic response. Hyperthermia is a frequent complication of patients with scorpion envenomation, and patients should be monitored for the development of hyperthermia. Although there are limited data on the effectiveness of specific measures, commonly used measures for the treatment of scorpion-induced hyperthermia include cooling measures (sponge bath, evaporative cooling) and possibly antipyretics (acetaminophen). Routine laboratory tests in severe envenomations include complete blood count, electrolytes, creatinine, amylase, creatine phosphokinase, troponin, and urinalysis.

Children under 3 years of age are at the greatest risk of developing respiratory failure following envenomation by *C. exilicauda*; these children frequently require hospital admission for monitoring, particularly following envenomation by the bark scorpion (*C. exilicauda*).[44] All patients below one year of age and older children with systemic signs of envenomation (i.e., hypersalivation, hypertonus, priapism, fever, dyspnea) require monitoring in an intensive care unit (ICU).[88] For patients with severe, involuntary motor activity and agitation that does not respond to an initial dose of benzodiazepines (e.g., midazolam 0.05–0.1 mg/kg up to 1–2 mg), a midazolam infusion (0.1 mg/kg/h titrated to light sleep) is a treatment option.[89] These patients require careful monitoring in an ICU for respiratory depression, and they are candidates for antivenom therapy. Patients without signs of clinically significant cardiotoxicity can be discharged after a 6-hour observation period.[58]

Chapter 166

SPIDERS
(Order: Araneae)

Spiders are a successful, ancient group of arachnids from the phylum Arthropoda with fossil records dating back 300 million years (Carboniferous period). Although only a few spider species possess fangs large enough to envenomate humans, there are almost 40,000 species of spiders in the order Araneae. Only about 200 species from 20 genera produce clinically significant envenomations in humans even though all spiders are venomous with the exception of spiders from the family Uloboridae. Arthropods (e.g., centipedes, crabs, insects, lobsters, mites, ticks) are bilaterally symmetrical invertebrates that have true body segments, a chitinous exoskeleton, and jointed appendages (antennae, mouth parts, spinnerets, legs). The class Arachnida also includes ticks, mites, vinegaroons, scorpions, and solpugids (Camel spiders). Solpugids are large, quick arachnids that inhabit hot arid regions, such as the Arabian Peninsula. These nocturnal creatures subdue their prey with large chelicerae (jaws) that do not inject venom. The order Araneae is divided into two suborders: Orthognatha (mygalomorph) and Labidognatha (araneomorphs). Species (e.g., Australian funnel-web spiders, tarantulas) from the former are primitive or trapdoor spiders with chelicera projecting forward from the cephalothorax, while the fangs move downward. The chelicera on the araneomorphs (true spiders) project vertically and move together with the fangs like pincers. Figure 166.1 displays a specimen of the Chilean Rose Tarantula (*Grammostola rosea* Walckenaer).

Most bites by spiders cause minimal, if any, toxic effects.[1] Of the approximately 20,000 species of spiders in the United States, at least 50–60 species have fangs capable of penetrating the human skin.[2] Spiders have a cephalothorax and abdomen along with four legs in contrast to most insects (e.g., bees, wasps, mosquitoes, flies), which possess a head, thorax, abdomen, three pairs of legs, one or two pairs of wings attached to the thorax, and one pair of antennae. A hard convex coat (carapace) covers the dorsal aspect of the body, whereas a ventral plate (sternum) envelopes the underside of the cephalothorax. Eight legs and a pair of pedipalps (tactile sensing organ) emerge from the sternum. The anterior end of the cephalothorax contains a pair of jaws (chelicerae) composed of a basal segment and distal fangs. These fangs are mobile and heavily chitinized. A small opening at the tip of the fangs is connected to a venom gland located in the basal segment of the chelicerae in tarantulas. This poison gland extends to the cephalothorax in most spider species. A narrow pedicle connects the cephalothorax and the abdomen, which usually contains spinning organs (spinnerets) on the ventral surface.

Most spiders depend primarily on a sense of touch mediated by mechanoreceptive hairs covering the appendages and other parts of the body because they are extremely shortsighted. However, some hunting spiders have relatively good vision. Spiders inhabit almost every niche in terrestrial habitats including seashores, alpine meadows, deserts, and tropical rain forests. They generally live for 1–2 years. Spiders molt 5 to 10 times before maturity. During this period, they shed their hard shells and may change coloration or markings.

Most spiders are not aggressive or harmful to humans. They feed predominately on insects or other animals including frogs, lizards, and rodents. The major

constituents of spider venom are proteins, enzymes, polypeptide and polyamine neurotoxins, nucleic acids, monoamines, free amino acids, and inorganic salts. These components can cause cytotoxic, hemolytic, or neurotoxic effects. The targets for the neurotoxic components of spider venom are the neuronal receptors, neuronal ion channels, or the presynaptic membrane proteins involved in neurotransmitter release.[3] Components in these venoms can interact with glutamate receptors, ion channels (potassium, sodium, chloride, calcium), presynaptic neurotransmitter release, or cholinergic transmission. However, the weak venom apparatus and the small amount of injected venom limit toxicity in humans. Systemic toxicity of American spiders is limited to two genera (*Latrodectus* and *Loxosceles*), despite the fact that spider venom is more potent than pit viper venom on a weight for weight basis. Spiders are not known to transmit communicable diseases.

WIDOW SPIDERS and OTHER THERIDIID SPIDERS

HISTORY

Superstitions regarding spiders appear in Greek mythology, where the jealous goddess Aphrodite transformed the beautiful young weaver, Arachne, into a spider. *Latrodectus tredecimguttatus* Rossi is native to the northern Mediterranean region, where envenomation by this species probably accounted for the hysteria surrounding the tarantula in the 17th century.[4] Beginning in the 17th century in the southern Italian city of Taranto and then throughout Europe, panic spread concerning spider bites that caused muscle contractions and pain. These envenomations were attributed to the large European wolf spider (*Lycosa tarantula* L.), commonly called a tarantula. The tarantella was a dance devised to protect inhabitants from what was erroneously believed to be bites by the wolf spider. The mild-mannered North and South American tarantula species produce a bite similar to that of a hymenoptera sting without systemic toxicity.[5] Many species of tarantulas possess urticaria-producing hairs on the dorsal surface of the abdomen. A case series of 515 individuals bitten by the South American wolf spider indicates that local necrosis or severe systemic symptoms are not usually associated with bites by these species.[6] In the 1970s, *Latrodectus* venom was an experimental treatment to accelerate recovery from botulism.[7] In mice paralyzed by botulinum toxin, the injection of black widow spider venom was associated with enhanced sprouting of the axons and earlier return of muscle function compared with the injection of botulinum toxin alone.[8]

IDENTIFYING CHARACTERISTICS

Widow spiders (*Latrodectus* spp.) include about 40 species belonging to the family Theridiidae (comb-footed spiders). Other theridiid spiders capable of producing less severe human envenomation compared with widow spiders include spiders from the genera Steatoda and Achaearanea. The female widow spider is one of the largest female spiders with a leg span up to 5 cm (~2 in.) and a body length of 1–1.5 cm (~0.4–0.6 in.). *L. mactans* Fabricius and *L. geometricus* C. L. Koch females have the characteristic red or orange-red hourglass spot on the ventral surface of their black, shiny abdomen, whereas the *L. tredecimguttatus* Rossi (European widow spider) has two red marks that do not coalesce. Three US species are predominantly black (i.e., *L. mactans* Fabricius, *L. hesperus* Chamberlin & Ivie, *L. variolus* Walckenaer), whereas other *Latrodectus* species are brown (*L. geometricus* C. L. Koch, *L. indistinctus* O. P.-Cambridge) or orange-red (*L. bishopi* Kaston). *Latrodectus geometricus* C. L. Koch has well-demarcated geometric markings, ranging in color from cream to brown-orange. Marked intraspecies variation may occur as a result of molting. These black spiders become darker with less prominent red spots with each molt. In contrast to most other black spiders, the legs of

Latrodectus species are smooth. The substantially smaller male spider retains the more colorful white markings and geometric patterns during the immature stages of development.

Widely distributed cosmopolitan spiders from the genus *Achaearanea* are common inhabitants of houses and bushland in Australia and the United States. *Steatoda* species (cupboard spider, false widow spider, brown house spider) are small brown or black spiders that usually have white markings without red coloration. These spiders are typically smaller than black widow spiders, but larger specimens (e.g., *Steatoda grossa* C. L. Koch) may resemble the black widow spider.

EXPOSURE

Geographic Distribution

Latrodectus species are cosmopolitan spiders that inhabit all parts of the world except ecological extremes (e.g., high mountains above 8,000 feet, hot deserts, polar ice caps), in part, as a result of human transport.[9] Members of *Latrodectus* species are present in North and South America, Southern Europe, Southern Africa, the Middle-East, Asia, New Zealand, and Australia. There are about 30 species of *Latrodectus* distributed throughout the world as demonstrated by Table 166.1. Widow spiders include the red-back spider in Australia, the brown and black button spider of South Africa, the New Zealand katipo, and the widow spiders of Europe and South America.

TABLE 166.1. Distribution of Some Relatively Well-Known Species of *Latrodectus*

Latrodectus Species/ Authority	Distribution
antheratus Badcock	Paraguay, Argentina
apicalis Butler	Galapagos Islands
atritus Erquhart	New Zealand
bishopi Kaston	United States, Florida primarily
cinctus Blackwell	Cape Verde Islands, Africa, Kuwait
corallinus Abalos	Argentina
curacaviensis Muller	Lesser Antilles, South America
dahli Levi	Middle East to Central Asia
erythromelas Schmidt & Klaas	Sri Lanka
geometricus C. L. Koch	Worldwide
hasselti Thorell	Southeast Asia, Australia, New Zealand
hesperus Chamberlin & Ivie	Western United States
hystrix Simon	Yemen, Socotra Island
indistinctus O.P.-Cambridge	Namibia, South Africa
karrooensis Smithers	South Africa
katipo Powell	New Zealand
lilianae Melic	Spain
mactans Fabricius	North America
menavodi Vinson	Madagascar, Comoro Islands
mirabilis Holmberg	Argentina
obscurior Dahl	Cape Verde Islands, Madagascar
pallidus O.P.-Cambridge	Libya to Russia and Iran
quartus Ablos	Argentina
renivulvatus Dahl	Africa, Saudi Arabia, Yemen
revivensis Shulov	Israel
rhodesiensis MacKay	Southern Africa
tredecimguttatus Rossi	Mediterranean to China
variegatus Nicolet	Chile, Argentina
variolus Walckenaer	United States, Canada

North and South America

One of the five US species of *Latrodectus* is present in every state except Alaska. These species include *Latrodectus mactans* Fabricius (black widow from the South and East), *Latrodectus hesperus* Chamberlin & Ivie (western black widow), *Latrodectus variolus* Walckenaer (eastern United States, Canada), *Latrodectus bishopi* Kaston (red or red-legged widow spider from limited area of scrub pines in central Florida), and *Latrodectus geometricus* C. L. Koch (brown widow). The latter species is found throughout the world. The prominent *Latrodectus* species in South America is *L. curacaviensis* Muller.

Asia–Pacific

Medically important widow spiders (family Theridiidae) from the Asia–Pacific region include the red-back widow spider (*L. hasselti* Thorell), the New Zealand katipo (*L. katipo* Powell), and the cupboard or false black widow spiders (*Steatoda* spp.). Spiders in this region other than Theridiidae that cause potentially serious neurotoxicity include the Australian funnel-web spiders (Atracinae subfamily) and Australian mouse spiders (Actinopodidae family).[10]

South Africa

The three species of *Latrodectus* found in South Africa are *L. indistinctus* O. P.-Cambridge (black widow or black button spider), *L. geometricus* (brown widow or brown button spider), and *L. rhodesiensis* MacKay (Rhodesian widow spider). Macroscopically, the latter

two species are indistinguishable, but the egg sac of *L. geometricus* is several times larger and wooly. *L. indistinctus* O. P.-Cambridge is an endemic species to South Africa found throughout rural areas (bushes, shrubs, grass tufts, loose debris), whereas *L. geometricus* C. L. Koch is primarily an urban species.

Behavior

Latrodectus species are general predators that feed on a variety of prey including other arachnids, insects, crustaceans, and small vertebrate (i.e., mice, geckos, lizards).[11] The male is smaller, shorter lived, and less aggressive than the female; consequently, the male does not usually produce latrodectism. Female widow spiders are venomous from birth, but their venom toxicity is seasonal, peaking in the warmer months. These shy, sedentary, trapping spiders use their venom to paralyze and extract the hemolymph from prey, primarily at night. A period of postcopulation lassitude allows the male spider to escape unless the female has a voracious appetite. Female widow spiders form irregular, untidy three-dimensional webs in dark, hidden protected places (e.g., crevices, ground cover, stone walls, woodpiles, barns, stables, outdoor toilets). *Latrodectus* bites usually occur when the widow spider is disturbed while residing in man-made objects (clothes, shoes, furniture, closets, sheds, attics, woodpiles), primarily on an extremity. Contrary to popular belief, both females and males often live together.

PRINCIPAL TOXINS

Venom Composition

Medically important *Latrodectus* species produce potent neurotoxins. Although *Latrodectus* venom contains low-molecular-weight purine derivatives and at least seven protein fractions (e.g., hyaluronidase, phosphodiesterase, GABA, and 5-hydroxytryptamine),[12] examination of the venom of European widow spider (*L. tredecimguttatus*) indicates that the major toxin is a high-molecular-weight (i.e., 120,000 Da), presynaptic neurotoxin called α-latrotoxin.[13] Other high-molecular-weight neurotoxins (e.g., α-latroinsectotoxin, δ-latroinsectotoxin) also are present, but the role of these neurotoxins following envenomation requires further study.[14,15] Although the presence of α-latrotoxin in all *Latrodectus* species has not been confirmed, *Latrodectus* venoms are probably structurally similar because of the clinical similarity of toxic effects produced by most *Latrodectus* venoms.[1] The low-molecular-weight compounds probably do not contribute to the neurotoxicity associated with latrodectism.[16] Variation in venom potency occurs between species and during different seasons based on animal studies.[17] Animal susceptibility is variable with sensitivity relatively high in camels and horses compared with rats.

Venom Apparatus

The small size of the male fangs prevents envenomation under most circumstances. The female widow spider has a pair of venom glands in the cephalothorax with the walls of these glands containing striated muscles that control the delivery of the venom.[18] Figure 166.2 demonstrates the venom apparatus of *Latrodectus* species.

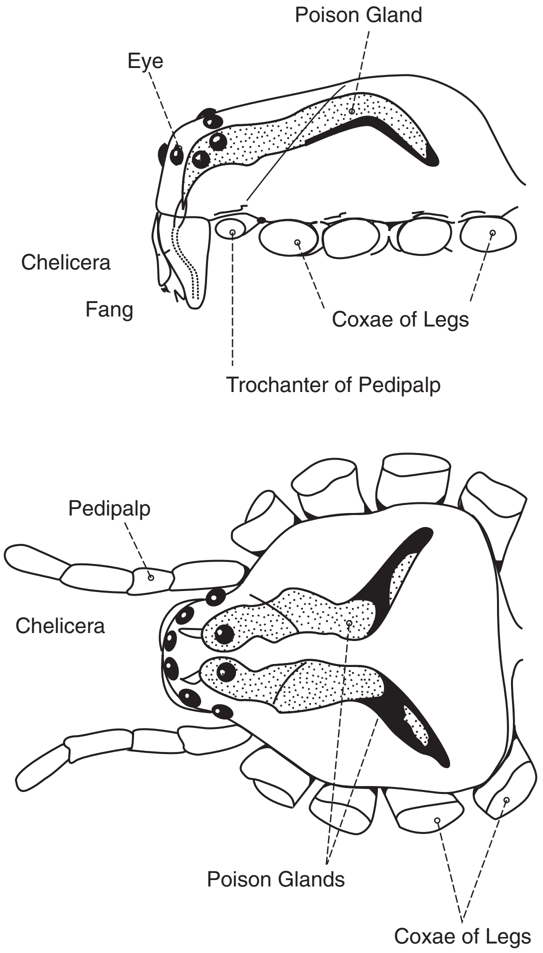

FIGURE 166.2. The venom apparatus of *Latrodectus* species. Adapted from Wong RC, et al. Spider bites. Arch Dermatol 1987;123:99.

Dose Response

The severity of an envenomation depends on a number of factors including the size of the spider, the physical condition of the spider, season, locations of the bite, amount of venom injected, susceptibility of the victim, and, to a lesser extent, on the species. In animals, the LD_{50} of *L. geometricus* venom is lower than *L. mactans* (i.e., 0.43 mg/kg vs. 1.39 mg/kg, respectively). Black button spiders (*L. indistinctus*) characteristically produce more severe envenomation compared with brown button spiders (*L. geometricus*).[19] Based on LD_{50} tests in mice, the venom of *L. indistinctus* was 3–4 times more potent than the venom of *L. geometricus*.[20]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Black widow spider venom contains several large proteins (i.e., latrotoxins), which selectively target different classes of animals including vertebrates, crustaceans, and insects.[21] Latrotoxins act by several Ca^{++}-dependent and Ca^{++}-independent mechanisms based on pore formation and receptor activation.[22] All latrotoxins including α-latrotoxin produce massive, spontaneous release of several types of neurotransmitters (GABA, norepinephrine, acetylcholine) by facilitating synaptic vesicle exocytosis from presynaptic nerve terminals.[23] These neurotoxins cause the clinical features (e.g., diaphoresis, muscle fasciculation) associated with latrodectism. The postsynaptic membranes remain unaffected. α-Latrotoxin is a 120 kDa protein that depletes presynaptic vesicles by binding to two distinct families of neuronal cell-surface receptors to trigger exocytosis.[10,24] Major high-affinity receptors for α-latrotoxin include a G protein-coupled receptor (latrophilin) and a single-transmembrane receptor (neurexin). Exocytosis of classical neurotransmitters (glutamate, GABA, acetylcholine) is calcium-independent as a result of the direct intracellular action of α-latrotoxin, whereas exocytosis of catecholamines requires extracellular calcium. High concentrations of calcium theoretically facilitate the release of neurotransmitters by endogenous electrical stimulation while inhibiting venom-induced release.[4] However, the clinical efficacy of calcium for relief of pain associated with widow spider envenomation is questionable. Both botulinum toxin and black widow spider venom cause presynaptic blockade of neuromuscular transmission. However, botulinum toxin impairs the release of acetylcholine and persistent paralysis of skeletal muscle that requires sprouting of axons and formation of new motor end-plates prior to recovery.

CLINICAL RESPONSE

Latrodectus Species

Envenomations by all species of *Latrodectus* produce similar clinical features depending on the degree of envenomation and slight differences in the potency of the venom.[25] The predominant feature of *Latrodectus* envenomation is pain. Although *Latrodectus* bites may be painless, most bites cause a mild pinprick sensation that produces local pain, sweating, erythema, and piloerection in the affected extremity within 1 hour of envenomation. The characteristic skin reaction is a halo or target lesion characterized by two central punctuate fang marks 1 mm apart surrounded by an outer erythematous ring. Slight swelling may develop along with urticaria and pruritus, particularly following bites by *L. hesperus*. Necrosis does not occur following envenomation. Local symptoms often subside within a few minutes, and cutaneous signs of envenomation may be absent when the patient presents for medical care. Approximately 75% of *Latrodectus* bites involve only local symptoms that do not progress to systemic effects.[26] The presence of localized piloerection and sweating is highly suggestive of latrodectism, particularly when a target lesion is present.

In about 25% of *Latrodectus* bites, systemic evidence of envenomation develops with severe pain being the most consistent feature of *Latrodectus* envenomation.[27] Within the first few hours after envenomation, the gradual onset of progressive, local pain, sweating, piloerection, and muscle fasciculations occurs.[28] Diaphoresis may be generalized or limited to the local area of the envenomated extremity. Common symptoms of severe envenomations involve intense, generalized abdominal, back, and leg pains.[29] Muscle spasms begin on the upper body following upper extremity bites or in the abdominal wall following bites in lower extremities. Chest or abdominal pains may become severe with the intensity of the abdominal pain simulating acute peritonitis (i.e., without direct or indirect abdominal tenderness to palpation). The sudden onset of irritability, hypertension and sweating in a child is suggestive of *Latrodectus* envenomation.[30]

Associated clinical features of latrodectism include nausea, vomiting, headache, tremulousness, anxiety, tachycardia, chest tightness, sweating, mild pyrexia, lacrimation, salivation, and increased bronchorrhea.[31] Hyperesthesias (especially on the feet), paresthesias, fasciculations, ptosis, hyperreflexia, urinary retention, uterine contractions, and convulsions also occur. The course of symptoms may follow a cyclical pattern with spontaneous improvement and then deterioration.[28] Most envenomations by the *Latrodectus* species produce

symptoms that peak in 3–4 hours, and resolve within 2–3 days.[32,33] However, subjective symptoms of weakness, headache, insomnia, myalgias, paresthesias, and malaise may persist for weeks, particularly in patients not receiving antivenom.[34,35] Death is rare, even in young children.[36] Susceptible patients include the elderly, infants, patients with preexisting cardiovascular disease, and pregnant women. Hypertension occurs frequently, but few case reports associate complications secondary to hypertension during latrodectism. Rare complications include renal dysfunction,[37] priapism, herpes zoster,[38] and pulmonary edema.[39] Several case reports of pregnant women envenomated during the second and third trimesters of pregnancy did not describe adverse fetal effects.[40]

Other Theridiidae Species

Some theridiid spiders other than *Latrodectus* species (e.g., *Steatoda* spp.) produce a neurotoxin that causes nausea, vomiting, feverishness, intense radiating pain, and diffuse myalgias. The envenomation by spiders from the genus *Steatoda* may cause prolonged pain and the systemic effects similar, but usually less severe, than envenomations by *Latrodectus* species.[41] However, diaphoresis is not usually part of the clinical course following envenomation by *Steatoda* species.[42] These spiders inhabit many parts of the world including the Americas, Australia, Europe, and South Africa. Most bites by the theridiid spiders (false button spiders, false widow spiders, cob-web spiders) produce no or mild local symptoms without systemic complaints. Bites by spiders from the genera *Achaearanea* may cause moderate to severe, prolonged pain along with some mechanical trauma (puncture marks, local bleeding).

DIAGNOSTIC TESTING

Analytical Methods

There are no clinical tests to detect latrodectism. The diagnosis of *Latrodectus* envenomation is based on clinical features and the identification of the spider. The presence of localized piloerection and sweating is almost pathognomonic of latrodectism, particularly when a target lesion is present. However, the appearance of these clinical features is not required for the diagnosis of latrodectism.

Abnormalities

Most laboratory tests remain normal following *Latrodectus* envenomation. Leukocytosis and mildly elevation of the serum creatine kinase (CK) may occur in moderate to severe cases. Albuminuria may develop, but renal function usually remains normal unless prerenal azotemia occurs.

TREATMENT

Prehospital treatment of latrodectism involves limitation of activity, comfort measures, and transport. There are inadequate clinical data to support the use of any specific first-aid measures (tourniquet, local incision, suction). Wounds should be cleaned and tetanus prophylaxis given as indicated. Antibiotics are not usually indicated. The treatment of envenomation by other theridiid spiders (e.g., *Steatoda* species) usually involves only supportive care, except following severe envenomation that may require antivenom.

Antivenom

Latrodectus antivenom is available in the United States (Merck & Co., West Point, PA), Australia (Commonwealth Serum Laboratories, Melbourne, Australia), South Africa (South African Institute for Medical Research, South Africa), and Mexico (Instituto Bioclon, Calzada de Telapan, Mexico; Aracmyn®).[43] The latter antivenom is a polyvalent antivenom for latrodectism and loxoscelism. There is substantial cross-reactivity between *Latrodectus* venom within US species and throughout the world. *In vitro* data suggests that antivenom for numerous *Latrodectus* species (e.g., *L. mactans, L. hesperus, L. hasselti, L. katipo, L. tredecimguttatus*) produce antibodies against α-latrotoxin and provide at least partial protection from envenomation by these species based on animal studies[44,45] and case reports.[46] The antivenom from the United States is a hyperimmune, equine whole IgG (150 kDa) serum product derived from *L. mactans* venom, and this antivenom is effective for all US species. Skin testing prior to the use of the antivenom is recommended by the US manufacturer, but not in Australia where the antivenom is a trypsin-digested, equine $F(ab)_2$ IgG fragment (100 kDa). Although skin testing may detect a highly allergic individual, a negative skin test does not exclude the possibility of an allergic response following the administration of antivenom. Prior or current evidence of horse serum sensitivity is a contraindication to the use of *Latrodectus* antivenom or skin testing because most envenomated patients respond to supportive care. Most patients with mild to moderate envenomations require only supportive care.

Anecdotal evidence suggests that the use of *Latrodectus* antivenom reduces the duration of symptoms

associated with severe envenomations by *Latrodectus* species.[29] Patients with signs of systemic envenomation or severe local symptoms unresponsive to parenteral analgesics are candidates for the administration of antivenom. Therefore, indications for antivenom use include pain unresponsive to parenteral analgesics, particularly in pediatric or geriatric patients, pregnant women,[47] patients with cardiovascular disease and uncontrolled hypertension, and patients with respiratory depression. However, few controlled studies of humans document the efficacy and safety of *Latrodectus* antivenom.[32] The usual dosage is 1 or 2 vials diluted in 50–100 mL of saline and infused over 30 minutes to 1 hour. A preliminary study of Red-back spider antivenom (Commonwealth Serum Laboratories) suggested the average amount of antivenom used for patients presenting to Western Australian hospitals with Red-back spider envenomation was 2–3 vials with only 21% receiving one vial to control symptoms.[48] This study did not detect a significant difference between the intramuscular and intravenous administration of antivenom, but the small number of cases and the large number of patients lost to follow-up limits conclusions regarding the most efficacious route of antivenom administration. Rapid infusion of antivenom may cause histamine release and an anaphylactoid reaction. Symptoms usually resolve within an hour after the infusion ends, and the presence of systemic signs of envenomation over 2 hours after the infusion ends suggests the need for an additional vial of antivenom.[26,29] Pregnancy is not a contraindication to the use of *Latrodectus* antivenom.[49] Case reports suggest that patients with signs of systemic envenomation may respond to antivenom therapy even though envenomation occurred several days earlier.[50] Patients, who respond to the administration of *Latrodectus* antivenom without complications, do not require admission to the hospital because relapse of systemic symptoms is unusual.

Serum sickness and anaphylactoid reactions are rare (i.e., 1–2%) following the intramuscular use of Australian purified *Latrodectus* antivenom, but patients should be re-evaluated within 1 week for the development of serum sickness.[51,52] Case reports suggest that some envenomated patients, who fail to respond to intramuscular injections of the antivenom, will respond to *Latrodectus* antivenom administered by intravenous infusion.[53] Fatalities are rare during the use the antivenom, although a case report documented the occurrence of an asthmatic dying of severe bronchospasm during treatment with US *Latrodectus* antivenom. Severe envenomation by the female Australian Cupboard spider (*Steatoda grossa* C. L. Koch) produces clinical features similar to latrodectism, and the administration of red-backed widow spider venom from Australia (Commonwealth Serum Laboratories) to these patients resulted in rapid clinical improvement.[54]

Supplemental Care

Generalized spasms may respond to the judicious use of intravenous opiates (morphine 0.1–0.2 mg/kg every 2–4 hours, hydromorphone 1–2 mg for an adult every 3–4 hours) and/or muscle relaxants (diazepam 0.04–0.2 mg/kg, lorazepam 0.01–0.015 mg/kg) with careful observation of the adequacy of respirations. Warm moist compresses are often soothing. Some authors recommend 10% intravenous calcium gluconate (0.2 mL/kg or 0.1 mEq Ca^{++}/kg up to 10 mL) given slowly with continuous cardiac monitoring. Calcium gluconate is the preferred calcium solution because calcium chloride is more irritating to tissues. The analgesia provided by intravenous calcium is often inconsistent and short-acting. Case series of latrodectism suggest that calcium administration in this setting frequently does not relieve the pain associated with *Latrodectus* envenomation.[29] Intravenous methocarbamol (Robaxin®, Whitehall-Robins, Richmond, VA) is probably inferior to intravenous calcium for the pain associated with latrodectism based on case reports.[55] There are inadequate clinical studies to evaluate the efficacy of benzodiazepine compounds (diazepam, lorazepam) or dantrolene (1 mg/kg over 15 minutes every 2 hours).[56]

ARMED (BANANA) SPIDER

These large (30 mm/~1 in.) South American banana (wandering) spiders belong to the genus *Phoneutria* (Ctenidae family) that inhabit eastern areas of Central and South America. In Brazil, the clinically most important species is *P. nigriventer* Keyserling (west central, southeast, south).[57] Other species of Brazilian wandering spiders include *P. fera* Perty (Amazon, Ecuador, Peru, Guiana) and *P. reidyi* F.O.P.-Cambridge (Amazon). The genus is characterized by the location of three rows of eyes distributed as follows: the first row of two

eyes near the edge of the chelicerae, the second row containing four eyes, and the third row composed of two eyes. These large spiders (body length: 3 cm/~1 in., leg span: 15 cm/~6 in.) are covered with short, gray to gray brown hairs on the body and red hairs on the basal segment of the chelicerae. These large neurotoxic spiders can be confused with large, harmless *Cupiennius* spiders, which also inhabit banana clusters and possess similar distinctive brushes of red hairs surrounding the chelicerae. These aggressive, hunting *Phoneutria* spiders actively defend themselves by menacingly holding the front pair of legs toward the offending stimulus. These venomous spiders are found primarily along the coast of Brazil. They wander into rural dwellings and attack inhabitants during sleep or work. They do not build webs.[58]

The venom of *Phoneutria* spiders interferes with transmission of impulses in calcium and sodium channels found in excitable cells. The neurotoxic venom of *P. nigriventer* Keyserling is a complex mixture of polypeptides (T×1, T×2, T×3, T×4) that are potent activators and blockers of ionic channels.[59,60] The main neurotoxic effect is the action of the venom on voltage-gated Na^+ channels that causes repetitive-action potential discharge and depolarization of the muscle membrane. These neurotoxins produce a variety of effects in animal models including activation of voltage-dependent sodium channels, neuromuscular blockade, release of acetylcholine and norepinephrine, contraction of smooth muscle, and local edema.[61,62] In experimental animals, polypeptides of molecular mass ranging from 4–9 kDa also block calcium channels, resulting in flaccid paralysis.[63] In these animal models, T×3–3 inhibits ω-agatoxin IVA-sensitive calcium channels, which controls exocytosis by decreasing calcium influx and glutamate release.[64] Animal studies indicate that *P. nigriventer* venom temporarily disrupts the blood–brain barrier and allows the passage of molecules into the brain.[65]

Most envenomations by these spiders produce mild pain, edema, local sweating, elevated blood pressure, nausea, and piloerection that resolve within 24–48 hours.[57] Rarely, severe envenomations may occur, particularly in young children. Clinical features of severe envenomations include parasympathetic stimulation, profuse sweating, muscle spasms, priapism, bradycardia, hypotension, and pulmonary edema.[57] Antivenom is available in Brazil (Butantan Soro Antiarachnidico Butantan Institute, Sao Paulo, Brazil) for intravenous administration in doses of 2–5 ampules intravenously or intramuscularly. Supportive care includes wound cleansing, tetanus prophylaxis, elevation, and immobilization of the affected extremity, and warm compresses.

AUSTRALIAN FUNNEL-WEB SPIDERS

The Australian funnel-web spiders (*Atrax* spp., *Hadronyche* spp.) belong to the family: Hexathelidae: subfamily: Atracinae. These large (body length: 24–32 mm/~1-1¼ in.), highly venomous spiders inhabit the moist, eastern seaboard of Australia and Tasmania, as well as limited areas in southern Australia near Adelaide. Most reports of funnel-web spider bites involve the Sydney funnel-web spider (*Atrax robustus*) found in densely populated areas of the Sydney basin. A review of documented funnel-web spider envenomation indicated that the funnel-web spider species most commonly associated with severe envenomations included *Atrax robustus* O.P.-Cambridge (Sydney), *Hadronyche formidabilis* Rainbow (Northern tree), *H. cerberea* L. Koch (Southern tree), *H. infensa* Hickman (Toowoomba), and *H. versuta* Rainbow (Blue mountains).[66] Funnel-web spiders build long silk retreats in the ground with two large spinnerets, frequently near a tree. These nocturnal spiders adopt an upright stance when provoked. Mygalomorph spiders other than species in the Hexathelidae family include the mouse spiders (*Missulena* species) and other funnel-web spiders of the Hadronyche species. In general, these spiders are medium to large in size with characteristic prominent forward facing jaws (chelicerae) and large parallel fangs. These mygalomorphs (i.e., mouse, diplurid, idiopid, and nemesiid spiders) are difficult to distinguish from funnel-web spiders.[67]

PRINCIPAL TOXINS

The venom from the Australian funnel-web spider (*Hadronyche versuta* Rainbow) contains at least 100 components.[68] Adverse effects of funnel-web spider envenomations on mammals result primarily from the actions of δ-atracotoxins on the peripheral nervous system. In a manner similar to scorpion α-toxins, these excitatory neurotoxins cause spontaneous repetitive firing and prolongation of action potentials in excitable cells via slowing of voltage-gated Na^+ channel inactivation and the hyperpolarizing shift of the voltage-dependence of activation.[69] The spontaneous repetitive firing of action potentials and the release of excessive amounts of neurotransmitters (e.g., epinephrine, acetylcholine, norepinephrine) cause muscle fasciculations and autonomic instability.[70] The voltage-

dependent binding of δ-atracotoxins to neurotoxin receptor site-3 is similar, but not identical, to the binding of α-scorpion toxins and sea anemone toxins.[71]

Primates are much more susceptible to the effects of δ-atracotoxins than other vertebrates.[72] Although the female funnel-web spider secretes much more venom than a male spider, the venom of the female spider demonstrates much lower neurotoxicity compared with male spider venom.[73] Janus-faced atracotoxins are a unique family of invertebrate-specific potassium channel blockers that are being investigated as insecticides.[74] The venom of the Eastern mouse spider (*Missulena bradleyi* Rainbow) contains a neurotoxin that facilitates neurotransmitter release by modifying tetrodotoxin-sensitive sodium channel gating, similar to δ-atracotoxin in funnel-web spider venom.[75] Consequently, bites from this spider potentially produce similar clinical effects as funnel-web spider envenomation.

CLINICAL RESPONSE

The clinical features of funnel-web spider bites are difficult to predict because many bites do not cause systemic envenomation. In a case series of 4 bites by *Atrax robustus* O.P.-Cambridge and 12 bites by *Hadronyche* species, 10 patients had only local effects that resolved within 3 hours, whereas 4 patients had moderate envenomation and 2 patients had severe envenomation requiring antivenom therapy.[67] Typically, the bite of a funnel-web spider is very painful as a result of the relatively large size of the fangs and the acidic pH of the venom. The initial pain over the puncture site may last for 30–60 minutes along with local bleeding from the puncture wound. Initial local features of envenomation include the rapid onset of local muscle fasciculation, sweating, and piloerection within minutes after envenomation. Local muscle fasciculation and paraesthesias are highly characteristic of envenomation by this spider. Early symptoms of systemic envenomation involve profuse sweating, salivation, lacrimation, dyspnea, and neuromuscular excitation including paresthesias and generalized muscle fasciculations. Rapid progression to confusion, agitation, coma, metabolic acidosis, cerebral edema, and noncardiogenic pulmonary edema may occur within 1–2 two hours after envenomation. Other features of funnel-web spider envenomation include muscle spasms, tachycardia, hypertension, cardiac arrhythmias, and gastrointestinal distress. Late effects include persistent hypotension, coma, rhabdomyolysis, coagulopathy, disseminated intravascular coagulation, and multiorgan failure. Death may result from noncardiogenic pulmonary edema or cerebral edema.[76] In a review of severe cases of documented funnel-web spider envenomations, clinical effects associated with a majority of severe envenomations included diaphoresis, hypertension, tachycardia, fasciculations, and pulmonary edema.[66]

Envenomations by some *Hadronyche* species can produce a life-threatening clinical syndrome indistinguishable from that of *Atrax robustus* including Port Macquarie funnel-web, Southern Tree funnel-web (*Hadronyche cerberea*), Northern Tree funnel-web (*Hadronyche formidabilis*), and the Darling Downs funnel-web (*Hadronyche infensa*).[77] Clinical features of envenomation by *H. infensa* (Toowoomba funnel-web) included generalized paresthesias, muscle spasm, blurred vision, fasciculations, local induration and pain, salivation, lacrimation, and altered consciousness.[78] Envenomation by mouse spiders (*Missulena* spp.) typically cause local effects, occasionally with paraesthesias and diaphoresis, but the envenomation is not usually serious.[67]

TREATMENT

Recommended first aid treatment in Australia includes the use of pressure-immobilization (i.e., wrapping of the extremity with a large pressure bandage similar to an ankle sprain along with immobilization).[79] Although there are few data on the efficacy of pressure-immobilization to limit the spread of atraxotoxin, case reports associate the removal of pressure-immobilization bandages with clinical deterioration.[80] Rabbit-derived IgG antivenom (Commonwealth Serum Laboratories) to the Sydney funnel-web spider (*Atrax robustus*) was introduced in the 1980s. *In vitro* studies suggest that the venom of most Australian funnel-web spiders share common antigens.[81] Symptomatic patients are candidates for the administration of antivenom, particularly if the symptoms progress rapidly. The initial adult and pediatric dose is 2–4 vials (100 mg IgG/vial) of antivenom intravenously, repeated in 15 minutes if symptoms do not significantly improve. Additional doses may be necessary for severe envenomations. Skin testing is not usually recommended. Although some physicians administer H_1 and H_2 receptor antagonists prior to antivenom administration, there are few clinical data to guide management. Patients should be carefully monitored in an intensive care setting for the development of urticaria, stridor, bronchospasm, and hypotension. The decision to continue antivenom therapy despite the appearance of clinical signs of anaphylaxis depends on the clinical evaluation of the risks and benefits of antivenom therapy. Pre-treatment of antihistamines, concurrent administration of epinephrine, and a slow rate of antivenom administration

are therapeutic options for restarting antivenom therapy in these patients when anaphylactic responses occur.[82]

This antivenom demonstrates cross-reactivity with other funnel-web spiders (*Hadronyche* spp.), although antivenom requirements may be greater.[77] Envenomations by mouse spiders (*Missulena* spp.) rarely produce systemic symptoms as severe as funnel-web spiders,[83] but the administration of funnel-web spider antivenom has been associated with remission of a severe envenomation by the Eastern mouse spider (*Missulena bradleyi*).[25] All patients with signs of Australian funnel-web envenomation should be observed in an intensive care unit for the development of delayed noncardiogenic pulmonary edema.

BROWN RECLUSE SPIDERS

HISTORY

Caveness first described *Loxosceles*-induced, necrotic skin lesions in the US medical literature in 1872.[84] In 1929, Schmaus associated a case of necrotic arachnidism with the bite of *Loxosceles reclusa* Gertsch & Mulaik (i.e., initially identified as *L. rufescens*, but probably *L. reclusa*).[85] However, the bite of the *Loxosceles* spider was not confirmed as a cause of necrotic lesions until 1947 when Macchiavello confirmed necrosis in a guinea pig model following the bite of *Loxosceles laeta* Nicolet in Chile.[86,87] Although clinical cases of fever associated with brown spider bites were reported in the United States from the late 1800s[84] to the 1940s,[88] the causal relationship between cutaneous necrosis and *Loxosceles* bites was not confirmed in the United States until the late 1950s.[89]

IDENTIFYING CHARACTERISTICS

Loxosceles species belong to the Sicariidae family (formally in Loxoscelidae or Scytodidae), which includes primitive hunters in the genera *Loxosceles* (100 species) and *Sicarius* (21 species).[90] These medium-sized (6–10 mm/~0.2–0.4 in.), nondescript spiders possess a uniformly colored cephalothorax that is dull yellow to light brown to gray. The cephalothorax contains a dark-brown, violin-shaped marking on the dorsal surface that is somewhat variable. The presence of the fiddle-shaped mark on the anterior carapace varies depending on species, age, and condition of the specimen. Other brown spiders (*Kukulcania* species, Filistatidae family) may exhibit similar markings. The abdomen usually is olive-tan. The legs and abdomen are covered with fine hairs, and the legs lack the large leg spines commonly present on most brown spiders.[91] The presence of the violin-shaped marking and six eyes arranged in three diads (one anterior, two lateral) suggests that the spider belongs to the genus *Loxosceles*. Two closely related species (*Scytodes* spp., *Sicarius* spp.) have similar eye patterns; therefore, the presence of six eyes alone does not confirm the presence of *Loxosceles* spiders. Spiders of this genus seldom have a prominent colored pattern. There are 11 species of native *Loxosceles* spiders in North America.[92]

Common Name: Brown Recluse, Fiddleback, Violin or Brown Spider

Scientific Name: *Loxosceles reclusa* Gertsch & Mulaik

Physical Description: These medium-sized, brown spiders possess short, hairy bodies about 7–12 mm (average 9 mm/~0.35 in.) long with long, thin, hairy legs up to a span of 1–5 cm (~0.4–2 in.). The hairs are fine and dark. Their color varies from fawn to dark brown depending on the stage of molting and on the species. For example, *L. laeta* Gertsch & Mulaik is pale brown, whereas specimens of *L. gaucho* Gertsch are dark chocolate. The anterodorsal portion of the cephalothorax has a violin-shaped dark brown to yellow marking with the larger end cephalad. Brown recluse spiders have three pairs of eyes in contrast to most spiders, which have four pairs of eyes. The size and venom apparatus of female and male brown recluse spiders are similar; therefore, both sexes of violin spiders are equally capable of producing loxoscelism.

EXPOSURE

Geographic Distribution

The distribution of the genus *Loxosceles* is worldwide in temperate and tropical regions with about 100 species throughout America, Europe, Africa, Asia, and Oceania. There are 11 native and 2 nonnative *Loxosceles* species in the United States that inhabit primarily the Southeast and warmer portions of the Midwest. Endemic *Loxos-*

celes species in North America include *L. deserta* Gertsch and *L. reclusa* Gertsch & Mulaik. The highest number of *Loxosceles* envenomations in the United States occurs in Arkansas, Tennessee, Missouri, and Kansas.[93] At least 17 *Loxosceles* species (e.g., *L. spinulosa* Purcell, *L. speluncarum* Simon, and *L. parrami* Newlands) inhabit Africa that can produce necrotic lesions.[94] *Loxosceles rufescens* Dufour occurs in countries in the Mediterranean region, particularly in Israel.[95] *Loxosceles* species also appear in Asian–Pacific countries (e.g., China, Japan, Australia),[96] South Africa (*L. spinulosa* Purcell, *L. speluncarum* Simon, *L. parrami* Newlands),[94,97] and South America (*L. gaucho* Gertsch, *L. laeta* Nicolet, *L. similis* Moenkhaus, *L. adelaida* Gertsch, *L. hirsuta* Mello-Leitao, *L. amazonica* Gertsch, *L. intermedia* Mello-Leitao).[98]

Loxosceles Reclusa Gertsch & Mulaik

This spider is endemic to the midwestern and southeastern portions of the United States except Florida. The range of this spider is primarily the Missouri–Ohio–Mississippi River basin from southeastern Nebraska to southern Ohio and south to Texas and across to Georgia. Other states containing *Loxosceles reclusa* include Alabama, Arkansas, Illinois, Indiana, Iowa, Kansas, Louisiana, Tennessee, and South Carolina.[99] The northern range of *Loxosceles* species in the United States is Illinois, Indiana, and Iowa.[100] The southern extent of their geographic distribution is the Gulf of Mexico. These spiders are not endemic to Canada. *Loxosceles reclusa* does not survive through the seasons in hot desert climates. The diagnosis of *Loxosceles reclusa* spider bites outside endemic areas is suspect.[92] Figure 166.3 demonstrates the distribution of *Loxosceles* species in the United States.

Loxosceles Laeta Nicolet

Although this brown spider is endemic to South America (Argentina, Brazil, Chile, Ecuador, Peru, Uruguay), modern transportation allowed the establishment of isolated colonies in the United States including California during the 1960s. However, the clinical significance of these colonies is unclear because of the lack of well-documented cases of envenomation by *L. laeta* in the United States. Other *Loxosceles* species in South American include *L. intermedia* and *L. gaucho*.

FIGURE 166.3. US distribution of *Loxosceles reclusa* and other US *Loxosceles* species. From Swanson DL, et al. Bites of brown recluse spiders and suspected necrotic arachnidism. N Engl J Med 2005;352:701.

Loxosceles Deserta Gertsch

This desert recluse inhabits rural areas of western deserts of Arizona, Nevada, New Mexico, Texas, Utah, and southern California including the Mohave Desert. These spiders rarely reside indoors except in homes surrounded by desert habitats. Consequently, human contact is rare.

Loxosceles Arizonica Gertsch & Mulaik

The distribution of *L. arizonica* is similar to the desert habitat of *L. deserta*, particularly in Arizona.

Loxosceles Rufescens Dufour

This species is native to the Mediterranean region. However, this species has been widely dispersed by modern transportation, and colonies are found in the eastern United States, California, Washington, Ohio, Georgia, and Texas, as well as areas throughout Europe, Africa, and Australia.

Behavior

Loxosceles spiders are sedentary and nocturnal, and these spiders prefer dark, quiet areas, such as wood piles, construction materials, paper, the underside of stones, and holes.[101] They adapt easily to dark, dry, indoor areas (clothes, stored personal items, stairwells, basements, boxes, closets). These spiders primarily are hunters, but occasionally they weave irregular, white, flocculent webs to sense prey. Brown recluse spiders (*L. reclusa*) can tolerate months without food and water depending on ambient temperature.[102] In an experimental study, food was withheld from brown recluse spiders. The survival of the spiders ranged between 2 weeks at 40 °C (104 °F) and 4–7 months at 5 °C (41 °F).[103] The average life span of *Loxosceles reclusa* Gertsch & Mulaik is about 1–3 years,[104] whereas specimens of *L. laeta* can live 3–7 years.[105] The long lifespan, resistance to starvation, and propensity to hide in dark places allows survival during accidental transport.[90] However, these spiders do not easily disperse from their new environment because they do not travel on air currents and they experience a reduction of egg production and fecundity unless mating recurs. These spiders are usually absent from areas surrounding buildings infested with brown recluse spiders. In northern climates, brown recluse spiders do not survive in low winter temperatures.

Most envenomations occur from April through October. The brown recluse spiders usually hibernate during the winter months. Envenomations also tend to occur in the morning when one is most likely to open the closet and choose the day's clothing. Multiple bites are not characteristic of *Loxosceles* species, and the presence of multiple lesions suggests an etiology other than spider bites. Large numbers of *L. reclusa* species may be present in a building without causing envenomations in occupants; consequently, the presence of *Loxosceles* species does not necessarily implicate these spiders as a cause of skin lesions.[106]

PRINCIPAL TOXINS

Venom Composition

The venoms of the native US *Loxosceles* species (*L. deserta, L. rufescens, L. arizonica*) are less potent compared with the venom of *L. reclusa*. The venom is primarily cytotoxic, particularly to endothelial tissue. At least three *Loxosceles* species have similar venom,[107] and the dermonecrotic and lethal factors in the venom reside in homologous proteins in the range of 32–35 kDa based on animal studies.[108] Almost all of the venom consists of spreading factors and enzymes (e.g., hyaluronidase, collagenase, esterase, protease, phospholipase, deoxyribonuclease, ribonuclease, dipeptides), but several of these enzymes (hyaluronidase, alkaline phosphatase, 5′ ribonucleotide phosphohydrolase) are apparently not responsible for the dermal necrosis.[109] The nonproteolytic 30–35 kDa protein, sphingomyelinase D, is probably the main toxin in *Loxosceles* venom.[101] Animal studies indicate that sphingomyelinase D causes activation of the classical pathway of complement resulting in platelet aggregation, dermal necrosis, and hemolysis.[110] This compound is rare in other species of spiders and venomous animals.[111] Sphingomyelinase D also activates the alternative pathway of complement on human erythrocytes by removing glycophorins secondary to the activation of endogenous metalloproteinase. This compound produces profound dermal inflammation as a result of the interaction with cell membrane sphingomyelin and the release of choline and *N*-acylsphingosine phosphate. These latter compounds cause serotonin release, platelet aggregation, and local ischemia. *Loxosceles* venom induces the release of interleukin 8, E-selectin, and granulocyte-macrophage colony-stimulating factor similar to the effects of tumor necrosis factor-α.[112] The dermonecrotic fraction of *L. gaucho* contains several proteins (e.g., loxnecrogin A and B) that produce necrosis in rabbit models, but the mechanism of necrosis probably involves more than one or two proteins.[113] Compounds involved with the hematological effects of *Loxosceles* venom include metalloproteinases (loxolysin A and B), serine protease, and other proteases.[114]

Venom Apparatus

The venom glands of *L. intermedia* include an external layer of striated muscle fibers and an internal muscle layer in contact with simple glandular epithelium. The epithelial cells project into the lumen of the glands and these projections contain venom-rich, secretory vesicles. A basal lamina separates the secretory epithelial cells from the multinucleated muscular cells, and this layer contains laminin, entactin, glycoproteins, and glycosaminoglycan sulfated residues.[115] The total volume of the venom is minute (i.e., about 4 µL), and the venom contains about 65–100 µg proteins.[114] The estimated amount of venom injected with each bite has not been well-studied, but the anecdotal data suggests that the *Loxosceles reclusa* injects about 2 µg venom/bite.[116]

Dose Response

As a result of variations in the biological activity of proteins, glycoproteins, and sphingomyelinase activity, the severity of cutaneous and system loxoscelism depends on the *Loxosceles* species as well as the sex (female > male).[117] Envenomations by *L. arizonica, L. deserta*, and *L. rufescens* cause relatively mild lesions.[93] However, animal models suggest that the size and depth of the eschar following subcutaneous injection of *Loxosceles* venom are dose-related.[118] The estimated LD_{50} of *L. intermedia* venom in four strains of mice ranged between 4.6–24.5 µg.[119] In a study of rabbits, large skin lesions developed following the intradermal injection of 3 µg venom from three species of *Loxosceles* (*L. gaucho, L. laeta, L. intermedia*).[108] The mean size of these lesions at 48 hours ranged between $1.8 \pm 0.8\,cm^2$ (*L. laeta*) to $5.4 \pm 3.6\,cm^2$ (*L. gaucho*). The intradermal LD_{50} for these species ranged between 0.48 mg/kg (*L. intermedia*) to 1.45 mg/kg (*L. laeta*), similar to the LD_{50} for the Brazilian species *L. similis* Moenkhaus.[120]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The exact mechanism of necrosis produced by *Loxosceles* venom requires further delineation, but overall *Loxosceles* envenomation produces an inflammatory infiltrate, thrombosis, hemorrhage, acute inflammation and induration, erythema, and a liquefaction necrosis similar to pyoderma gangrenosum.[114] The dermal effect of *Loxosceles* venom is species-specific with mice and rats relatively resistant to the venom and humans, rabbits, and guinea pigs susceptible to the venom. In animal models, *Loxosceles* venom aggregates platelets, liberates thromboxane B2, causes intravascular fibrin deposition and endothelial thickening, and enhances leukocyte chemotaxis. Sphingomyelinase D is a phospholipase in *Loxosceles* venom that interacts with plasma membranes of various cells including erythrocytes, platelets, and endothelial cells. Experimental data indicate that the dermal necrosis following *Loxosceles* envenomation results from vascular thrombosis secondary to platelet thrombi.[121] The venom induces expression of E-selectin, and stimulates the release of pro-inflammatory mediators (chemokines) including interleukin-8, growth-related oncogene α, granulocyte-macrophage-colony-stimulating factor, and monocyte chemoattractant protein-1.[122] These markers amplify the inflammatory response to *Loxosceles* venom. Animal studies indicate that histological changes include interstitial edema, local hemorrhage, pronounced infiltration of polymorphonuclear leukocytes, degeneration of vascular walls, plasma exudation, thrombosis, coagulative necrosis, and vasculitis.[123,124] Light microscopy demonstrates early dermoepidermal separation, full-thickness dermal edema, thrombosis of small arterioles, infiltration of neutrophils and eosinophils, and extravasation of erythrocytes.[171] Electron microscopy of tissue biopsies from *Loxosceles*-envenomated animals demonstrates subendothelial blebs, vacuoles, and intravascular endothelial cell membrane degeneration along with thrombus formation within blood vessels.[125] A well-delineated zone of eosinophilic coagulative necrosis develops in the skin surrounded by a dense band of neutrophils. Necrosis is greatest in fatty areas of the buttocks, thighs, and abdomen. *In vitro* experiments indicate that *L. reclusa* venom attaches directly to red blood cell membranes and causes structural changes.[126] Venom attachment to erythrocyte membranes is apparently a prerequisite for hemolysis of human cells.

CLINICAL RESPONSE

The hallmark of *Loxosceles* envenomation is the development of a necrotic skin lesion with gravitational spreading. Clinical features of *Loxosceles* bites range from no or mild local necrosis to severe systemic effects including hemolysis and disseminated intravascular coagulopathy. The frequent lack of identification of *Loxosceles* specimens following envenomation complicates the determination of the incidence and clinical features of loxoscelism. A substantial number of *Loxosceles* bites are clinically insignificant.[127]

Cutaneous Loxoscelism

Typically, *Loxosceles* bites produce mild initial pain similar to a pinprick, but the bite may be painless.[127] The progression of cutaneous responses to *Loxosceles* envenomation is highly variable. Most *Loxosceles*

envenomations in the United States produce only a mild inflammatory reaction including a mild urticarial reaction.[128] A rapidly expanding, single lesion may spontaneously regress before necrosis occurs. The presence of multiple necrotic lesions indicates an etiology other than *Loxosceles* envenomation, such as pyoderma gangrenosum (i.e., a rare skin disease with recurrent deep skin ulcers and impaired cell-mediated immunity). A mild skin response may occur characterized by the formation of a small, erythematous papule that becomes very firm before healing. Typically, severe lesions become obvious within 12–24 hours, and the lack of necrotic signs within 48–96 hours indicates that necrosis will not occur.[129] Localized urticaria may persist several days after the bite.[130] More severe cutaneous reactions to *Loxosceles* bites result from cytotoxicity. Variable degrees of pain and erythema begin within 2–6 hours of envenomation, followed by formation of an irregular bleb at the bite site surrounded by a white ring of ischemia 12–24 hours after envenomation. Although occasionally a transient, bluish discoloration develops within the first 24 hours, the skin reaction usually progresses from red to violet forming a dependent, eccentric-shaped lesion that displays a characteristic gravitational spread. The central bleb develops necrosis after 3–4 days, and a black eschar forms within one week that sloughs within several weeks. Eventually, the eschar sinks below the surface of the skin in a pattern called the "red, white, and blue sign." The indurated ulcer heals by secondary intention over 6–8 weeks depending on the size of the ulcer.[131] The lowering of the eschar below the surface of the skin differentiates necrotic from non-necrotic lesions, which remain red and elevated above the surrounding skin. Large areas of necrosis may occur, particularly in areas surrounded by thin skin and abundant, subcutaneous fat. Skin grafting may be necessary to cover the lesion. Secondary infection of the eschar is uncommon. In patients with cutaneous loxoscelism, nonspecific symptoms may develop within 48 hours after envenomation characterized by mild fever and malaise, but laboratory evidence of hemolysis is usually absent.[132]

The appearance of diffuse macular erythema over the trunk is a good prognostic sign. Rarely, a generalized vasculitis without cutaneous necrosis occurs after *Loxosceles* envenomation.[133]

Color and configuration differentiate *Loxosceles* bites from nonnecrotic lesions because the latter bites remain raised and erythematous. Hence, the rapid expansion of the blue macular area along with severe pain signifies necrosis and probable *Loxosceles* envenomation in endemic areas. However, the diagnosis of Loxosceles envenomation by clinical examination alone is difficult, and frequently biopsies are necessary to exclude other causes of necrotic skin lesions.[134] *Loxosceles* lesions are often confused with other necrotic spider bites, other arthropod bites, and systemic disease. Each suspected *Loxosceles* bite should be carefully evaluated for other potential sources, in part, because the diagnosis of loxoscelism does not correlate to known populations of *Loxosceles* species.[135] Important differential diagnoses for the suspected *Loxosceles*-induced lesions include neoplasia, cutaneous anthrax, tularemia, necrotizing fasciitis, Rocky Mountain spotted fever, Lyme disease, pyoderma gangrenosum, and sporotrichosis.[136] Other differential diagnoses of suspected *Loxosceles*-induced cutaneous lesion include various arthropod bites (ticks, mites, bedbugs, fleas, ants, mosquitoes, biting flies, bees, caterpillars), erysipelas, vasculitis, necrotizing fasciitis, pyoderma gangrenosum, adverse drug reactions, herpes zoster, thermal or chemical burns, and urticaria. Table 166.2 lists conditions associated with *Loxosceles*-like dermal lesions described in the medical literature. There is no clinical evidence to indicate that the risk of adverse effects from *Loxosceles* envenomation increases during pregnancy.[137]

Viscerocutaneous Loxoscelism

Systemic reactions are uncommon, and the occurrence of systemic symptoms does not correlate to the severity

TABLE 166.2. Conditions Associated with Loxosceles-like Dermal Lesions

Disease Type	Cause
Bacterial	*Pseudomonas aeruginosa, Staphylococcus* (methicillin resistant), *Streptococcus*, cutaneous anthrax, gonococcemia, Lyme disease, Rocky Mountain spotted fever, tularemia
Fungal	Aspergillosis, cryptococcosis, sporotrichosis
Parasitic	Leishmaniasis
Viral	Herpes simplex, herpes zoster
Vascular disease	Erythema nodosum, small-vessel occlusive disease, vasculitis, statis ulcer, polyarteritis nodosa, Wegener's granulomatosis, pressure ulcers, Stevens-Johnson syndrome, erythema multiforme, polyarteritis nodosa
Neoplastic disease	Primary cutaneous neoplasms, lymphoma, lymphomatoid papulosis
Other diseases	Chemical or thermal burns, toxic epidermal necrolysis, phytodermatitis, radiation, cryoglobulinemia, diabetic ulcer, pemphigus vegetans, pyoderma gangrenosum, septic emboli, arthropod bites (flea, mite, biting fly, bees, ants)

Source: Adapted from Ref 90.

of cutaneous lesions.[138] Typically, systemic symptoms develop within 24–48 hours of envenomation. Children appear more susceptible than adults.[139] Clinical features of a systemic reaction to *Loxosceles* envenomation based on case reports include fever, chills, malaise, nausea, vomiting, myalgias, arthralgias, petechiae, hemolysis,[140] hypotension,[141] hemoglobinuria,[142] and consumptive coagulopathy (DIC).[143,144] Low-grade fever and arthralgias can occur during cutaneous *Loxosceles* envenomation, and these symptoms are not specific to viscerocutaneous loxoscelism. The most serious complications of *Loxosceles* envenomation are sepsis, hemolysis, and disseminated intravascular coagulation. Coma, convulsions, and renal dysfunction are probably secondary to venom-induced hemolysis.[145] Hemolytic anemia may be insidious, often requiring 2–3 days to develop. Deaths from *Loxosceles* envenomation in the United States have not been well-documented during modern times when intensive supportive care has been available, in part, because of the lack of confirmed *Loxosceles* envenomation.[146] However, the presence of significant hemolysis is potentially life-threatening.[147] Oliguria and dark urine suggest the intravascular hemolysis and rhabdomyolysis that can cause anemia and acute renal failure. Several case reports of pregnant women envenomated during the second and third trimesters of pregnancy did not report adverse fetal effects.[40]

DIAGNOSTIC TESTING

Analytical Methods

There are no routine laboratory tests available to diagnose necrotic arachnidism or *Loxosceles* envenomation. Research methods have been developed for the detection of *Loxosceles* venom including the passive hemagglutination inhibition test[148] and a *Loxosceles* species enzyme-linked immunosorbent assay (ELISA) based on animal models.[116,149] Complicated laboratory techniques and delayed results (6–24 hours) limit the clinical application of the passive hemagglutination inhibition tests for *L. reclusa* envenomations. The ELISA test demonstrates moderate cross-reactivity with related spider genera depending on the amount of venom present. In rabbit models, this assay can detect venom in hair, wound aspirate, and dermal biopsies up to 7 days after envenomation, but this method did not demonstrate evidence of envenomation in the serum.[150] There is substantial cross-reactivity on immunoassays between North American *Loxosceles* species.[151] The diagnosis of *Loxosceles* envenomation is based on a history of a relatively painless bite, characteristic lesion (increasingly painful solitary plaque with central, white ischemia surrounded by erythema), and the identification of the spider in an area containing endemic species of *Loxosceles*.

Abnormalities

Intravascular hemolysis may develop during the first 96 hours after envenomation and persist up to 1 week. Reduced hemoglobin concentrations and increased plasma-free haptoglobin concentrations develop during intravascular hemolysis, and normal serum haptoglobin concentrations exclude the presence of intravascular hemolysis.[152] Analysis of the urine during hemolysis may or may not demonstrate free haptoglobin with a positive urine dipstick for blood and minimal evidence of erythrocytes on microscopic examination because hemolysis may occur in extravascular areas (e.g., spleen). The anemia is usually Coombs-negative, but case reports of *Loxosceles* envenomation document the presence of Coombs-positive hemolytic anemia.[153,154] Characteristically, the serum hemoglobin decreases during hemolysis while the reticulocyte count increases. Substantial leukocytosis (i.e., up to 30,000 cells/cm^3) may also occur without evidence of a secondary infection. Rarely, case reports associated a severe envenomation with rhabdomyolysis,[155] myoglobinuria, hepatorenal dysfunction, and/or a consumptive coagulopathy (decreased fibrinogen, clotting factors, and platelets; increased fibrin degradation products). Antithrombin III is an important physiological inhibitor of coagulation, and antithrombin III decreases substantially during clinically significant coagulopathies.

TREATMENT

Systemic Reaction

All patients with systemic reactions should be followed in the hospital for evidence of increasing hemolysis, coagulopathy, and renal failure with serial hemoglobin, free plasma haptoglobin, serum creatinine, serum electrolytes, and serum creatine kinase. Treatment for hemolysis and coagulopathy is supportive (i.e., red blood cell transfusions, platelets, cryoprecipitate, fresh-frozen plasma, monitoring of fluid/electrolytes). Generous fluid replacement is important following the development of hemolysis and hemoglobinuria. Urine alkalinization is also a treatment option, but there is limited data on the efficacy of this treatment in preventing hemoglobin-induced renal damage. Anecdotal data suggests that corticosteroids (1–2 mg methylprednisolone/kg loading dose, 0.5–1 mg/kg maintenance dose every 6 hours for 5–10 days) may reduce hemolysis from *Loxosceles* envenomation, but clinical data are limited.

There are no clinically effective antidotes for *Loxosceles* envenomation. Evaluation of patients with systemic symptoms should include a complete blood count, including platelets, coagulation profile (prothrombin time, partial thromboplastin time, fibrinogen level, fibrin degradation products), urinalysis, blood electrolytes, liver function tests, serum creatinine and serum creatine phosphokinase. Children with moderate to a severe systemic reaction should be observed for the development of hemolysis, renal dysfunction, and coagulation abnormalities. The presence of venom-induced antibody interference may complicate cross-matching for blood products during *Loxosceles* envenomation. Transfusions with packed red cells, fresh frozen plasma, and cryoprecipitate should be used cautiously, and the administration of whole blood should be avoided because the complement in whole blood may increase hemolysis.[156] Antithrombin III concentrates may be needed to reverse severe coagulopathies, if available. Hyperkalemia and renal failure may require hemodialysis.[153]

Cutaneous Reaction

There are no proven treatments for brown recluse spider bites based on controlled, randomized studies. Most suspected brown recluse spider bites heal with supportive care alone; therefore, conservative, local wound care is the most important treatment of cytotoxic responses to *Loxosceles* venom.[157] Supportive measures include cold applications, elevation, and antibiotics when indicated by the presence of secondary infections. General wound care (cleansing with bactericidal agents, tetanus prophylaxis as indicated, limited motion, neutral or elevated position, cold compresses), serial observation, and antipruritic agents (e.g., hydroxyzine, diphenhydramine) are the main treatments.[158] Antibiotics are limited to documented evidence of secondary skin infections (*Staphylococcus, Streptococcus, Clostridium perfringens*, other anaerobes). Examination of the fangs and venom of some *Loxosceles* species (*L. intermedia*) demonstrated the presence of *Clostridium perfringens*,[159] but the role of this anaerobe in the clinical progression of the skin lesions associated with loxoscelism remains undetermined.

The progression of skin lesions to necrosis is difficult to predict based on the initial cutaneous lesion. Surgical incision is not usually necessary until 2–8 weeks after envenomation, when the acute-phase reactants are degraded and the wound is fully mature. Rarely, surgical intervention may be necessary 2–3 weeks after envenomation for cosmetic purposes, especially when the ulcer exceeds 1–2 cm (~0.4–0.8 in.). Although *Loxosceles* antivenom is available in Mexico and Brazil, there are limited experimental and clinical data to support the efficacy of the antivenom, particularly against local responses more than several hours after envenomation.[43,160]

There are few clinical data to support the use of adjunctive therapy (dapsone, steroids, hyperbaric oxygen, heparin, electric shock) for the treatment of dermal lesions associated with *Loxosceles* envenomation.[93] Animal experiments do not support the use of intra-lesional or systemic steroids for the treatment of cutaneous skin reactions when administered more than a few hours after envenomation. Experimental studies in guinea pigs suggested that treatment with dapsone, an inhibitor of the local infiltration of polymorphonuclear leucocytes, reduced the average size of *Loxosceles*-induced skin lesion.[161,162] A retrospective study suggested that a better clinical outcome results from the use of dapsone (4,4′-diaminodiphenyl-sulfone) therapy combined with delayed surgical excision rather than early surgical excision alone.[163] However, numerous design flaws including the use of different surgical techniques in the two groups limits extrapolation of this study to other groups of patients. Other experimental studies of *Loxosceles*-induced skin lesions in the rabbit[164] and guinea pig[165] model did not detect clinically significant differences between dapsone-treated group and controls, when administered 4 hours and 36 hours, respectively, after envenomation. Complications of dapsone therapy include hemolysis (glucose-6-phosphate dehydrogenase deficiency), agranulocytosis, aplastic anemia, hypersensitivity syndrome, toxic epidermal necrolysis, methemoglobinemia, and rarely a hypersensitivity reaction (fever, headache, nausea, vomiting, hepatitis, hemolysis, leukopenia).[166,167] Inadequately controlled and documented human cases, as well as the difficulty in predicting the course of the cutaneous lesions, indicates that incisional therapy prior to the development of lesions is contraindicated. The use of hyperbaric oxygen for the treatment of *Loxosceles*-induced skin lesions remains controversial because of the lack of supportive experimental[168] and clinical data.[164,169]

For patients with signs of necrotic lesions, baseline complete blood count and urinalysis should be followed daily for the first several days to exclude the development of hemolysis and hemoglobinuria. All patients receiving dapsone must be screened for glucose-6-phosphate dehydrogenase deficiency, anemia, and liver dysfunction. The appearance of fever or dark urine requires immediate follow-up by a physician.

NECROTIZING ARACHNIDISM

Necrotizing arachnidism applies to necrotic lesions produced by spiders other than *Loxosceles* species. However, the clinical disorder of necrotic arachnidism is poorly defined, and the sources of necrotic lesions after spider bites are not well documented.[170] These lesions typically are single, rarely clustered, and usually are located on an extremity. A central punctum or vesicle may be present along with vasodilation, ischemia, and thrombosis manifest as a classic "red, white, and blue sign." Dependent erythema with irregular borders develops as venom spreads in the direction of gravity.[171] At least four American species of spiders, excluding *Loxosceles* species, are capable of producing necrotic lesions.[172] Most spider bites do not cause necrotic lesions, and spider bites are frequently confused with other medical conditions (e.g., bacterial infections, insect bites). Minor features of bites from these spiders include immediate, transient pain occasionally associated with local effects (bleeding, puncture marks, pruritus, redness).[173,174] Rarely, infections may develop in the area of the bite. Table 166.3 lists spiders associated with painful, indurated lesions that do not typically produce necrosis. The differential diagnosis of necrotic spider bites includes infective ulcers (*Staphylococcus, Streptococcus, Mycobacterium ulcerans, Chromobacterium violaceum, Sporotrichosis, Cutaneous nocardiosis, Pseudomonas* species), pyoderma gangrenosum, vasculitis, allergic reactions, and arthropod envenomation (sandfly, blister beetle).

TABLE 166.3. Spider Genera Associated with Painful, Indurated, Nonnecrotic Lesions

Genus and Species	Common Name	Family
Agelenopsis aperta Gertsch	Grass spider	Agelenidae
Avicularia avicularia L.	Pink toe tarantula	Theraphosidae
Herpyllus ecclesiasticus Hentz	Parson spider	Gnaphosidae
Lampona	White-tailed spider	Lamponidae

Black-and-Yellow Garden Spiders

These large, brightly colored spiders weave large, conspicuous webs that trap prey (insects).[175] Some orb weavers build relatively permanent webs and store prey in the webs, whereas other spiders from this family build new webs daily.[176] The golden orb weaver (black-and-yellow garden spider, *Argiope aurantii* Lucas) is a common inhabitant of gardens in California, Oregon, and the eastern United States. This black spider has bright yellow and orange spots on the dorsal surface of the abdomen. The females are about 4 times larger than the males, reaching 7.5 cm (~3 in.) in length with legs extended. Bites usually occur at night or during outdoor activities. Although the venom from some *Argiope* species contain low-molecular-weight compounds (argiotoxins) that block postsynaptic glutamate receptors,[177,178] envenomation by these spiders does not usually result in systemic effects. Envenomation may produce local pain, surrounding erythema, and vesicles, but necrosis does not usually occur.[179,180] Treatment involves conservative wound care (elevation, tetanus prophylaxis as indicated, antibiotics for secondary infection, analgesics).

Running or Sac Spiders

The genus *Cheiracanthium* contains about 200 species belonging to the family Miturgidae. These long legged, nondistinct spiders average about 7–10 mm in length with olive-green to pale yellow or brown coloration. There are eight eyes arranged in two parallel rows of four eyes. *C. inclusum* Hentz is a common garden spider that inhabits most of the United States with exception of the cold, northern latitudes. *C. mildei* L. Koch (sac

spider, cream house spider) is a common house spider throughout the United States that moves indoors during autumn and winter months. These nocturnal spiders do not weave webs, and they usually rest in fine, white, silken sacs woven in curled leaves or crevices. Most bites occur while the victim is asleep or while dressing in clothes containing these spiders.

Although medical references frequently list spiders from the genus *Cheiracanthium* as a cause of necrotic arachnidism, necrotic lesions following envenomation by these spiders are not well documented. In a review of 20 verified bites by *Cheiracanthium* spiders from the United States and Australia, there were no necrotic lesions.[181] This group also reviewed 39 verified *Cheiracanthium* bites from the international literature with documentation of only one case of mild necrosis by a European species (*C. punctorium* Villers). In cases of suspected (i.e., not necessarily documented) cases of *Cheiracanthium* bites, case reports associated bites by *Cheiracanthium* species with sharp pain followed by a red wheal and the formation of a crusted, slightly necrotic lesion within several days.[182,183] Induration and erythema surrounds the lesion, and the lesion may be painful or pruritic.[184] The size of the lesion is variable, and pain may occur without clinical signs of inflammation.[185] Most *Cheiracanthium* bites do not ulcerate, and the lesion becomes asymptomatic after about 2 days.[186] Occasionally, mild systemic complaints can develop within 3 days following envenomation by *Cheiracanthium* spiders including low-grade fever, headache, abdominal cramps, vomiting, and rash.[97]

Wolf Spider

These medium to large spiders (Lycosidae family) have elongated, cylindrical bodies (1–30 mm/~0.4–1.2 in.) with colored bands on the carapace and small clumps of white hairs on the abdomen that form spots. They are superb hunters with good vision to distinguish movement (but not form) and a characteristic pattern of eyes. Four small, anterior eyes are set close together. Above these four eyes are two large eyes that are directed forward and two large eyes that are directed upward. These diurnal hunters use their strong front legs and powerful jaws to hold and crush prey. They do not hunt in packs, and they prefer open, disturbed habitats (e.g., urban parks, gardens). *Lycosa* venom contains peptides (lycotoxin I, lycotoxin II) that promote efflux of Ca^{2+} from synaptosomes, induce erythrocyte hemolysis, and dissipate voltage gradients across muscle membranes *in vitro*.[187] The venom of *Lycosa* species also contains substantial amounts of histamine.[188] In animal models, the venom of *Lycosa godeffroyi* L. Koch causes necrotic lesions.[189] However, necrosis following bites by *Lycosa* species is unusual, and most symptoms following envenomation involve varying degrees of pain rather than ulceration.[190,191] Case reports associate bites by *Lycosa* species with pain, swelling, and lymphangitis.[192] Treatment primarily involves conservative wound care including the use of antihistamines.

Green Lynx Spider

The lynx spider (*Peucetia Viridans* Hentz) belongs to the family Oxyopidae that inhabits large areas of the southern United States, particularly around plants. These diurnal hunters average about 2 cm (~1 in.) in length, and the bright, translucent green body usually contains rows of small, red dots. Aids to the identification of this spider include bright green coloration, spindly legs covered with spiny hairs, and large size. Their typical habitat includes grassy areas, cultivated fields (cotton, soybeans), and ornamental gardens in the lower latitudes of the United States to Central America. Typically, bites by this spider produce local pain, pruritus, erythema, and induration without necrosis.[193] Occasionally, a pustule may develop following envenomation, but systemic effects do not develop.[194] Treatment involves supportive wound care.

Black Jumping Spiders

The genus *Phidippus* contains the largest spiders in the family Salticidae with some specimens reaching 1 cm (~0.4 in.) in length. The identification of the jumping spider (*Phidippus audax* Hentz) is based on the characteristic short legs, white stripes, bands of hair on the carapace, and fluorescent green mouth parts (chelicerae). These spiders also have a characteristic pattern of eyes. The first row of four eyes are enlarged, particularly the middle two eyes, with a second row of two small eyes above and a third row of larger eyes posterior to the second row. These spiders are excellent hunters, and they can jump over 40 times their body length.[195] They do not build webs. *In vitro* studies suggest that *Phidippus* venom is cytotoxic and capable of producing necrotic lesions.[196] Envenomation produces a sharp, painful site that may develop into urticarial swelling and pruritus lasting several days to a week.[197] A small ulcer potentially may develop in the area of the bite, but the formation of necrotic lesions in humans is not well documented. Treatment is supportive.

Six-Eyed Crab Spiders

These flat, medium-sized (17 mm) spiders inhabit remote areas of Africa and South America. They usually avoid human contact by burying themselves in sand. Their venom is proteolytic.

Hobo Spiders

The hobo spider, *Tegenaria agrestis* Walckenaer, and the related species *Tegenaria duellica* Simon are very similar European spiders that inhabit the northwestern United States (Washington, Oregon, Idaho, northern Utah, the western Montana, western Wyoming) and southern British Columbia.[198] These members of the Agelenidae family have a distinctive, funnel-shaped web, but this spider should not be confused with the more dangerous, unrelated Australian funnel-web spider (*Atrax robustus* O.P.-Cambridge). These medium-sized (7–14 mm/~0.3–0.6 in.), brown spiders often have a dorsal herringbone pattern on their abdomen, but the lack of distinctive features requires identification by qualified experts. They wait for prey inside a horizontal, trampoline-like mat of silk.

Several case reports associate bites from the hobo spider (*Tegenaria agrestis* Walckenaer) with necrotic lesions found on patients from the northwestern United States, but these case reports did not include adequate data to exclude infectious causes of these lesions.[199,200] These case reports delineate a clinical course involving painless erythema and induration followed by vesicle formation that subsequently forms an eschar and subeschar necrosis; however, these reports lack expert identification of the involved spiders.[201] Furthermore, hobo spiders are common spiders that do not usually bite, and the presence of these spiders in the vicinity of the patient does not necessarily imply envenomation. Systemic complaints associated with hobo spider bites in these case reports include dry mouth, anorexia, disorientation, arthralgias, paresthesias, and headaches.[202] The ability of these spiders to cause necrotic lesions remains equivocal, in part, because this spider is a native European species, where necrotic arachnidism is not associated with this species. Examinations of the venom from European and American specimens of the hobo spider did not demonstrate substantial differences in their venoms.[203]

B Centipedes

Chapter 167

CENTIPEDES
(Subclass: Chilopoda)

IDENTIFYING CHARACTERISTICS

Centipedes belong to the phylum Arthropoda, class: Chilopoda. Fossil records dating back 420 million years document the worldwide distribution of these animals, and there are over 3,300 species of centipedes belonging to five extant orders.[1] Centipedes occur in all continents except Antarctica, primarily in warm temperate regions and the tropics. In some classifications, Chilopoda is part of the subphylum Myriapoda that includes Diplopoda (millipedes), Symphyla, and Pauropoda. Centipedes are slender, multisegmented arthropods that possess one pair of short legs per flattened segment in contrast to millipedes, which possess two sets of legs per segment and no venomous claws. Although some giant millipedes (*Polyconoceras* spp.) from Papua, New Guinea can spray noxious secretions that irritate mucous membranes and eyes,[2] millipedes are harmless vegetarians that do not bite. The odd number of segments on centipedes range between 15–191, and the first pair of legs is modified into a venom-delivering organ. There is one set of antennae. Their length ranges between 1–30 cm (~0.4–12 in.), and their coloration varies from bright yellow to brown black. The last pair of legs is elongated. All four orders of centipedes are venomous including Geophilomorpha (soil centipedes), Lithobiomorpha (rock or garden centipedes), Scolopendromorpha (tropical or giant centipedes), and Scutigeromorpha (house centipedes). The order Scolopendromorpha contains the most aggressive species and voracious predators.[1] Some classifications include a fifth order (Craterostigmomorpha) that contains only one genus (*Craterostigmus*). This genus represents a stage between scolopendrids and lithobids. They have only 15 pairs of legs and only seven sets of spiracles. The largest centipedes belong to the Scolopendridae family. These yellow-brown creatures with orange and blue cephalic parts reach 8–15 cm (~3–6 in.) in length.

Common Name: American House Centipede
Scientific Name: *Scutigera coleoptrata* L.
Family: Scutigeridae
Physical Description: These centipedes are elongated, dorsoventrally flattened arthropods with 15 segments. The hindmost segment is modified for sensory and defensive purposes. This arthropod matures in 3 years.

Common Name: Centipede
Scientific Name: *Scolopendra subspinipes* Leach
Family: Scolopendridae
Physical Description: This large, aggressive centipede ranges in length up to 10–20 cm (~4–8 in.). Their color varies, but most of specimens are red to brown with yellow to orange legs. These centipedes have 18 to 19 segments on their antennae with the first 6 segments being smooth. The terminal legs have three spines. There are at least eight subspecies of *S. subspinipes*.

EXPOSURE

Geographic Distribution

Centipedes inhabit warm temperate and tropical climates throughout the world. Centipedes occur com-

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

monly in the southern portions of the United States from California, Arizona, and Texas to Alabama, Louisiana, and Georgia as well as Hawaii. The distribution of *Scolopendra subspinipes* includes tropical and subtropical areas of eastern and southern Asia as well as Hawaii.

Behavior

Centipedes have no waxy waterproofing layer on their cuticle, and almost all centipedes are terrestrial. Hence, they prefer dark, damp environments (e.g., undersurface of stones, rotting logs, leaf litter, tree bark) and during rainy weather these creatures will invade indoor habitats. The females deposit eggs in the soil. They are nocturnal carnivores with a wide range of prey including insects, worms, slugs, and small snakes. Centipedes are typically solitary except during breeding and the care of hatchlings.[1] In contrast to centipedes, millipedes are herbivores. Centipedes paralyze their prey prior to capture and ingestion. These creatures do not typically hold onto the victim following the sting, except in rare circumstances.[3] Centipedes hide in bedding or clothing; therefore, humans are most likely exposed to these creatures in bed or as they dress. Exposure to centipedes in the United States typically occurs July through September.

Uses

Centipedes (*Scolopendra subspinipes mutilans* L. Koch) are a traditional part of Chinese and Korean medicine for the treatment of cardiovascular diseases.[4] Extracts of centipede are used in traditional Chinese medicine to treat cognitive decline, and chloroform extracts of *Scolopendra subspinipes mutilans* L. Koch demonstrate some anticholinesterase activity *in vitro*.[5]

PRINCIPAL TOXINS

Venom Composition

The composition of centipede venom is not well studied. These venoms are diverse and contain a variety of unique proteins.[6] The venom of these creatures contains a variety of compounds including pain mediators (serotonin, histamine), acetylcholine, a cardiodepressant lethal factor (Toxin-S), proteinases, lipoproteins, and cytolysin.[7,8] The tissue of the Korean centipede (*Scolopendra subspinipes mutilans* L. Koch) contains a novel serine protease that demonstrates potent fibrinolytic activity as well as the unique quinoline alkaloid, scolopendrine or 2-hydroxy-7-[(4-hydroxy-3-methoxyphenyl)methyl]-3-methoxy-8-quinolyl sulfate.[9,10]

Venom Apparatus

Centipedes are carnivores that prey on soil invertebrates (earthworms, insects) by capturing their prey with modified appendages. The venom apparatus of a centipede resides in the telopodites of the postcephalic segment, which is the first segment behind and ventral to the head. This pair of legs is modified into two sharp stinging structures connected to a muscular venom gland. The venom apparatus consists of 1) venom gland, 2) venom duct ending in the tip of the structure, 3) venom claw, and 4) muscles that operate the claw.[11] The venom duct carries the venom into the venom claw, which injects the venom through a subterminal pore in the outer curvature of the claw. The structure of the venom claw maximizes the size of the wound and the depth of venom injection. This venom apparatus typically produces two tiny puncture wounds on the victim several millimeters to 1.5 cm apart depending on the size of the centipede. These puncture wounds may bleed or develop subcutaneous hemorrhage. Double bite marks may appear after envenomation.[4]

Millipedes secrete odoriferous droplets from the glands on both lateral surfaces of the body segments. The extrusion of these malodorous secretions is a defensive maneuver that produces irritation. These secretions contain phenols, aldehydes, and nitroethylbenzene compounds,[12] but toxicity of these substances is not well documented.

Dose Response

The venom of the centipede does not usually produce serious systemic toxicity in humans. Based on extrapolation from rodent studies, over 1,000 centipede bites would be necessary to cause death in a human.[11]

TOXICOKINETICS

The main toxins in centipede venom have not been identified, and there are few data on the toxicokinetics of the toxic constituents.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The venom from centipedes causes local pain and edema. There are no lethal factors identified in the venom to date. Components of some centipede venoms are structurally similar to allergens in bee venom. Potentially, these components can cause hypersensitivity responses as well as some cross-reactivity between these venoms.[13]

CLINICAL RESPONSE

Centipede bites typically cause moderate to severe local pain, localized swelling, and erythema, but systemic symptoms are usually absent or mild.[14,15] In contrast to viper envenomations, centipede bites do not typically produce hemorrhagic blebs or progressive swelling more than 10–20 cm (~4–8 in.) beyond the bite. Local effects include the rapid onset of erythema, edema, intense pain, paresthesias, lymphangitic steaks, and lymphadenitis.[16,17] The skin response usually remains localized to the area immediately (i.e., 10 cm/~4 in.) around the bite,[4] and evidence of envenomation does not usually progress beyond the affected extremity.[18,19] Skin necrosis may occur at the site of the bite, but these lesions typically heal spontaneously without the need for grafts. Nonspecific systemic complaints include mild constitutional symptoms (e.g., nausea, lightheadedness, weakness, anxiety, palpitations, fever). Symptoms usually resolve within a few hours to a week.[20] Fatalities following centipede envenomation are not well documented.[21] The ingestion of a centipede by a 6-month-old infant produced vomiting, hypotonia, and pallor that resolved within 48 hours.[22]

Patients usually recover from centipede envenomations without sequelae.[4] Complications include a type II hypersensitivity reaction (immune complex deposition) manifest by recurrent swelling and pruritus several weeks after envenomation as well as the development of nephrotic syndrome.[23] A case report documented the development of a compartment syndrome, rhabdomyolysis, and acute renal failure following massive swelling of the lower extremity of a 44-year-old woman following a centipede envenomation.[24] She was allergic to bee stings, and she developed wheezing after the envenomation. An additional case report associated the ingestion of an alcoholic beverage made from a Korean centipede soaked in 53% ethanol with rhabdomyolysis, bullous skin lesions, renal failure, and an upper extremity neuropathy.[25] However, the patient was lying comatose in a narrow space overnight, and a compartment syndrome with a compression neuropathy may account for the clinical features of this case report. A case report associated the development of eosinophilic cellulitis (Wells' syndrome) with a centipede bite.[26] Rare case reports from Turkey temporally associate centipede bites with the development of transient increases in cardiac enzymes and ST-T wave changes.[27,28] These patients did not have underlying heart disease as determined by coronary angiography and exercise stress testing. Symptoms and signs of myocardial ischemia resolved within 12–24 hours.

DIAGNOSTIC TESTING

The specific toxins associated with centipede envenomation have not been identified, and there are no commercial biomarkers for the confirmation of envenomations by centipedes.

TREATMENT

Most centipede envenomations are benign and self-limited. Treatment of centipede envenomation is supportive including local wound care, antihistamines for pruritus, local and systemic analgesics as necessary, and tetanus prophylaxis. Case reports suggest that heat may reduce the intensity of the sting similar to some marine envenomations, but there are inadequate clinical data to confirm this observation of centipede envenomations.[14,16]

C Insects

Chapter 168

BEES, WASPS, and ANTS
(Order: Hymenoptera)

IDENTIFYING CHARACTERISTICS

Insects have three major body parts including the head, thorax, and abdomen with three pairs of legs (subphylum: Hexapoda). Common characteristics of Hymenoptera include two pairs of wings (bees, vespids), one pair of antennae, three body segments (head, abdomen, thorax) and, in females, a tubular ovipositor that evolved into a stinging apparatus. The large, diverse order of Hymenoptera contains over 70 families with over 100,000 species. The medically most important families in the order Hymenoptera include bees (Apidae), vespids (Vespidae), and fire ants (Formicidae).

Bees

There are at least five species of honey bees ranging in size from the dwarf (1 cm/~0.4 in.) honey bee (*Apis florae* Fabricius) to the large (3 cm/~1 in.) Himalayan or giant tree honey bee (*Apis laboriosa* Smith). The Apidae Family includes the European or common honey bees (*Apis mellifera* L.) and the Asian honey bees (*Apis cerana* Fabricius, *Apis dorsata* Fabricius), as well as the North American bumble bees (*Bombus pennsylvanicus* De Geer). Commercial production of honey is limited to *A. mellifera* L. and *A. cerana* Fabricius because of the behavioral limitations of other *Apis* species, particularly open-air nesting. Africanized honey bees are hybrids of the African honey bee and the European honey bee, and the former subspecies is slightly smaller than European honey bees. Africanized honey bees are grossly indistinguishable from European honey bees. Identification of the former requires morphometry or analysis of mitochondrial DNA.

Vespids

The Vespidae Family includes the genera *Vespula* (yellow jackets), *Dolichovespula* (aerial yellow jackets, bald-faced or white-faced hornet, yellow hornet), *Vespa* (hornets), and *Polistes* (paper wasps). Wasps have an egg-shaped abdomen supported on the thorax by a slender stalk. Hornets possess a truncated abdomen and a shorter waist than wasps. Characteristic yellow and black stripes of the male yellow jacket distinguish the nonstinging male from the stinging, black-faced female.

Fire Ants

There are about 18 species of fire ants (genus *Solenopsis*) with workers ranging in size between 1.8–6 mm/~0.1–0.2 in. in size. The three species of native US fire ants (*S. geminata* Fabricius, *S. xyloni* McCook, *S. aurea* Wheeler) produce small colonies that do not cause economic or medical problems. The imported red fire ant (*Solenopsis wagneri* Santschi) now dominates large areas of the southeastern United States. The imported red fire ant is bright red in color, and this insect inhabits loose dirt mounds about 30 cm (~12 in.) in diameter and 5–10 cm (~2–4 in.) in height. Imported red fire ants are inconspicuous, reddish brown ants that appear indistinguishable from common native species of ants. Identifying morphological characteristics of *S. wagneri* Santschi (*S.*

invicta) under magnification include two humps on the petiole that connects the thorax to the abdomen and clubbing of the last two segments of the antennae.[1]

EXPOSURE

Geographic Distribution

Bees

Honey bees are native to Europe, western Asia, and Africa, but with domestication the distribution of honey bees is now worldwide. Subspecies of the European honey bees (*Apis mellifera mellifera, Apis mellifera ligustica, Apis mellifera carnica, Apis mellifera iberica*) occur throughout North and South America with the exception of large tropical regions. The African honey bee (*Apis mellifera scutellata* Lepeletier) was accidentally introduced into Brazil during experimental studies in 1957,[2] and the habitat of this hybrid honey bee gradually expanded northward to include Texas, New Mexico, Arizona, Nevada, and California. Figure 168.1 displays the migration of the Africanized honey bee from Brazil to the southwestern United States. Theoretically, the habitat of these hybrid honey bees is limited by the requirement of a mean, high temperature exceeding 60 °F (~16 °C). This climatic condition includes areas from coastal California to Arizona, Texas, and portions of the southern United States. The African subspecies *Apis mellifera scutellata* Lepeletier (Africanized bee) is not present in Australia. The European hornet (*Vespa crabro* L.) occurs both in Europe and in North America whereas the Asian hornet (*Vespa mandarina* Smith) is limited to Asia. In the United States, the yellow jacket (*Vespula* species) is the most common cause of allergic reactions to insect stings.[3]

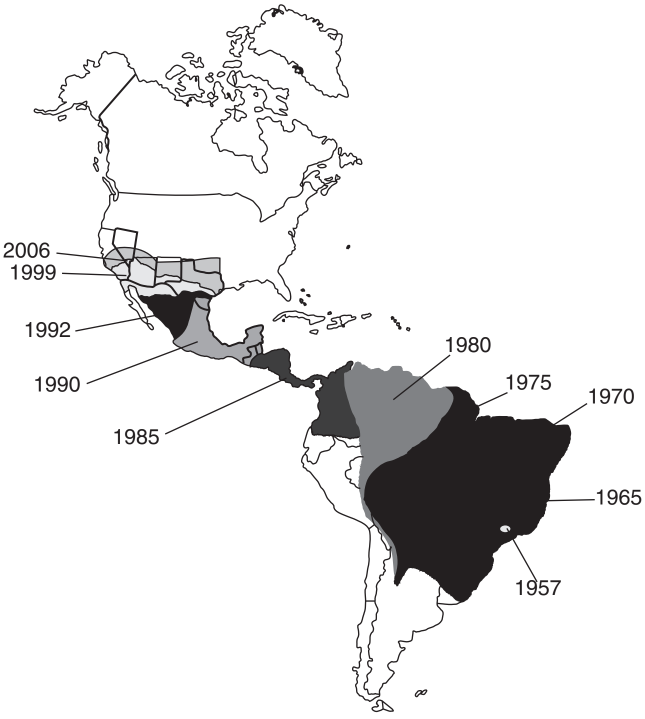

FIGURE 168.1. Migration of the Africanized honey bee. Adapted from Rodriguez-Lainz A, et al. Animal and human health risks associated with Africanized honeybees. JAVMA 1999;215:1800.

Wasps and Hornets

Hornets (*Vespa* spp.) are distributed mostly in Europe and Asia. The hornet species, *Vespa crabro*, is endemic in the northeastern United States. Yellow jackets are established in the United States as well as tropical and subtropical regions of Hawaii, Australia, New Zealand, South American, and South Africa.

Fire Ants

The black imported fire ant (*Solenopsis richteri* Forel) is a native of Argentina and Uruguay, whereas the red imported fire ant (*Solenopsis wagneri* Santschi, previously *Solenopsis invicta*) is a native species in Argentina, Paraguay, and Brazil.[4] The black fire ant was imported into the United States in the late 1910s or early 1920s, probably through the port of Mobile, Alabama.[5] In the late 1930s, importation of the red fire ant (*Solenopsis wagneri* Santschi) resulted in the gradual displacement of the imported black fire ant (*S. richteri*). The range of the imported black fire ant is now limited to northern Mississippi and Alabama. The red imported fire ant (*Solenopsis wagneri* Santschi) is the dominant species occupying millions of acres in Alabama, Arkansas, Florida, Georgia, Louisiana, Mississippi, North Carolina, Oklahoma, South Carolina, Tennessee, Texas, and Virginia. Colonies also occur in Arizona, California, New Mexico, and Puerto Rico. Figure 168.2 demonstrates the areas in the United States quarantined by the US Department of Agriculture because of infestation with imported red fire ants. The ultimate range of the imported red fire ant is unknown, depending on the climate (average minimum annual temperature >0 °F/~18 °C) and the development of cold tolerant red fire ant species.[6] Fire ants expand their habitat by mating flights, floating on flood waters, and the shipment of infested agricultural and nursery goods. Harvester ants (genus *Pogonomyrmex*) live in the arid sections of the western United States and Mexico. These ants produce painful stings, but are less aggressive than fire ants. Consequently, the medical significance of the presence of harvester ants is substantially less compared with fire ants. In addition to these ants, other causes of adverse effects of ants include the painful bites of the genus *Paraponera* from Central and South America, and the

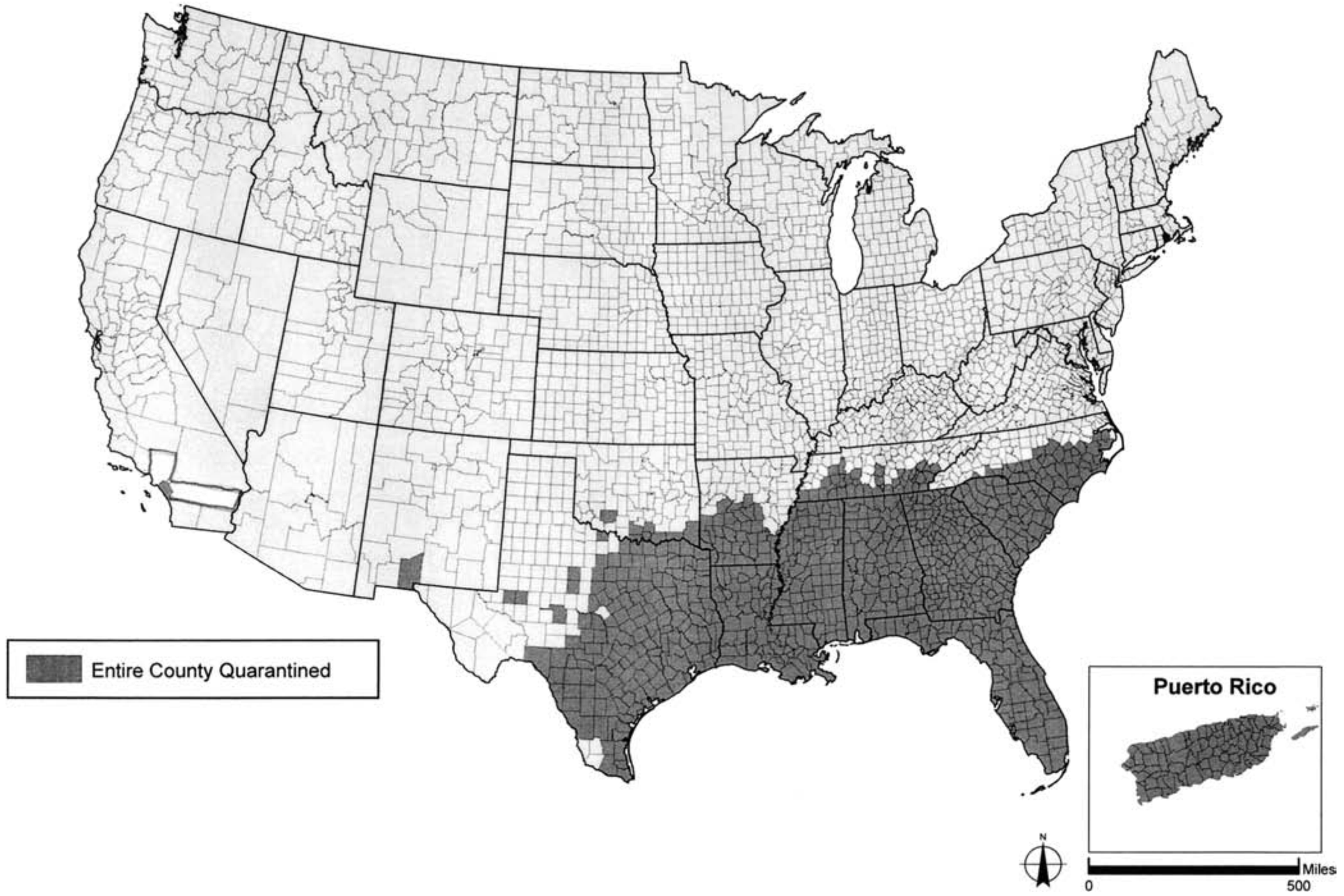

FIGURE 168.2. US Quarantine map of fire ants. Available at http://www.aphis.usda.gov/plant_health/plant_pest_info/fireants/downloads/fireant.pdf

severe allergic responses associated with the bites of the southeastern Australian bulldog ants (genus *Myrmecia*) including the jack jumper ant (*Myrmecia pilosula* Smith) and the bull ant (*Myrmecia pyriformis* Smith).[7] Other immunogenic ant species include the green-head ant (*Rhytidoponera metallica* Smith) from Australia and adjacent areas, as well as the Korean ant (*Pachycondyla chinensis* Emery).[8]

Behavior

Bees

Most bees are solitary, and their nomenclature reflects their particular habitat (e.g., miner, carpenter, mason, cuckoo). These bees do not usually defend their nests, but they will sting as a defensive maneuver when caught. Honey bees are social bees that form honey in a sophisticated colony (hive). Generally, honey bees are docile, and these insects usually sting only when disturbed or when their hive is threatened. In contrast to European honey bees, Africanized honey bees are easily agitated near their nest even with slight disturbances, and these honey bees remain agitated for hours. The Africanized honey bees reproduce and swarm at an accelerated rate compared with European honey bees, and the former frequently inflict hundreds of stings within several minutes.[9] Africanized honey bees are relatively indiscriminate about the selection of nesting habitat that includes open ground, tree branches, boxes, old tires, and buildings.[10] Although swarming honey bees are usually docile, these honey bees fiercely defend the hive once the colony settles on a location. Bees do not usually sting when foraging for pollen on flowers including Africanized honey bees. The bumble bee is a primitive bee that is relatively docile despite their large size and loud noises. Although they possess painful stingers and aggressively defend their nest, the relatively small nest population (i.e., about 200) limits their threat to humans.

Wasps and Yellow Jackets

Most wasps are solitary and harmless. Paper wasps (genus *Polistes*) may seek indoor shelter during winter, but these insects are not usually aggressive. These wasps build small umbrella-shaped hanging nests, commonly

under the eaves of houses. These colonies are smaller than yellow jacket colonies. The nests of paper wasps typically contain only 100–200 insects; therefore, paper wasps are not usually involved in mass envenomations. Wasps consume only liquid food. Yellow jackets are aggressive scavengers that forage food around areas (e.g., picnics) containing garbage. Their nests typically contain a few thousand individuals. These insects are common causes of anaphylactic reactions because of their aggressive behavior and highly antigenic venom. Hornets are relatively docile insects that nest either in the ground or above ground. Stings from these insects are uncommon unless their hive is threatened.

Fire Ants

Although almost all members of the ant family bite, the fire ant is the most vicious species with a relatively high attack rate and a well-developed stinging apparatus.[11] Fire ants are extremely prolific, in part, because of the presence of polygyne colonies (i.e., multiple fertile queens) in large conspicuous, above-ground, dome-shaped mounds. After mating in the air, the male fire ants die and the fertilized female flies about 6–24 hours (1–10 miles) before landing and shedding their wings. The queens that survive burrow into the soil to lay eggs. Over the next 25 days, the queen survives on the energy from wing muscles until worker ants mature enough to forage. A well-nourished queen produces up to 800 or more workers daily during her lifetime. Communication between ants results from the release of species-specific chemical pheromones as well as visual and vibrational stimuli. Fire ants contain magnetite, which orients the insect to north-south direction and attracts these insects to magnetic and electric fields present in underground power line. Fire ants fiercely defend their nest, stinging both humans and animals near their nest. A fire ant swarm can inflict 3,000–5,000 stings within seconds. Stings occur most commonly in the summer, particularly on the lower extremities of children.[4] While foraging for food or seeking shelter, fire ants may invade dwellings and attack infants or frail residents of long-term health care facilities.[12–14]

PRINCIPAL TOXINS

Venom Composition

Insect venoms have unique allergens as well as homologous allergen with partial sequence identity.[15] Consequently, multiple sensitivities to different insects may occur in an individual patient as a result of antigenic cross-reactivity of venom allergens or multiple exposures.

Bees

Honey bee venom is a complex mixture of vasoactive amines (dopamine, histamine, norepinephrine), enzymes (phospholipase A_2, hyaluronidase, acid phosphatase, lysophospholipase, α-D-glucosidase), and toxic peptides (melittin, apamin, protease inhibitor, secapin, peptide 401).[16] Histamine occurs in concentrations up to 1.5% of the venom. Peptide 401 is a mast cell-degranulating peptide that releases histamine and other vasoactive peptides. Melittin is a membrane-active polypeptide containing 26 amino acid residues. This substance causes local pain via histamine release and enhances phospholipase A_2-induced intravascular hemolysis as well as catecholamine release. Melittin disrupts membranes and then phospholipase A_2 cleaves bonds in the fatty acid portion of the bilipid membrane layer. Melittin accounts for about 50% of the dry weight of honey bee venom. The concentration of phospholipase A_2 in honey bee venom averages approximately 10% (dry weight). However, there is substantial variation in phospholipase A_2 content between individual European honey bees and between different honey bee colonies. In a study of phospholipase A_2 concentrations of 103 bees from approximately 10 colonies, the concentration of this enzyme varied between 1.8% and 27.4% (wt/wt).[17]

Hyaluronidase allows the spread of the venom through the dermis by disrupting the hyaluronic acid connective-tissue matrix and altering cell membranes. Apamin is a unique 18-amino-acid, single-chain structure with neurotoxic properties in small animals,[18] but the role of this toxin in humans has not been determined. In animal models, apamin in a convulsant that induces hyperactivity by blocking Ca^{++}-dependent potassium channels in the spinal cord and brain.[19] The venom of Africanized bees is similar to the venom of European honey bees with the latter containing slightly more hyaluronidase and less volume.[20] Consequently, the greater toxicity associated with Africanized honey bees results from the greater number of stings compared with European honey bees rather than a difference in the potencies of the venoms.

Although the composition of venom varies substantially among families within the order Hymenoptera, there are some homologous venom allergens.[21] Honey bee venom contains at least six allergens that include acid phosphatase, the glycoprotein phospholipase A_2 (PLA_2), the peptide melittin, apamin, peptide 401, and hyaluronidase.[22] Phospholipase A_2 and hyaluronidase are the major immunogenic components of honey bee venom that induce IgE-mediated anaphylaxis. The honey bee queens use venom only against other queens, and their venom does not contain the major allergens present in the venom of the worker honey bees.[16]

Bumble bee venom also contains venom protease, acid phosphatase, hyaluronidase, and PLA_2.[23] The latter allergen is structurally distinct from vespid phospholipase A_1 and partially cross-reactive with honey bee PLA_2.[24]

Wasps and Hornets

Vespid venom has some structural similarities to bee venom, but the variability of components in wasp venoms is greater than in bee venoms. Phospholipase A_2 and melittin occur only in bee venom, whereas antigen 5 occurs only in vespid venom. Both wasp and hornet venoms also contain phospholipase B.[25] Studies of hornet venom (*Vespula arenaria* Fabricius, *Vespula maculata* L.) indicated that the antigenic and allergic properties of vespid venom did not change significantly during the peak season (summer) of allergic responses to Hymenoptera stings.[26] *In vitro* studies indicate that venom from the Oriental hornet (*Vespa orientalis* L.) contains anticoagulants that prolong the activated partial thromboplastin time (aPTT) and, to a lesser extent, the prothrombin time (PT). However, there was no evidence of fibrinogenolytic or antithrombin activity.[27] Case reports of serious toxic reactions following multiple oriental hornet stings have not documented bleeding or clinically significant prolongation of the aPTT or the PT.[28]

Vespid venoms include at least four allergens (antigen 5, hyaluronidase, PLA_1, a protease) and two low-molecular-weight proteins (kinin, mastoparan). The peptide, mastoparan (CAS RN: 72093-21-1), causes histamine release by degranulating mast cells. The biological significance of antigen 5 is unclear. Although honey bee and vespid venoms are relatively distinct antigenically, both venoms contain immunologically cross-reactive hyaluronidase. The sequence identity of vespid and bee venom hyaluronidases is approximately 55%.[24] Patients sensitized to wasp venom are not usually allergic to bee venom.[29]

Fire Ants

In contrast to winged Hymenoptera venoms, fire ant (genus *Solenopsis*) venoms contain primarily water-insoluble alkaloids (solenopsins) with distinctive piperidine bases. These venoms contain only small amounts (i.e., about 0.1%) of proteins. The alkaloid portion of the venom consists of 2,6-dialkylpiperidine compounds that produce mast cell degranulation and histamine release via a nonallergenic mechanism.[30] There are age- and size-related changes in the alkyl and alkenyl groups in the venom from different fire ant workers as well as differences in isomers between different species.[31] Imported red fire ant venom contains at least four antigens (Sol i 1-4) with two of these antigens being homologous to vespid antigen 5s protein (Sol i 3) and phospholipase A_1 (Sol i 1). The venoms of the imported red and black fire ants are highly cross-reactive, but the venom of the imported black fire ant lacks the Sol i 4 protein.[32,33] Yellow jacket (*Vespula*) venom cross-reacts the Sol i 1 component of fire ant (genus *Solenopsis*) venom, and systemic allergic responses may occur in individuals sensitized to *Vespula* venom following the first-documented fire ant sting.

Venom Apparatus

Venomous members of the order Hymenoptera (ants, bees, wasps) inject venom via a tapered, posterior structure that is attached to a venom gland. Scorpions have a similar venom apparatus, but insects inject venom through their mouth parts. The sting is designed primarily as a defensive mechanism to discourage contact with the organism.

Winged Hymenoptera

The stinger of the European honey bee contains two reverse-barbed lancets connected to a venom sac, two membranous pump diaphragms, nerve ganglions, and a muscle. The curved barbs provide one-way traction that causes the barb to penetrate deeper into tissue as a result of the action of the detached muscles. Figure 168.3 demonstrates the stinging mechanism of the honey bee. A valve and piston on the proximal ends of the lancets forces the venom (i.e., about 50 μg) from the venom sac into an opening near the tip of the lancets. Unlike the stinging apparatus of other members of the order Hymenoptera, the stinging apparatus separates from the abdomen during the sting. Withdrawal of the stinger from the victim causes the tearing of the distal segment of the abdominal wall of the bee. During this process, the release of alarm pheromones (e.g., isoamyl acetate) from the area of the sting attracts other honey bees to the site of the sting. These pheromones evaporate from the surface of the sting with a banana-like smell. The eviscerated bee soon dies, but the reflex action of the pulsating muscles continues to inject venom. The Africanized honey bee has a smaller venom gland than the European honey bee.[20] In contrast to honey bee venom apparatuses, vespid stingers do not usually detach from their body during envenomation.[16]

The most primitive members of the order Hymenoptera (i.e., wasps) possess ovipositors to insert eggs into plant tissue. In some parasitic wasps, this structure evolved into a stinging apparatus to inject venom to obtain prey for developing larvae. Specialization of the

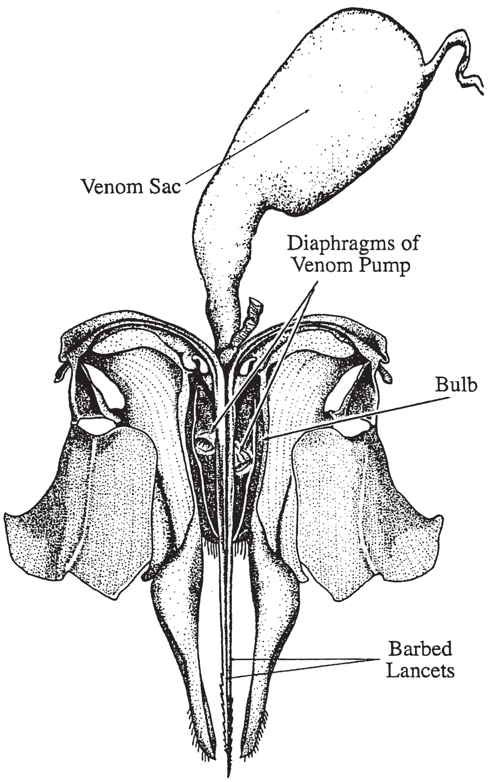

FIGURE 168.3. Stinger mechanism of honey bee. From Vetter RS, et al. Bites and stings of medically important venomous arthropods. Int J Dermatol 1998;37:484. Reproduced with permission from John Wiley & Sons Limited.

stinging apparatus by modern wasps resulted in an exclusively defensive weapon. Bees and ants evolved from the wasps, and the stinging apparatuses of these more modern organisms are primarily defensive.[16] The stinging apparatus of the wasp family lacks the barbs present on the stingers of honey bees. This feature allows the wasp to withdraw the stinger easily and to reinsert the stinger. Hence, multiple stings may occur from a single wasp, and retained wasp stingers are uncommon.

Fire Ants

Fire ant workers have well-developed stinging organs. The venom apparatus of the imported fire ant (*Solenopsis* spp.) is located on the distal abdomen as a modification of the ovipositor. Most ants (e.g., harvester or agricultural ants) grasp the skin with their jaws, and then these insects sting or spray locally irritating venom. During envenomation, the fire ant attaches to the skin with powerful mandibles, arches its body, and injects about 0.04–0.11 µL of venom containing approximately 10–100 ng proteins.[34] Compared with winged Hymenoptera, the sting is slower and lacks the immediate onset of pain. When undisturbed, the fire ant may rotate after 20–30 seconds and inflict several more stings in a circular pattern.[35] This maneuver produces a characteristic arc-shaped lesion.

TABLE 168.1. Types of Allergic Reactions

Type of Reaction	Clinical Features
Limited, local reaction	Pain, erythema, and swelling in immediate area of sting
Large, local reaction	Spread of local reaction *contiguously* beyond the local site of sting
Anaphylaxis	Urticaria, angioedema, dyspnea, bronchospasm, lightheadedness, hypotension
Delayed hypersensitivity	Maculopapular rash with serum sickness (arthralgias, malaise)

Dose Response

About 50–100 simultaneous Hymenoptera stings produce systemic symptoms in a nonsensitized adult, whereas the estimated fatal dose of bee venom involves 500–1500 stings. Most patients survive attacks from hundreds of wasps or approximately 1,000 bees,[36] and case reports document the survival of patients stung over 2,000 times.[37] A 52-year-old man developed transient hypotension and acute tubular necrosis after being stung by an estimated 1,200 Africanized bees.[38] He recovered with minimal renal dysfunction. A 30-year-old man survived over 2,000 honey bee stings following the development of shock and multiorgan failure.[39] Envenomation of a six-year-old boy by at least 60 Oriental hornets (*Vespa orientalis* L.) was associated with intravascular hemolysis, rhabdomyolysis, acute renal failure, and thrombocytopenia. The child survived without sequelae after peritoneal dialysis.[28] Fatal Hymenoptera evenomation in allergic individuals typically involves one to four stings.[40] The venoms of the Africanized honey bee and the European honey bee are similar; therefore, toxic responses from multiple envenomations by the Africanized honey bee are typically a dose-related phenomenon.[41] Fire ant stings do not usually produce toxic reactions despite massive numbers (>5,000–10,000) of stings.[42,43]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Table 168.1 lists the four types of allergic reactions associated with Hymenoptera envenomation. Most allergic responses to Hymenoptera envenomation are either local toxic responses or systemic type I immediate

hypersensitivity reactions mediated by IgE antibodies directed against the specific venom.[29] Limited local responses result from release of biological amines in the venom rather than an IgE-mediated response.[44] Although IgE is probably the primary immunoglobulin responsible for anaphylaxis, homocytotropic IgG or activated complement contribute to the degranulation of mast cells and basophils. Sensitized individuals synthesize excessive IgE antibodies when re-exposed to Hymenoptera venoms. Such antibodies cause the release of vasoactive substances that cause hypotension and smooth muscle contraction.

Type III (Arthus) hypersensitivity produces delayed reactions mediated by precipitating IgG and IgM antibodies. These proteins form immune complexes with the antigen that subsequently fix complement. Local tissue damage may result when platelet aggregates form on vascular endothelium and produce thrombi. Following massive envenomation by winged Hymenoptera, dose-related toxic reactions may result from the injection of large amounts of vasoactive substances. Toxic reactions do not usually develop following multiple stings by imported fire ants.

Pathological Changes

Massive Envenomation

Massive envenomations by species of winged Hymenoptera are associated with renal damage secondary to acute tubular necrosis, myoglobinuria, and hemoglobinuria. Histological changes following massive Hymenoptera envenomation include hyaline membrane disease, fatty degeneration of myocardium, liver, and kidneys, acute tubular necrosis, splenic hemorrhage, and cerebral vascular thromboembolism.

Fire Ant Lesions

The pustule formed by fire ant stings is pathognomonic for fire ant envenomation. Within the first hour, early spongiosis of the epidermis occurs with a surrounding red halo deepening in color following dilation of superficial dermal blood vessels.[45] The central papule evolves into a pustule as the overlying epidermis erodes during the first 24 hours. About one-half of these stings produce a biphasic reaction characterized by the resolution of the initial wheal-and-flare reaction followed within about 6 hours by a hypersensitivity reaction (edema, erythema, pruritus, pain) that peaks at 24 hours.[46] After 48–72 hours, healing begins from the base of the pustule. Microscopic examination of the lesions demonstrates a late-phase, mast-cell-dependent reaction characterized by infiltration of eosinophils and neutrophils along with the deposition of fibrin.[46] Superficial scars may form over the immediate area of atrophic skin.[47] A variety of ant species are capable of causing serious anaphylactic reactions in addition to fire ant species (*Solenopsis* spp.) including ant species belonging to at least six different subfamilies (Formicinae, Myrmeciinae, Ponerinae, Ectatomminae, Myrmicinae, Pseudomyrmecinae) and nine genera (*Formica, Hypoponera, Myrmecia, Odontomachus, Pachycondyla, Pogonomyrmex, Pseudomyrmex, Rhytidoponera, Tetramorium*).[48]

Postmortem

Most fatalities from Hymenoptera envenomation result from anaphylaxis, primarily massive edema, bronchoconstriction, and secretions causing bronchiolar obstruction.[49] Less often anaphylactic shock, airway obstruction, and vascular events (myocardial infarction, cerebral hemorrhage) cause death. There are no pathognomonic signs of anaphylaxis and postmortem findings in these cases of anaphylaxis are usually nonspecific.[50] Marked angioedema and laryngeal edema may or may not be present during autopsy.[40] The presence of stings or local reactions may be difficult to detect on postmortem examination despite a careful search, except following imported fire ant envenomation.[51,52] Common abnormalities present in postmortem examinations of victims of anaphylaxis include hyperemia, edema and hemorrhage of the larynx, pulmonary congestion and hemorrhage, and pleural petechiae.[40] Postmortem findings in fatal cases of anaphylaxis following fire ant envenomation involve characteristic skin lesions as well as increased blood concentrations of imported fire ant venom-specific IgE antibodies and tryptase.

CLINICAL RESPONSE

The most common response to winged Hymenoptera envenomations is a local reaction manifest by a sharp, stabbing pain followed within several minutes by intense, burning pain. The release of vasoactive amines causes a toxin-related wheal and flare reaction around the sting characterized by central erythema and a circumferential, white ring and edema. In most patients, the edema usually resolves within several hours. Pruritus and a warm sensation may persist several hours.

Fire ant envenomations produce a wheal-and-flare reaction within 20 minutes, followed in 24 hours by the formation of a characteristic, painful, sterile pustule. This lesion usually resolves within 3–10 days. Characteristically, multiple bites occur in a circular pattern; however, the absence of pustules does not rule out fire ant bites. Sensitized individuals may develop large local reactions (erythema, edema). The differential diagnosis of fire ant lesions includes blister beetle bites (bullous)

and the nonpruritic, nonpustular papular eruptions of *Molluscum contagiosum* (poxvirus).

Allergic Reactions

Large Local Reactions

Hymenoptera envenomations can produce an exaggerated response secondary to an allergic response manifest by a lack of systemic complaints and contiguous swelling that extends from the site of envenomation. These large local reactions seldom cause serious sequelae unless obstruction of vital structures (upper airway, esophagus) occurs. Severe local symptoms (pruritus, pain) may develop during the first 48–72 hours after envenomation and resolution may require up to one week. Vesiculation may occur in dependent areas of the extremities. An allergic response is usually associated with less pain and more pruritus compared with an infectious process. Painful, red streaks radiating up the extremity indicate the occurrence of lymphangiitis, particularly following yellow jacket stings. Rarely, case reports associate bullae formation, rhabdomyolysis, and myoglobinuria with large local reactions following a single hornet envenomation.[53] Acute bullous lesions may develop after fire ant envenomation, which progress to scar formation.[54]

Anaphylaxis

Approximately 0.4–4% of a random adult population report systemic allergic responses after stings by winged Hymenoptera.[55] Predicting which adults will develop severe anaphylactic reactions is difficult, and children appear to develop less severe, recurrent systemic reactions than adults.[56] Less than one-half of adults with positive venom skin tests to Hymenoptera and previous severe allergic reactions (laryngeal edema, severe bronchospasm, hypotension) will develop the same severe reaction after a subsequent hymenoptera sting.[57] Systemic symptoms of an immediate hypersensitivity reaction range from mild (urticaria, diffuse erythema, angioedema, nausea, vomiting, pruritus, anxiety) to severe (hypotension, laryngeal edema, severe bronchospasm, dyspnea). Systemic symptoms usually begin within 10 minutes after envenomation.[29] The presence of a sense of impending doom, wheezing, hoarseness, profound weakness, or confusion indicate a severe reaction, particularly during the first hour after envenomation. Similar anaphylactic reactions also occur in individuals with sensitivity to bites of the imported red fire ant including the occurrence of anaphylaxis without a history of prior sensitization of Hymenoptera stings.[58] However, the incidence of anaphylactic reactions per sting is less compared with winged Hymenoptera.[59]

Delayed Hypersensitivity

Delayed symptoms of serum sickness may occur about 7–14 days after envenomation. The clinical features of delayed hypersensitivity reactions include fever, malaise, lymphadenopathy, headache, arthralgias, myalgias, and urticaria.[60] Local tissue necrosis may result from delayed hypersensitivity.

Fatalities

Annually, anaphylactic responses to Hymenoptera envenomations account for approximately 40–50 US deaths, but the actual number of fatalities may be higher as a result of unsuspected deaths related to anaphylaxis.[61] Frequently, these patients do not have a history of prior anaphylactic reactions.[49] Symptoms of a severe allergic reaction typically develop immediately, and death occurs within one hour of envenomation secondary to respiratory obstruction or anaphylactic shock. Vascular events including coronary artery occlusion or cerebral thromboembolism may contribute to fatal outcomes in susceptible patients. Fatalities from massive Hymenoptera envenomations usually involve multiorgan failure including intravascular hemolysis, respiratory distress syndrome (ARDS), hepatocellular necrosis, acute renal failure with myoglobinuria and hemoglobinuria, focal subendocardial necrosis, and disseminated intravascular coagulation.[62] Fatalities secondary to toxic reactions from multiple fire ant stings are not well documented, and fatalities from fire ant envenomations usually result from anaphylaxis after a few stings.[32,63]

Toxic Reactions

Severe, immediate toxic reactions may result from massive envenomation by bees, hornets or wasps, particularly Africanized honey bees. The clinical features of a massive envenomation are similar to anaphylaxis, and symptoms include fatigue, headache, weakness, fever, muscle spasm, diarrhea, nausea, vomiting, lightheadedness, and transient loss of consciousness. Rarely, convulsions may occur usually along with multiorgan failure.[64] Within 24 hours, hemolysis, hemoglobinuria, rhabdomyolysis, and elevation of serum hepatic aminotransferases can develop.[65] The presence of hypotension, rhabdomyolysis, and hemoglobinuria may cause acute tubular necrosis, hyperkalemia, and renal failure.[66,67] Subendocardial damage and elevation of serum cardiac enzymes can occur in the absence of hypotension or anaphylaxis.[68] Serious complications of massive envenomations from vespids and bees also include intravascular hemolysis, disseminated intravascular coagulation, hepatic necrosis, acute renal failure secondary to hemolysis,

rhabdomyolysis, or direct nephrotoxicity,[69] intra-cranial hemorrhage, and myocardial infarction.[70,71] Case reports associate the development of acute interstitial nephritis after wasp stings secondary to hypersensitivity response in the absence of hemolysis or rhabdomyolysis.[72]

Signs of multiorgan failure after massive envenomation (>50–100 stings) may be delayed up to 18 hours, particularly in older patients with underlying systemic diseases.[73] Although case reports associate some neurologic disorders (multiple sclerosis, optic neuritis, myasthenia gravis, Guillain-Barré syndrome, Parkinson's disease) with recent hymenoptera envenomation, the causal role of Hymenoptera venom in the etiology of these neurological diseases is questionable. Fire ant stings do not usually produce toxic reactions despite massive numbers of stings.[42,74] Rarely, seizures are associated with fire ant stings, usually in the setting of anaphylaxis.[75] Complications of fire ant stings include secondary infection, primarily in immunocompromised hosts (e.g., diabetics, peripheral vascular disease), and rarely cutaneous sporotrichosis (dimorphic fungus).[76] Rare case reports associate massive fire ant envenomation with anaphylaxis, altered consciousness, rhabdomyolysis, and acute renal failure.[77]

Reproduction

Although there are few data on anaphylaxis during pregnancy, Hymenoptera-related anaphylaxis is a potential cause of fetal abnormalities and fetal loss. A case series of pregnant mothers with a history of anaphylaxis did not detect any significant abnormalities after anaphylaxis (one case) or the use of venom immunotherapy (26 women, two mild adverse reactions).[78]

DIAGNOSTIC TESTING

Analytical Methods

Hypersensitivity Testing

The gold standard for detecting hypersensitivity to Hymenoptera envenomations is intradermal testing. Venom-specific IgE antibody measurements with radioallergosorbent tests (RAST) or nonisotopic variants (e.g., the capsulated hydrolic carrier polymer radioallergosorbent test or CAP-RAST System) are alternative diagnostic methods to intradermal testing. Although 50–80% of patients with large local reactions to Hymenoptera envenomations will demonstrate positive skin tests or venom-specific antibody measurements, only about 1–2% of these patients will develop life-threatening systemic reactions to subsequent stings.[79] The presence of venom-specific IgE does not imply that an allergic response will occur following each sting. Venom-specific IgE eventually disappears from the blood, although the elimination of venom-specific IgE may require years following envenomation.

About 30% of adult patients with clear clinical histories of anaphylaxis following envenomation by Hymenoptera species do not demonstrate positive response to intradermal testing.[22] However, some of these patients do demonstrate positive venom-specific IgE-antibody serology, such as RAST or the CAP-RAST System (Pharmacia Diagnostics, Uppsala, Sweden).

Postmortem

Positive RAST tests and serum tryptase concentrations confirm the presence of hypersensitivity in postmortem serum samples.[80] The radioallergosorbent test (RAST) for venom-specific IgE is positive in most, but not all postmortem samples from patients dying from anaphylaxis; however, the concentration of venom-specific IgE antibodies does correlate to the severity of the anaphylactic reaction. In a study of postmortem samples from fatal anaphylactic reactions, the radioallergosorbent test did not detect specific IgE antibodies in about 10% of the victims.[81] Tryptase is mast-cell-specific enzyme released during the degranulation of the mast cell. Peak concentrations of tryptase occur within 1–2 hours after anaphylaxis begins, and the serum half-life of tryptase is about 2 hours.[82] Although this test is highly specific for anaphylaxis in antemortem specimens,[83] the lack of specificity in postmortem samples indicates that this test must be interpreted with other evidence of anaphylaxis (venom-specific IgE, clinical history, differential diagnosis, pathological findings).[84]

Abnormalities

Intravascular hemolysis may occur after massive Hymenoptera evenomation. Case reports associate transient, nonspecific ST-T wave changes, elevated CPK-MB fractions, and myocardial wall motion abnormalities with winged Hymenoptera envenomation despite the presence of normal coronary arteries.[85] These changes usually resolve within about one week without complications.[68]

TREATMENT

Stabilization

Anaphylaxis

Anaphylactic reactions are medical emergencies that require the prompt use of epinephrine. The most impor-

tant therapeutic measures are the prompt use of epinephrine, the maintenance of blood pressure, and the support of oxygenation. Most deaths occur within the first hour, and these fatalities typically result from respiratory failure in patients who did not received parenteral epinephrine. Patients with systemic symptoms of anaphylaxis should immediately receive oxygen, intravenous access, cardiac monitoring, and ventilatory support as needed. Substantial fluid replacement may be necessary in addition to epinephrine to treat hypotension. Patients with massive envenomation (>50–100 stings) may develop signs of anaphylaxis, and the treatment is similar to the treatment for anaphylaxis.

Ventilatory Support Patients with signs of upper airway edema should immediately receive parenteral epinephrine and oxygen. Inhaled racemic epinephrine may transiently reduce upper airway edema, but the limited absorption of epinephrine by the respiratory route limits reversal of other systemic symptoms. Bronchospasm should be treated with inhaled β_2-agonists (salbutamol, albuterol).

Epinephrine Epinephrine is the treatment of choice for anaphylaxis, and all patients with signs of a systemic response (generalized urticaria, angioedema, respiratory distress, shock) should receive epinephrine immediately.[86] For patients without obvious signs of shock, 0.1 mL/kg up to 0.3–0.5 mL of 1:1,000 epinephrine (adult dose: 0.3–0.5 mg) should be administered subcutaneously or intramuscularly. Studies in adults without anaphylaxis indicate that intramuscular epinephrine into the deltoid muscle produces higher and earlier peak plasma epinephrine concentrations higher than subcutaneous epinephrine.[87] Repeat doses of epinephrine at 5–15 minute intervals may be necessary to reduce symptoms and maintain blood pressure because of the short elimination half-life of epinephrine.[88]

Patients with cardiovascular disease and those over 40 years of age require careful cardiac monitoring for evidence of ischemia or dysrhythmias. Patients receiving β-blocker drugs may demonstrate a blunted response to epinephrine. The use of the mixed α and β agonist, epinephrine, in the presence of β blockade, produces primarily α-adrenergic effects, resulting in release of vasoactive mediators. Hence, patients with β blockade may be refractory to epinephrine and these patients may require an intravenous isoproterenol drip infused at a higher dose than the usual adult dosage of 1–20 μg/min.[89] The administration of glucagon is an option for these patients. The recommended dose for glucagon is 1–5 mg (20–30 μg/kg up to 1 mg for children) intravenously over 5 minutes followed by an infusion (5–15 μg/min) titrated to clinical effect.[86] The patients should be observed closely for the onset of emesis during the administration of glucagon.

Refractory Hypotension Aggressive fluid resuscitation is necessary for severely hypotensive patients unresponsive to epinephrine. Large volumes of crystalloid or colloid may be necessary to correct fluid extravasation and vasodilatation resulting from anaphylaxis. Intravenous epinephrine is an option for severe hypotension unresponsive to fluid infusion or cardiac arrest associated with anaphylaxis. There are few data on the clinical efficacy of intravenous epinephrine during the treatment of anaphylaxis, and intravenous epinephrine must be administered judiciously because of the potential for lethal arrhythmias. Epinephrine mixtures in resuscitation carts are usually a 1:10,000 dilution. For cardiac arrest *only* secondary to anaphylaxis, the recommended dose of epinephrine is 0.1–0.5 mg intravenously as a bolus compared with the standard 1-mg intravenous dose of epinephrine (10 mL of the 1:10,000 typically on crash carts) recommended by the American Heart Association for cardiac arrest. For patients with refractory hypotension, an intravenous epinephrine infusion by an infusion pump is an appropriate option. An epinephrine solution of 10 μg/mL (1 mg in 100 mL saline) is infused at 5–15 μg/min in adults according to the severity of the reaction.[90] The rate is titrated up or down based on response and side effects (i.e., tachycardia, tremor, pallor in a setting of normal or increased blood pressure). The infusion is stopped 30 minutes after resolution of the symptoms and signs of anaphylaxis. Vasopressors with strong α-adrenergic agonist properties (e.g., norepinephrine) may be necessary to support blood pressure if the patient does not respond to fluids and parenteral epinephrine. Case reports suggest that vasopressin (10–40 IU, intravenously) may restore blood pressure in patients with severe anaphylactic shock and no palpable blood pressure,[91] but there are few clinical data to determine if vasopressin is superior to norepinephrine for severe hypotension.

Antihistamines Antihistamines are slower in onset than epinephrine, and these H_1 and H_2 antagonists improve the cutaneous manifestations of anaphylaxis rather than hypotension.[86] Diphenhydramine hydrochloride (Benadryl®; Johnson & Johnson Consumer Companies, Inc., Skillman, NJ) should be administered in a dosage of 1 mg/kg (50–100 mg in an adult) either intramuscularly or intravenously depending on the adequacy of circulation. Frequently, an H_2-antihistamine blocker (e.g., ranitidine, 1 mg/kg in adults; 12.5–50 mg infused over 10 minutes for children) is administered intravenously for the treatment of cutaneous manifestations of anaphylaxis,[92] but there are few clinical data on

the efficacy of adding this drug to the outcome of anaphylaxis. Cyproheptadine is an alternative to diphenhydramine for the treatment of persistent local reactions.[53]

STEROIDS Corticosteroids are frequently administered to reduce the effects of delayed hypersensitivity reactions, despite the slow onset of action of these drugs. Typical steroid doses for serious systemic symptoms include are methylprednisolone 1–2 mg/kg intravenously.

Massive Envenomation

Toxic reactions resemble some of the manifestations of anaphylaxis, and treatment, in general, is similar to the treatment of anaphylaxis including antihistamines (H_1- and H_2-antagonists), epinephrine, steroids, and respiratory support as needed. The infliction of >50 stings in an adult or >1 sting/kg in a child indicated the need for at least 24 hours of monitoring of serum chemistries, serum creatine phosphokinase, and adequacy of urine output.[65] These patients should be evaluated for the development of renal failure, hepatic necrosis, intravascular hemolysis, and rhabdomyolysis. The presence of serum creatine phosphokinase concentrations exceeding 1000 μ/L indicates the need for generous fluid therapy to prevent renal damage.

Decontamination

Bees, but not wasps or hornets, may leave a stinger in the skin. Any stinger should be scraped off as soon as possible because the rhythmic action of the detached muscles continues for several minutes after envenomation. Experimental studies suggest that at least 90% of the venom sac contents are injected within 20 seconds and that venom delivery is almost complete within one minute.[93] Efforts to remove the stinger without touching the venom sac should *not* preclude the rapid removal of the stinger or interfere with treatment priorities.[94]

Supplemental Care

Patients with life-threatening allergic symptoms should be admitted for at least 24–48 hours of observation because of the potential for the onset of delayed biphasic reactions in up to 20% of patients with anaphylaxis.[95] Patients with massive envenomation (50–100 stings) by winged Hymenoptera may develop delayed signs of multiorgan failure, and these patients should be observed for 24 hours, particularly elderly patients or patients with underlying systemic diseases.[73] These patients should be evaluated for the presence of hemolysis, thrombocytopenia, hepatorenal dysfunction, rhabdomyolysis, and disseminated intravascular coagulation (DIC). Blood tests include complete blood count with differential, hepatic aminotransferase, electrolyte panel, DIC screen, creatinine, and creatine phosphokinase as well as a urinalysis. These tests should be repeated every 6 hours during the first day of admission.

Local Wound Care

The skin surrounding the sting may be cleaned with an antiseptic agent (e.g., povidone–iodine; Betadine™, Purdue Pharma, Stamford, CT) after inspection to ensure that the stinger has been removed. Remove constrictive jewelry immediately because of the potential for rapid swelling. Cold compresses, calamine lotion, and oral antihistamines (diphenhydramine, hydroxyzine) may help relieve pruritus and pain. A randomized, controlled trial of topical aspirin indicated that the application of a topical aspirin paste did not reduce the duration of swelling or pain after bee and wasp stings.[96] Systemic steroids are appropriate for patients with large local reactions (40 mg prednisone for 3 days), systemic symptoms, or delayed hypersensitivity reactions. Animal studies suggest that topical and systemic steroids, antibacterial medications, and antihistamines do not significantly alter the clinical course of fire ant stings,[97] but there are few clinical data in humans to confirm experimental data. Fingernails of children should be trimmed to reduce excoriation of the wound. The presence of pruritus and the absence of tenderness around the vesicles distinguish the sterile pustules from secondary infection.

Prevention

Patients with serious systemic reactions should receive a prescription of epinephrine self-injectors. EpiPen® and EpiPen JR® (Dey Inc., Napa, CA) are designed for self-administration of 0.3 and 0.15 mg epinephrine, respectively, subcutaneously at home, work, or recreational facilities.[98] These patients should wear a warning bracelet or tag at all times.

Sensitized individuals should wear muted, tight clothing that covers their extremities including their feet when outdoors. Bright, flowered clothing and attractive scents, soaps, and shampoos should be avoided. Long-sleeved clothing should be worn, especially for garden work. Materials or plants (e.g., clover, dandelions, uncovered sweet drinks) that attract stinging Hymenoptera species should be eliminated where possible, and Hymenoptera nests removed from close contact with living spaces of sensitized individuals. When confronted with winged Hymenoptera species, excessive

noise and motion should be avoided. Gently brush off the insect from the skin. Slowly retreat or stand still unless attacked by a swarm. When attacked by a swarm, run as quickly as possible in a zig-zag pattern to an indoor area (i.e., car, house). The face should be protected to avoid stings to the nose, mouth, and throat. Insect repellents (e.g., *N*,*N*-diethyl-3-methylbenzamide or *N*,*N*-diethyl-*meta*-toluamide [DEET]) do not repel stinging insects, such as bees, wasps, or fire ants.

Immunotherapy

Most authorities recommend desensitization with venom immunotherapy for those patients with previous immediate serious systemic symptoms (respiratory distress, asthma, marked hypotension, sudden collapse), and occasionally for patients with moderate systemic reactions (asthma, diffuse angioedema).[29,99] Commercial preparations of venom from honey bees, yellow jackets, white-faced hornets, yellow hornets, and wasps are available for diagnosis and venom immunotherapy. In contrast to winged Hymenoptera venom therapy, commercial fire ant immunotherapy involves only whole body extracts because of the lack of commercial fire ant venom extract.[100,101]

Mechanism of Action The exact mechanism for the reduction of symptoms following immunotherapy with increasing doses of insect venom is not known. Immune responses to protein antigens depend on the specific recognition of antigenic determinants (epitopes) by T and B lymphocytes. For example, bee venom phospholipase A_2 is the major antigen (allergen) of honey bee venom with three dominant immunogenic peptide and one glycopeptide T cell recognition sites. Specific antigen recognition by B cells can trigger distinct cytokine profiles in T cells leading to increased interleukin 4 (IgE synthesis), interleukin 5 (activation/attraction of eosinophils), and interleukin 3 (activation/attraction mast cells). Following immunotherapy, reduction of cytokine release by T_2-helper cells and increased cytokine release by T_1-helper cells occurs.[102] The reduced concentration of T_2-helper cells reduces the release of interleukins 3, 4, and 5. Additionally, increased T_1-helper cells increase the concentration of interleukin 2 and interferon gamma. The latter opposes the effects of interleukin 4 and reduces the secretion of venom-specific IgE.

Adverse Reactions In general, the use of venom immunotherapy is efficacious and the administration of immunotherapy does not usually cause serious adverse effects.[103,104] Mild systemic reactions may occur in up to 15% of patients during the initial course, but these patients are treated effectively with epinephrine and antihistamines.[29] Local reactions are common, but these reactions diminish with continued immunotherapy. Rarely, anaphylactic reactions may occur.

Indications Venom immunotherapy is a safe, effective therapy for the prevention of recurrent systemic reactions from Hymenoptera envenomations in patients with positive skin tests to Hymenoptera venom[105] as well as some fire ant and native ant [e.g., jack jumper ant (*Myrmecia pilosula* Smith)].[106] Patients with large local reactions and positive skin tests for venom-specific IgE-specific antibodies are not candidates for immunotherapy because very few (i.e., 1–2%) of these patients will develop life-threatening reactions following subsequent stings.[22] The decision to use venom immunotherapy in patients with positive skin tests and no prior reaction or with negative skin tests and prior systemic reactions requires physician judgment and experience.

Chapter 169

BUGS and BLISTER BEETLES

BUGS

IDENTIFYING CHARACTERISTICS

Most species in the order Hemiptera feed on plants. The only medically important families in the order Hemiptera (true bugs) are Reduviidae (assassin/kissing bugs, wheel bugs) and Cimicidae (bedbugs). The Reduviidae bugs vary substantially in body size and shape, ranging from a small, robust habitus to long, slender "walking sticks." The stout, three-segmented beak that fits into a grove on the prosternum distinguishes these insects from other members of the order Hemiptera. Of at least 10 species of kissing or cone-nosed bugs (*Triatoma* spp.), there are five common species in the continental United States including *T. gerstaeckeri* Stal, *T. protracta* Uhler, *T. rubida* Uhler, *T. rubrofasciata* De Geer, and *T. sanguisuga* LeConte.[1]

Common Name: Assassin Bug, Kissing Bug, Reduviid Bug, Western Cone-Nosed Bug

Scientific Name: *Triatoma protracta* Uhler

Family: Reduviidae

Physical Description: This black or brown bug is 2.5–4 cm (~1–1.5 in.) in length and has a long triply segmented proboscis (beak). Other species of *Triatoma* range in length from 1.2–3 cm (~0.5–1 in.). The elongated head has a transverse groove behind the eyes. This elongated head and short curved proboscis distinguishes the assassin bugs from plant-feeding bugs, which possess a proboscis that rests flat under their head. The meeting of the membranous wings just behind the head forms a distinguishing triangular shape.

Common Name: Wheel Bug

Scientific Name: *Arilus cristatus* L.

Family: Reduviidae

Physical Description: The wheel bug is a dark robust, bizarre insect with long legs and antennae, stout beak, and large eyes on a slim head. This 2–4 cm (~1–1.5 in.) long bug has a characteristic semicircular crest suggesting a cogwheel or chicken's comb on its prothorax along with a narrow head and stout proboscis. Females are longer and wider than males with the abdominal margins being more widely exposed in females. A fine yellowish pubescence occurs over most of the body with the exception of the bronze-colored elytral membrane over the wingcase. The background color is mostly dark brown. Variable amounts of tiny white patches or granules appear throughout the pubescence.

Common Name: Bedbug

Scientific Name: *Cimex lectularius* L.

Family: Cimicidae

Physical Description: The bedbug has a very flat dorsoventral shape with a broad, oval body of about 3–6 mm (~0.1–0.2 in.) in length.

EXPOSURE

Geographic Distribution

Fifteen species of assassin bugs occur in the United States distributed in a crescent-shape from Florida to northern California. Kissing bugs (*Triatoma* spp.) belong to the subfamily Triatominae of the insect family Reduviidae, and Figure 169.1 demonstrates the approximate US distribution of the five common kissing bug species. Kissing bug species are found in Mexico, Central America, and South America where they can inhabit the cracks and cervices of human dwellings. The wheel bug occurs in areas from Rhode Island westward through Iowa and Nebraska to California, and southward to Florida, Texas, Mexico, and Guatemala. There are four genera of wheel bugs in the New World, but only *Arilus cristatus* L. occurs in the United States. The common bedbugs (*Cimex lectularius* L.) occur in both tropical and temperate regions. The Asian species is *Cimex hemipterus* Usinger. Dissemination of bedbugs results from contact with infested clothing, baggage, beds, and laundry.

Behavior

Assassin and Kissing Bugs

Assassin bugs are predators, which feed on small animal (snails, insects, spiders, other arthropods). The proboscis of the assassin bug is curved outwards from the head, and the proboscis swings forward to attack prey. All members of the genus *Triatoma* (kissing bugs) feed on blood from vertebrate hosts (small- to medium-sized mammals, birds, humans) including males, females, and all developmental stages. The host for *T. protracta* Uhler is the wood rat (*Neotoma* spp.). The usual habitat of *T. protracta* Uhler is the den of wild rodents, armadillos, or opossums, but this insect readily adapts to human habitats. During summer, this bug leaves the host, usually during warm summer nights. These bugs are attracted to lights in human habitats. Although these nocturnal insects can fly when provoked, they prefer to crawl. The primary stimulus for flights of *Triatoma* bugs is starvation. High after-dark temperatures and calm air promote these flights, which are usually less than one mile (~1.6 km).[2] *Triatoma* bugs spend daylight hours in dark protected areas and feed nocturnally, inflicting multiple, painless bites on open or loosely covered areas of skin. The multiple bite marks probably represent temporary disruptions of feeding. The victim usually remains asleep during the 10–25 minutes of feeding. An adult kissing bug can ingest 2–4 times their body weight in blood, and the kissing bug deposits feces and undigested portions of the meal on the skin and wound after completion of feeding.[1] The name *kissing bug* is derived from the predilection of these nocturnal, blood-sucking insects for skin near the lips.

FIGURE 169.1. Distribution of five common kissing bug species in the United States. From Moffitt JE, et al. Allergic reactions to *Triatoma* bites. Ann Allergy Asthma Immunol 2003;91:123. Reproduced with permission from Adis International.

The wheel bugs produce one generation per year with the eggs laid during winter. This insect is diurnal, but lights attract prey and this bug. The wheel bug and

most other reduviids produce "chirping" sounds by rubbing the tip of the rostrum back and forth over transverse ridges on a longitudinal groove on the prosternum.

Bedbugs

Bedbugs cannot jump or fly because of the lack of wings. However, they can run relatively rapidly on their six legs during warm weather.[3] These large, flat brown bugs hide in protected crevices, roosts, or other protected places during the day and feed at night on exposed skin. After completing a meal in 4–10 minutes, bedbugs return to their hiding places (mattress seams/tufts, bed frames, springs, floor cracks, furniture, wall surfaces).[4] Bites are usually multiple and painless in an irregular, linear fashion involving groups of three. They cluster on dry, rough surfaces (wood, paper) rather than stone, plaster, metal, or textiles. They avoid wet surfaces. Well adapted to human habitats, the female bugs lay eggs in cracks on floors or on furniture. The mature bug emerges after 1–2 months to feed nocturnally.

PRINCIPAL TOXINS

Venom Composition

The composition of the saliva from assassin bugs and bedbugs are not well-characterized. Apyrases are nucleoside triphosphate-diphosphohydrolases found in the saliva of hematophagous insects (e.g., kissing bugs) that probably prevent ADP-induced platelet aggregation of the host during blood sucking.[5]

Venom Apparatus

Assassin bugs paralyze their prey by puncturing them with sharp stylets in their proboscis and injecting saliva. Thereafter, the assassin bug extracts the body fluids. Figure 169.2 displays the thorax and head including proboscis of a white-eyed assassin bug (*Platymeris biguttata* L.). *Triatoma* bugs feed by capillary puncture after the injection of anticoagulants in their saliva. The secretions of the salivary glands contain antigens capable of initiating allergic reactions.[6] Wheel bug saliva contains a toxic, paralytic substance that immobilizes and kills the prey soon after injection.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The lesions occurring after assassin bug bites probably results from an immune response rather than a toxic reaction.[7] A foreign protein in the saliva of kissing bugs causes allergic response ranging from pruritus, urticaria, lightheadedness, and gastrointestinal distress to anaphylaxis.[7]

FIGURE 169.2. White-eyed Assassin Bug (*Platymeris biguttata* L.). © 2007 Rune Midtgaard. See color insert.

CLINICAL RESPONSE

Assassin and Kissing Bugs

Bites from members of the Reduviidae family produce distinctive, but not pathognomonic lesions. Commonly, the kissing bug inflicts multiple erythematous, pruritic nodules clustered on a single, uncovered area (arms, neck, shoulders, face).[7] Bug bites produce marked variability in skin reactions as a result of differences in individual hypersensitivity to these bites.[8] One or more puncta may be visible on the skin lesions. A delayed hypersensitivity reaction produces erythematous, pruritic papules 24–48 hours after the bite. Kissing bug bites (*T. protracta*) may be associated with substantial swelling (i.e., 2–6 cm/~1–2.5 in.), ecchymosis, and pain compared with most nonstinging insects.[9] These lesions usually resolve over 24–48 hours, but lesions may last up to one week in sensitized patients.[7] Victims may awake with an anaphylactic reaction (urticaria, angioedema, flushing, pruritus, respiratory distress, syncope, wheezing, hypotension, nausea, vomiting, abdominal cramps) following an undetected bite by the kissing bug.[10] This insect is a vector for American trypanosomiasis and Chagas' disease. The mild-mannered wheel bug uses its snout to produce a temporarily painful laceration that usually heals without complications. These bugs produce several linear, often hemorrhagic lesions that do not usually cause a hypersensitivity reaction.

Bedbugs

Bedbugs (*Cimex lectularius*) typically inflict linear bites along with a characteristic track of black or brown excrement on the bed linen. These bites produce a wheal and papule with a small, central hemorrhagic punctum.[11] In contrast to bedbugs, kissing bug bites are nonlinear and grouped together; these lesions may be misdiagnosed as spider bites. Bedbug bites often do not produce sensitization in adults, but a papular urticaria is associated with flea and bedbug bites in children aged 2–7 years.[12]

DIAGNOSTIC TESTING

There are no biomarkers for the detection of bites by these bugs. Clinical laboratory abnormalities are not usually associated with bites by these insects.

TREATMENT

Management of the assassin bug bite is supportive. Medications containing menthol, phenol, or camphor may relieve itching. The presence of systemic reactions necessitates a search for the offending organism and its eradication from the home including removal of piles of paper, clothing, blankets, and sheets. *Triatoma* bugs rarely bite covered skin; therefore, victims should wear long sleeve pajamas to cover all the skin. Lesions should be observed for secondary infections. Immunotherapy may be necessary for patients developing serious anaphylactic reactions.[13] Bedbug treatment is supportive, with cool, wet compresses and mild analgesics.

BLISTER BEETLES

HISTORY

Cantharidin has a history of use in Medieval medicine as a skin irritant, vesicant, abortifacient, and aphrodisiac. Hippocrates prescribed cantharidin for the treatment of dropsy and amenorrhea. Dioscorides, a Greek army physician in the 1st century AD, advocated the use of cantharidin as an aphrodisiac. In a treatise published in 1698, Groeneveldt recommended the use of cantharidin for bladder and kidney infections, dropsy, renals stones, and some venereal diseases.[14] Widespread use of cantharidin as an aphrodisiac occurred during the 18th century, probably because of the priapism and pelvic congestion produced by the marked genitourinary irritation resulting from toxic doses of cantharidin.[15] Roviquet first isolated cantharidin in 1810. The dermatitis associated with the blister beetle has been known in the United States since the middle 1800s, when rove beetle epidemics occurred during flooding along the Colorado River.[16] Classic descriptions of blister beetle dermatitis were reported in the 1940s and 1950s.[17,18]

IDENTIFYING CHARACTERISTICS

There are three major families of blister beetles in the order Coleoptera including Meloidae (e.g., Spanish Fly), Staphylinidae (rove beetles), and Oedemeridae (e.g., false blister beetle, Nairobi fly). The Meloidae family contains the Spanish fly (*Lytta vesicatoria* L.) from Southern Europe. Of the three families, Oedemeridae is the smallest with members including the genera *Ananca* (*Eobia* spp., coconut beetles), *Hypasclera* (*Alloxacis*), *Oxacis*, and *Thelyphassa*.[19] These light-colored beetles are 5–12 mm (~0.2–0.5 in.) in length with the prothorax widest in the front, narrowing to the wing-case (elytron). The abdomen is relatively large, and the antennae are usually thread-like. The family Staphylinidae contains the African blister beetle called the Nairobi fly (*Paederus sabaeus* Erichson). This beetle is about 5–7 mm (~0.2–0.3) long with striking red, dark green, and black colorations.

EXPOSURE

More than 200 species of blister beetle occur worldwide; these beetles are most abundant in southern Europe and western Asia. The distribution of members of the Oedemeridae family primarily is the Pacific Basin (Papua New Guinea, Solomon Islands, Pago Pago, Samoa, Fiji, New Caledonia) and the Caribbean (Florida keys, Bahamas, Cuba, West Indies). This insect lives in brush, and exposure is accidental. Commonly, contact occurs painlessly during handling of garden plants in the eastern United States. Blister beetles do not bite or sting; the blisters associated with these beetles results from contact with cantharidin in the crushed beetle. Rove (Staphylinid) beetles are nocturnal predators attracted to light with about 26,000 species distributed worldwide. They do not bite or sting.

Cantharidin has been used for centuries as a sexual stimulant to enhance sexual pleasure.[20] Vascular congestion and inflammation result from the inhibition of phosphodiesterase and protein phosphatase activity as well as the stimulation of beta-receptors. However, the abuse of cantharidin causes substantial morbidity. Other traditional methods to increase sexual pleasure include the ingestion of live beetles (*Palembus dermestoides*

Farmaire) in Southeast Asia and triatomids in Mexico. Cantharidin is the active ingredient in a flexible collodion for the removal of warts. Blister beetles do not bite or sting.

PRINCIPAL TOXINS

All parts of the blister beetle in the families Meloidae and Oedemeridae contain the powerful vesicant, cantharidin (CAS RN: 56-25-7).[21] This volatile compound is a simple double-ringed structure that is the crystalline, anhydrous form of cantharidic acid as demonstrated in Figure 169.3. This vesicant is a colorless, odorless, glistening, water-insoluble compound. Cantharidin is the active ingredient in the apocryphal aphrodisiac "Spanish fly." Although the highest concentration of cantharidin occurs in the Chinese blister beetle (*Mylabris cichorii* L.), the source of most cantharidin is the Spanish fly (*Cantharis vesicatoria* De Geer). Table 169.1 lists some physical properties of cantharidin.

The dermatitis associated with beetles from the family Staphylinidae (e.g., *Paederus* spp.) result from contact with pederin (CAS RN: 27973-72-4) in the hemolymph, and the skin reaction is delayed substantially longer (i.e., 12–36 hours) compared with contact with cantharidin. The cutaneous reaction to pederin produces a more prominent urticarial dermatitis than cantharidin. Figure 169.4 displays the chemical structure of pederin.

The site of cantharidin and pederin synthesis is not known. All 10 stages of the blister beetle contain cantharidin, and the larvae extrude a milky oral fluid that contains this chemical when disturbed.[22] The adult beetles reflexively discharge toxic chemicals in the hemolymph extruded near leg joints. Although female beetles do not produce cantharidin, female beetles are able to extrude cantharidin as a result of the deposition of cantharidin in seminal fluid during copulation.[23] The mature adult male blister beetle contains about 17 mg of cantharidin, which represents up to about 10% of the beetle's live weight.[22] The highest concentration of cantharidin in male specimens of *Epicauta conferta* and *Epicauta occidentalis* were 2.48%/dry weight and 3.31% dry weight, respectively.[24]

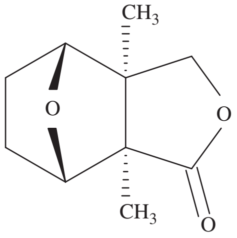

FIGURE 169.3. Chemical structure of cantharidin.

TABLE 169.1. Some Physical Properties of Cantharidin

Physical Property	Value
Melting Point	218 °C/424.4 °F
log P (Octanol-Water)	1.220
Water Solubility	30 mg/L (20 °C/68 °F)
Atmospheric OH Rate Constant	1.68E-11 cm^3/molecule-second (25 °C/77 °F)

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Contact with hemolymph from the blister beetles causes irritant contact dermatitis characterized by intraepidermal and subepidermal blistering, epidermal necrosis, and acantholysis.[25] Cantharidin causes the activation of neutral proteases that destroy dense desmosomal plaques, and this compound is a potent inhibitor of protein phosphatases 1 (PP1) and 2A (PP2A). The loss of these plaques results in the detachment of tonofilaments from the desmosomes and the appearance of intraepidermal blisters. Skin biopsies of these lesions demonstrate large intraepidermal vesicles with fibrin, polymorphonuclear cells, and acanthocytes.[21] A light, superficial, perivascular infiltrate may be present in the area underneath the intact stratum corneum along with necrotic keratinocytes, but eosinophils are generally few. Because the action of cantharidin is entirely epidermal, lesions heal without scarring. Large doses of cantharidin may produce acute renal tubular necrosis with loss of brush borders and varying degrees of cloudy swelling and hydropic degeneration.[26] Pederin in the

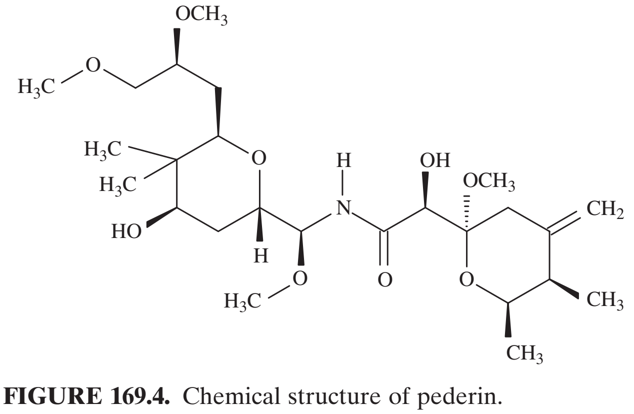

FIGURE 169.4. Chemical structure of pederin.

hemolymph from beetles from the family Staphylinidae causes a spectrum of histopathologic changes ranging from acute epidermal necrosis and vesiculation to marked acanthosis with mitotic figures in later stages.

CLINICAL RESPONSE

Cantharidin is a skin vesicant and a potent irritant of the gastrointestinal and genitourinary mucosa.[27] Following oral exposure, this irritation causes vesiculobullous lesions, mucosal edema, and hematuria.[28]

Cutaneous Effects

Blister beetle dermatosis is a seasonal vesiculobullous skin disorder resulting from contact with hemolymph from beetles in three beetle families (Meloidae, Staphylinidae, Oedemeridae). There is large individual variation in the response to cantharidin. Within several hours of contact with the hemolymph of the blister beetle, 5–50 mm (~0.2–2 in.) vesicles or bullae develop. The vesiculation associated with beetles of the *Paederus* species (whiplash rove beetles) is delayed 12–96 hours compared with the occurrence of vesicles within 2–3 hours after exposure to cantharidin from the Meloidae and Oedemeridae families.[29] The vesicles and bullae contain clear fluid, and the skin surrounding the lesion demonstrates no or minimal erythema. The initial contact is painless, and the victim is usually unaware of contact with the beetle. The flaccid, asymmetric blebs may become painful and hemorrhagic, but the lesions are usually only mildly or moderately pruritic. The geographic shape resembles the pattern caused by hot water splashed on the skin. The skin on the neck and exposed extremities are the most common site of injury. Secondary blisters may appear in opposing tissue (e.g., popliteal fossa). Skin lesions usually resolve over 5–7 days without scarring.[30]

A periorbital, vesicular dermatitis and keratoconjunctivitis may develop after transfer of the toxin from contaminated fingers to the facial skin.[31] These adverse effects usually resolve over several weeks. The differential diagnosis of this dermatitis includes irritant or allergic contact dermatitis, thermal or chemical burns, pemphigus, dermatitis herpetiformis, herpes simplex, herpes zoster, impetigo, and porphyria. Contact with rove beetles is associated with the development of vesicles with large areas of surrounding erythema in the area of contact. The lesions may become pustular.[32]

Systemic Effects

Systemic effects (fever, lymphangitis, lymphadenopathy, wheezing, dyspnea, lightheadedness, joint swelling) are usually absent following dermal exposure to blister beetles. A case report associated the presence of cantharidin-induced skin lesions with the development of nephritis (edema, renal failure, hematuria), but there is no clear evidence that transdermal absorption of cantharidin causes renal abnormalities.[33] Although experimental animal data suggest that cantharidin may be cardiotoxic,[34] there is no clinical data to confirm a causal link between cantharidin exposure in humans and cardiac damage.

Ingestion of blister beetle produces profound gastrointestinal irritation manifest by abdominal pain, nausea, and vomiting along with vesiculation, hemorrhage, and ulceration of the mucosa in the oropharynx and in the gastrointestinal tract.[18,35] Hematemesis may occur as a result of excoriation of the gastrointestinal tract. Blistering of the mouth and throat may cause dysphagia and dysphonia. A fatality has been associated with the use of cantharides from dried Chinese medicine (Ban Mao) as an abortifacient.[36] A 23-year-old female died of renal failure and disseminated intravascular coagulation 2 days after ingesting the boiled extract of 200 blister beetles (*Mylabris phalerata* Pallas). Postmortem examination of the kidneys indicated acute tubular necrosis, primarily involving the proximal renal tubules.

DIAGNOSTIC TESTING

Analytical methods for the quantitation of cantharidin in biological samples include gas chromatography (GC), gas chromatography/mass spectrometry (GC/MS), and high performance liquid chromatography (HPLC).[37] The postmortem cantharidin concentration in a patient, who died 2 days after the ingestion of a boiled extract containing cantharidin as an abortifacient, was 0.11 μg/mL as determined by GC using trichloroacetic acid as an extractant.[36] The antemortem blood and urine cantharidin concentrations were 0.27 μg/mL and 4.45 μg/mL, respectively. The cantharidin concentration in the postmortem blood from a patient who died shortly after admission to the hospital was 0.073 μg/mL as measured by GC/MS with selected ion monitoring technique.[38] Reportedly, the deceased ingested cantharides powder containing 0.87% cantharidin prior to the onset of illness. Laboratory abnormalities associated with oral exposure to blister beetles include hematuria and mild proteinuria with normal renal function.[39]

TREATMENT

Treatment is supportive. Application of steroid cream to skin blebs may be helpful. Lesions usually subside in 2–3 days.

Chapter 170

FLEAS
(Order: Siphonaptera)

IDENTIFYING CHARACTERISTICS

Of the more than 2,400 species and subspecies of fleas, only a few species are medically important to humans including *Ctenocephalides felis* Bouche (cat flea), *Ctenocephalides canis* Curtis (dog flea), *Xenopsylla* spp. (oriental rat flea and vector of endemic typhus and bubonic plague), *Tunga penetrans* L. (sand flea), *Echidnophaga gallinacea* Westwood (stick-fast flea of poultry), *Ceratophyllus niger* C. Fox (chicken flea), and *Pulex irritans* L. (human flea and vector of plague).[1] The flea is an intermediate host for the tapeworm *Dipylidium caninum* L., which infects dogs, cats, and occasionally, humans. Most fleas prefer a particular host, but these ectoparasites will attack a range of hosts when hungry.

Fleas are small (2–3 mm/~0.1 in.), dark, shiny, wingless, blood-sucking insects with a highly compact, laterally compressed body and specialized head. The flattened lateral body and posteriorly directed spines allows easy traversal of skin containing hair or feathers.

EXPOSURE

Geographic Distribution

Fleas are distributed worldwide in association with their hosts.

Behavior

Fleas usually prefer specific hosts (e.g., dogs, cats, birds, humans), but they remain on their host only long enough to obtain a blood meal. These wingless ectoparasites attack humans in the absence of their normal host (e.g., during absence of a host pet in a home). They are intermittent, blood-sucking insects that prefer covered areas of skin to avoid light. Fleas can live for several months in rugs and furniture without a meal. Their long, strong hind legs allow vertical jumps of 7–8 in. (~18–20 cm) and horizontal jump of 14–16 in. (~36–41 cm).[2]

Cat and dog fleas undergo four separate stages (egg, larva, pupa, adult) in their life cycle as depicted in Figure 170.1. The time required for each cycle ranges from 3 months to several years depending on the species and on environmental factors (e.g., food sources, humidity, temperature). Adult cat and dog fleas mate on the host, and the female must ingest a blood meal to lay fertile eggs. During feeding, the female fleas excrete long tubular coils or fine pellets containing incompletely digested blood. Flea eggs are oval, white, nonadherent objects that typically hatch in 1–10 days. The eggs drop from the host and become widely distributed in the surrounding area. The larvae develop in the house, and they feed on organic debris in dark places (rugs, floor cracks, furniture, pet bedding). The larvae enter the pupal stage after forming silken cocoons, which can protect the flea for about 6 months in the absence of desiccation. The adult flea emerges from the cocoon after appropriate stimulation (e.g., vibrations).

PRINCIPAL TOXINS

Fleas penetrate skin with a needle-lick proboscis (labrum epipharynx), and they feed on blood extravasated from surrounding capillaries. The oral secretions injected from the salivary gland during the bite include

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

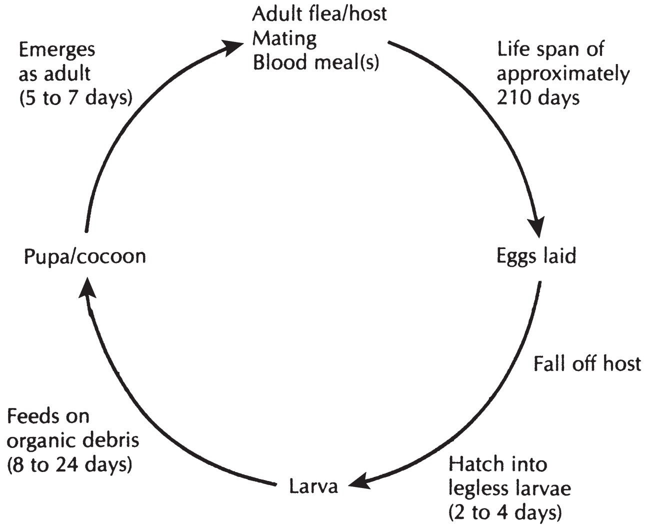

FIGURE 170.1. Life cycle of dog and cat fleas.

anticoagulants, local anesthetics, and antigens. Cat fleas and flea debris may contribute to the complex allergens associated with house dust.[3]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The bite of the flea involves penetration of the mouth parts that usually causes a light-colored, punctate lesion surrounded by erythema.

CLINICAL RESPONSE

Although fleas are important disease vectors (e.g., murine typhus, bubonic plague), their primary clinical manifestation is the appearance of bite sensitivity. The inflammatory papules caused by flea bites characteristically are arranged in linear groups of three or four limited by tight clothing. A central punctum occurs where the mouth parts penetrate the skin. The roseate papule may become hemorrhagic or bullous in highly sensitized individuals. Cat and dog fleas typically produce lesions on the ankles in ambulatory individuals, whereas bird fleas usually produce more widespread lesions. Flea bites are common in children, particularly in children with papular urticarial lesions on the lower extremities. Papular urticaria is the term for chronic or recurrent eruption of irregular, pruritic papules affecting primarily children between 2–7 years of age.[4] These lesions typically persist for 2–10 days with temporary hyperpigmentation. Excoriations of these intensely pruritic lesions frequently cause secondary infections. The most common causes of these lesions are the cat flea, dog flea, or human flea.[5] Other causes include the bedbug and less commonly mosquitoes or various species of mites. Infants and adults in the same household may not develop papular urticaria despite the presence of this condition in young children from the affected household.

Flea bites on the genital, perianal, and axillary regions are unusual. Severe attacks generally occur in patients moving into a new residence that previously contained pets because fleas become aggressive when they lose their host. Tungiasis is a cutaneous ectoparasitic infestation by the female sand flea (*Tunga penetrans* L.) that primarily involves the feet where the flea burrows underneath the stratum corneum of the toes and causes paronychia.[6] This disease occurs mostly in impoverished areas of sub-Saharan Africa, the Caribbean, Latin America, and South America.[7]

DIAGNOSTIC TESTING

The diagnosis of flea bites is a clinical rather than laboratory diagnosis. The presence of a group of several hemorrhagic puncta surrounded by an erythematous urticarial papule is characteristic of flea bites, particularly when located on the ankles and legs.[8]

TREATMENT

Most flea bites resolve without treatment. Calamine lotion and oral antihistamines are effective antipruritic agents. Cool wet compresses (Epsom salts or Domeboro tablets) provide symptomatic relief. Application of a menthol ointment 3–4 times a day provides relief from the burning and pain associated with the bites. The treatment of papular urticaria involves the use of mild topical steroids and system antihistamines for control of pruritus. Secondary infections may occur that necessitate the use of oral antibiotics. Removal of fleas is the most important preventive measure.[9] Eradication of fleas requires a multistep approach including treatment of the infested animals with insecticide and the cleaning of the surrounding habitat. The pet bedding should be washed in hot water, and the area in contact with the infested pet should be vacuumed thoroughly. The vacuum cleaner bag should be sealed and discarded after cleaning. All pets in contact with the infested pet also should be treated. After the house has been cleaned, the house should be treated with an approved pesticide spray (resmethrin, malathion, carbaryl, diazinon). Newer pet products for the topical treatment include imidacloprid (Advantage™, Bayer HealthCare, LLC, Shawnee Mission, KS) and fipronil (Frontline®, Merial, Ltd., London, UK), whereas orally administered pet products include insect growth regulators (methoprene, fenoxycarb, pyriproxyfen) and insect development inhibitors

(lufenuron). Repeat treatment may be necessary, especially during heavy infestations because of the relative resistance of the eggs and pupae to treatment.

Chapter 171

FLIES and MOSQUITOES
(Order: Diptera)

IDENTIFYING CHARACTERISTICS

A single pair of wings characterizes the members of this order of blood-sucking insects (biting flies and mosquitoes). A small knobbed structure that functions as a stabilizer appears behind the wings.

Common Name: Mosquito
Scientific Name: Family *Culicidae*
Physical Description: Mosquitoes have slender bodies about 3–6 mm (~0.1–0.2 in.) in length that is divided into a head, thorax, and abdomen. There are six long, thin legs with tiny claws at the ends and two wings covered with flat scales. Most other flies have four wings. The head has two antennae and a long proboscis, which allows the mosquito to suck liquid from prey. The abdomen is a long, slender tube with eight pairs of spiracles.

Common Name: Sandfly
Scientific Name: *Lutzomyia* spp. (*Phlebotomus* spp.)
Physical Description: Sand flies are tiny, hairy gnats (1–3 mm/~0.1 in.) that breed in dark, damp crevices during the day.

Common Name: Black Flies, Midges, Buffalo Flies
Scientific Name: *Simuliidae* spp.
Physical Description: Black flies, midges, and buffalo flies are small (1–5 mm/~0.1–0.2 in.) flies that have a hump-backed appearance.

Common Name: Stable Fly
Scientific Name: *Stomoxys calcitrans* L.
Physical Description: The stable fly is physically similar to the common housefly.

Common Name: Horsefly Family
Scientific Name: Family: *Tabanidae*
Physical Description: The horse fly is a large (20 mm/~0.8 in.), slow-moving, blood-sucking insect that is usually easily repelled.

Common Name: Deer Fly
Scientific Name: *Chrysops* spp.
Physical Description: These stout-bodied, fast-flying insects range in size from 6–30 mm (~0.2–1.25 in.).

EXPOSURE

Geographic Distribution

Mosquitoes are aquatic breeders found worldwide, even beyond the Arctic Circle.

Important mosquito species (Diptera: Culicidae) include *Aedes vexans* Meigan, *Aedes aegypti* NPV, and *Culex quinquefasciatus* Say. The latter two mosquito species are distributed worldwide throughout the tropical regions, whereas *Aedes vexans* Meigan inhabits North America, Asia, Africa, and Eurasia. The insect family Tabanidae comprises approximately 3,000 species of flies throughout the world except at the extreme

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

northern and southern latitudes. Deer flies are found in wet, underdeveloped areas throughout the United States.

Behavior

Mosquitoes are most active during cooler, shady times of the day. These insects are attracted by smell as well as sight and temperature.[1] The female *Aedes* mosquito is responsible for most bites because the male *Aedes* mosquito lacks the penetrating mouth parts present on female mosquitoes. Attractants for female mosquitoes include moisture, carbon dioxide, warmth, odor, and estrogen.[2] Tabanids (horse flies, deer flies, clegs, gadflies) are wasp- or bee-like insects that often land unnoticed on humans while outdoors. Most females of the Tabanidae family require a blood meal to complete egg development. Female sand flies feed exclusively on blood at night. Female deer flies feed on animals and occasionally on humans. These flies are attracted by carbon dioxide and large, dark, moving objects. Bites from deer flies (*Chrysops* spp.) occur from late May until the middle of September.[3] These insects produce painful bites, and frequently bite unremittingly. The male tabanids feed on nectar; they do not possess the modified mouth parts capable of biting humans. Tabanids are holometabolous (i.e., undergo complete metamorphosis) insects that undergo four life stages (egg, larva or maggot, pupa, adult) similar to other true flies.

Black flies, midges, and buffalo flies breed in fast-flowing streams. Black flies swarm in late spring and early summer. Biting midges swarm at sunset, forming dense clouds. This behavior distinguishes biting midges from the night-biting sand flies and day-biting black flies. The stable fly is a blood-sucking fly that breeds around farm animals and feeds at one spot for several minutes before moving to a different location.

PRINCIPAL TOXINS

Venom Composition

The salivary ducts of mosquitoes contain local anesthetics as well as antigens that can cause immediate or delayed hypersensitivity reactions in sensitized individuals.[4] Salivary extracts of tabanids (horseflies, clegs, deerflies) include peptides and small proteins that inhibit thrombin activity in a dose-dependent manner.[5] The salivary secretions of *Tabanus bovinus* L. contain a 7-kD peptide (tabanin) that is a thrombin inhibitor. Other anticoagulants present in the salivary secretions from deer flies (*Chrysops* spp.) include platelet aggregation inhibitors and glycoprotein IIb/IIIa fibrinogen receptor antagonists (chrysoptin).[6] The salivary secretions of deer flies also contain a 69 kD IgE-binding protein capable of producing an anaphylactic reactions.[7]

Venom Apparatus

Deer flies (*Chrysops* spp.) and other tabanids (horseflies, clegs) possess a scissor-like proboscis that incises the skin of the prey; they feed on the blood extruded from these wounds. Anticoagulants in the saliva help extract blood from the victim. Injected fluids produce local tissue damage as well as mild local hypersensitivity reactions.

Dose Response

The reactions to bites from mosquitoes and flies result from hypersensitivity reactions; therefore, the response to these bites is not dose-related.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Clinical and experimental data suggests that various reactions to mosquito bites result from sensitization to the mosquito saliva injected into the skin during feeding.[8–10] These reactions include both IgE-mediated and T-lymphocyte-mediated hypersensitivity responses. The size of the immediate wheal and flare reaction correlates to the presence of IgE-specific antibodies, and there are strong cross-reactive skin and IgE-mediated responses among common mosquito species.[11] The immediate skin reaction involves an irregular, central punctate lesion in the epidermis surrounded by superficial edema.[12] Marked vasodilation develops in the dermis along with perivascular infiltration of leukocytes (polymorphonuclear, eosinophils). In addition to an Arthus-type mechanism, cutaneous late-phase reactivity and cell-mediated immunity may also be involved in the formation of delayed papules.[13] Frequent exposure to mosquito bites may produce blocking (IgG) antibodies and desensitization to the bites.[14] The saliva of deer flies contains immunogenic proteins that cause IgE-mediated anaphylactic reactions.[7]

CLINICAL RESPONSE

Cutaneous responses to mosquito bites range from immediate wheals and delayed papules to severe Arthus-type reactions with systemic complaints.[15] Individual responses to mosquito bites are highly variable; the type of response includes vesicular, urticarial, eczematoid, and granulomatous lesions. These lesions may become bullous and excoriated. The initial mosquito bite causes

no response, but subsequent bites produce delayed papular lesions. The typical response to mosquito bites in sensitized individuals involves the formation of pruritic wheals 2–10 mm (~0.1–0.4 in.) in diameter. Pruritic papules commonly develop several hours after the wheal and flare reaction, and the symptoms peak over 24–48 hours. These delayed papules typically resolve over several days, but occasionally these papules may persist a few weeks. Repeat mosquito bites can produce cutaneous reactions at old bite sites. Large local reactions occur occasionally. The appearance and intensity of delayed hypersensitivity reactions decreases with age and the frequency of bites.[16]

Rarely in sensitized asthmatic patients, mosquito bites may produce Arthus-type reactions (joint swelling, fever, adenopathy, nausea, headache) or anaphylaxis (wheezing dizziness, lethargy, urticaria, angioedema, hypotension).[17,18] A seasonal bullous eruption of the lower legs has been associated with bites by the *Aedes detritus* Haliday mosquito.[19] Mosquito bites can transmit filariasis, dengue fever, malaria, yellow fever, chikungunya fever, and viral encephalitis to humans.[20,21] However, mosquitos probably do not transmit HIV disease because of the absence of T_4 antigen on cell surfaces and low titer of the virus in human body fluids.[22]

Rarely, severe anaphylactic responses (e.g., hypotension, dyspnea) may occur after bites from horse flies (*Tabanus* spp.)[23,24] or from deer flies (*Chrysops* spp.).[25] Common house flies (*Musca domestica* L.) are rarely associated with respiratory sensitization in asthmatic patients.[26] Black flies, midges, and buffalo flies produce an extremely painful, pruritic, erythematous lesion that usually begins one hour after the bite. Later, the lesion may develop into a nodular, eczema-like patch or a hard pigmented nodule.

DIAGNOSTIC TESTING

Clinical abnormalities are not usually associated with bites from these insects other than those associated with infectious or allergic processes. There are no commercial biomarkers for these insect bites.

TREATMENT

Supportive care for mosquito and fly bites is similar to the treatment of flea bites. Washing horse and stable fly bites with an antiseptic solution [e.g., povidone-iodine (Betadine®, Purdue Pharma, Stamford, CT)] or soap and water and the application of a topical antibiotic ointment may prevent infection. Topical corticosteroid ointment may reduce swelling, redness, and itching associated with the bites, but the use of topical antihistamine creams is probably not efficacious.[9] Oral antihistamines (e.g., cetirizine 10 mg) reduce the pruritus and wheal associated with mosquito bites, but these antihistamines do not alter the intensity or duration of the delayed symptoms.[27] A volunteer study suggests that dilute ammonia solution (3.6%) applied minutes after the mosquito bite may reduce the wheal and flare reaction.[28] Other topical agents include preparations with menthol and camphor.

Insect repellents containing DEET (*N,N*-diethyl-*m*-toluamide) effectively repel biting insects, such as mosquitos, biting flies, gnats, chiggers, and ticks. Currently available non-DEET repellents do not provide the duration of protection from mosquito or fly bites compared with DEET-based repellents.[29] The repellent should be applied to all exposed areas of the skin except the eyelids and any skin lesions. Field entomological studies indicate that electronic mosquito repellants have no effect on preventing mosquito bites.[30]

Chapter 172

LICE
(Order: Phthiraptera)

HISTORY

Lice have been present since the beginning of recorded history as documented in the Old Testament and ancient Egyptian writings.[1]

IDENTIFYING CHARACTERISTICS

There are two species of lice (Anoplura: Pediculidae) that infect humans: *Pediculus humanus* L. and *Pthirus pubis* L. Synonyms for the former species include *P. humanus capitis* De Geer (head lice) and *P. humanus humanus* L. or *P. humanus corporis* (body lice).

Common Name: Head Lice
Scientific Name: *Pediculus humanus* L. (*Pediculus humanus capitis* De Geer)
Physical Description: The head louse is a small (2–3 mm/~0.1 in.), pale gray insect that lives on the hair closest to the scalp. Both body lice and head lice have flattened, elongated, triple-segmented thoraces and long slender legs that allow greater mobility than the body of the pubic louse. Two short antennae with five segments protrude from the lateral aspect of the cylindrical head.

Common Name: Body Louse
Scientific Name: *Pediculus humanus* L. (*P. humanus corporis, P. humanus humanus*)
Physical Description: Body lice are morphologically similar to head lice, except for the location of this louse on the body. The tan to grayish-white, adult body louse has six legs and is about the size of a sesame seed.

Common Name: Pubic Louse, Crab Louse
Scientific Name: *Phthirus pubis* L.
Physical Description: The pubic louse has a shorter body (≤2 mm/<0.1 in.) compared with head lice. Three sets of legs are attached to the anterior portion of the abdomen with the middle and hind sets possessing specialized claws and opposing tibial thumb to grasp hair shafts. The body of the pubic louse is more appropriate for grasping pubic, axillary, and rarely eyelid hair shafts than crawling on the body.

EXPOSURE

Geographic Distribution

Infestations with head lice occur at any age and within all socioeconomic groups. Epidemics of pediculosis occur worldwide. The incidence of head lice is highest in school-age children, particularly Caucasians and women.[2] Head lice are less common in African Americans than in Caucasians probably because of differences in the shape of the hair shaft.[3] However, head lice in Africa have adapted claws for grasping the oval-shaped hair shafts of African Blacks. Body lice are more common in colder months, whereas head lice are more common in warmer parts of the year.[4]

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Behavior

Eyes are present on the lateral portion of the head near the base of each antenna, and these organs help the louse avoid light. The peg organ is located on the distal segment of the antenna. This organ detects odor and humidity. Lice crawl rather than jump or fly. Pets are not vectors for the transmission of lice, and these insects require human contact to complete their life cycle. Lice also require symbiotic bacteria to digest their blood meals, probably as a source of B vitamins.[5] The female louse lays up to 300 eggs or nits in her 30-day life cycle. Although lice can survive up to 2 days away from the human host, lice typically pierce the skin every few hours to obtain a blood meal.

Head Louse

The spread of head lice results primarily from direct head-to-head contact.[6] However, there are some data to support the spread of lice by contact with personal belongs (e.g., brushes, combs, hats) of an infested individual,[7] although lice found on these objects are often unhealthy.[8] Fertilized females deposit approximately one to six oval egg sacs (nits)/day on base of the hair shafts. These 1-mm-long egg sacs are initially translucent, but after hatching in 7–14 days, the empty egg cases become white. Viable nits are camouflaged with pigment similar to the hair of the host. Empty nits are more visible, particularly in the posterior hairline. Nits are firmly attached to the hair shafts, and the nits move away from the scalp as the hair grows. The distance of the nit from the scalp is a measure of the duration of the infestation based on hair growth of 1 cm/month.

Body heat incubates the eggs within 7–14 days. The nymphs grow during the next 9–12 days before mating. The louse lives on the head by injecting small amounts of saliva and extracting tiny amounts of blood from the scalp every few hours. The life cycle repeats every 3–4 weeks. Head lice usually survive only 1–2 days away from the scalp, and the eggs do not hatch at temperatures below the ambient temperature of the scalp.

Body Louse

Most body lice live on clothing and bedding with a few attached to body hairs. Body lice are found in clothing seams of infested patients. These ectoparasites live preferentially in cold climates and infest individuals in overcrowded, impoverished conditions.[9] Body lice do not survive over 10 days at 15 °C (59 °F), and survival is shortened during colder and warmer periods.[1] Body lice are not usually detected on body surfaces during feeding. These insects hide in the seams of clothing where they lay eggs and complete their life cycle.

Pubic Louse

Pediculosis pubis is a venereal disease acquired by direct physical contact with infested sexual partners or clothing. These lice usually remain localized in the pubic and inguinal region, but they may infest the axilla or rarely the eyelashes, beard, areolar hair, and scalp hair. In daylight, the louse remains motionless or moves into the relative darkness of skin fold. The bodies of pubic lice are modified to attach to hair shafts rather than move on the skin, and the pubic louse does not survive over 24 hours away from the human host.[10] Infestations with pubic lice are more common in low socioeconomic classes. Frequently, pubic lice are present along with other sexually transmitted infections.[11]

PRINCIPAL TOXINS

Skin lesions associated with lice bites result from hypersensitivity reactions rather than direct toxic effects.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Lice bites cause excoriation and occasionally urticarial lesions secondary to a hypersensitivity response. Clinical manifestations of this hypersensitivity response may require up to 30 days from the first blood meal.

CLINICAL RESPONSE

Most lice bites do not cause immediate pain, except during a heavy infestation of lice when a stinging sensation may occur. The initial skin lesion is a minute red macule that does not cause inflammation. Repeated exposure to lice over a course of 7–10 days results in a hypersensitivity response and pruritus. Consistent with most hypersensitivity responses, the individual response to lice bites is highly variable.

Head Lice

The most common symptom of head lice infestation is variable numbers of pruritic papules on the scalp, particularly in the occipital and retroauricular regions. After an asymptomatic period of about 24–48 hours, sensitization develops and pruritic papules with central puncta appear. A wheal then occurs followed by delayed hypersensitivity response at the bite site.[12] Systemic reactions to lice bites do not usually develop. Excoriation may produce secondary infections, impetigo-like

lesions, posterior cervical and postauricular adenopathy, and fever. The sequence of skin responses following body lice and head lice bites is similar.[13] Unlike body lice, head lice do not transmit any communicable diseases; therefore, head lice are not a health hazard.[14]

Body Lice

Typical lesions associated with the bites of body lice involve small, pruritic, red papules under the arm and on the back. Heavy infestations and frequent itching produce pyoderma in areas normally covered with loose clothes. Ulcerations, excoriations, and secondary infections occur, particularly in the trunk, axilla, and groin. Body lice can transmit such diseases as epidemic typhus (*Rickettsia prowazekii*), trench fever (*Bartonella quintana*), and relapsing fever (*Borrelia recurrentis*).[15]

Pubic Lice

Pubic lice (*Pthirus pubis* L.) produce an infestation limited to the short hairs, primarily in the pubic region. Nits may also be present on eyelashes, eyebrows, beards, axillary hair, body hair, and occasionally on the short hair of the occipital region of the scalp. Pubic lice are not disease vectors for humans, but the incidence of sexually transmitted diseases is higher in these patients compared with patients without pubic lice.[16] Occasionally, bluish brown, irregular macules (maculae caeruleae) about 5 mm/–0.2 in. in diameter occur in the lower abdomen or eyelid after pubic or body lice infestations, probably as a result of the deposition of hemosiderin at sites of intradermal hemorrhage.[17] Phthiriasis palpebrarum is an uncommon cause of blepharitis and conjunctivitis associated with infestation of the eye lashes with pubic lice.[18] Symptoms range from pruritic lid margins to blepharitis with marked conjunctival inflammation.

DIAGNOSTIC TESTING

Confirmation of head lice infestation involves the detection of multiple, oval, grayish-white egg capsules (nits) firmly attached to the hair shafts. A white towel is placed around the neck and the tangles are removed with a standard comb or brush. The hair should then be examined by through-combing for at least 5 minutes with a louse comb.[19] Nits are transparent, flask-shaped egg cases that are tightly cemented to hair shafts (head lice, pubic lice) or clothing (body lice). Nits are more visible at the nape of the neck and behind the ear within 1 cm (~0.4 in.) of the scalp. Unlike dandruff, the nits are firmly attached to the hair shafts. Hair casts (pseudonits) are opaque amorphous remnants of the inner root sheath that remain near the hair shaft and may be confused with nits. These casts are also mobile in contrast to nits. Viable nits develop an "eye spot" visible under a microscope within several days after deposition on the skin, and these nits seldom occur over 1 cm (~0.4 in.) from the scalp. Nits found more than several millimeters from the scalp are usually nonviable. The demonstration of nits within ¼ in. (~5 mm) of the scalp suggests an active infestation. However, the presence of nits without live lice does not necessarily indicate an active infestation because nits may remain firmly attached to the hair shafts for months.[20]

Under the low power of the microscope, the presence of adult lice, immature nymphs, and/or viable eggs indicates an active infestation of head lice. Live head lice may be difficult to find because they can crawl up to 6–30 cm (~2–12 in.) /minute.[3] Taping the affected area and trapping the lice with transparent adhesive tape may be helpful. The use of a fine-toothed or louse comb improves the sensitivity and facilitates the detection of live lice when compared with visual inspection of the scalp hair.[21] The separation between teeth on these combs is approximately 0.2–0.3 mm (~0.01 in.). After removal of tangles with a standard brush or comb, the fine-toothed comb is inserted near the hairline on the face next to the scalp, and the comb is drawn firmly over the head. The entire head should be combed at least twice. The nits of pubic lice and head lice are similar, and lice may be detected on hair shafts with microscopic examination of the hair shafts. Body lice are usually detected by examination of the seams of clothing from the infected individual.

TREATMENT

Head Lice/Pubic Lice

Successful treatment of lice infestations requires destruction of both the adult lice and the eggs. Permethrin, synergized pyrethrin, and malathion (Ovide®, Taro Pharmaceuticals, Hawthorne, NY) are effective agents for the treatment of head lice, and the choice of the pediculicide depends on local patterns of resistance.[22,23] There is substantial resistance of head lice to 1% lindane, and this product lacks significant ovicidal properties.[24,25] Consequently, 1% lindane is not currently indicated for head lice infestation. Case reports indicate that repeated, excessive use of topical lindane over one week causes neurotoxicity including seizures and altered mental status.[26] These neurological effects usually resolve after cessation of lindane use. There are inadequate data to support the use of physical methods ("bug-busting," wet-combing) or herbal preparations alone to eliminate lice.[22]

Preparation

The hair should be washed with a regular shampoo (no creme rinse or conditioner), rinsed with water, and dried thoroughly. The hair should not be rewashed for 1–2 days after treatment. These agents should not be applied to wet hair because dilution, decreased contact time, and poor penetration of the agent reduce the effectiveness of the pediculicide. Hair removal is not necessary to control lice infestations.

Permethrin

1% Permethrin (synthetic pyrethroid) cream rinse is applied generously, left on for 10 minutes, and rinsed with water. Pyrethroids are not consistently ovicidal, and successful eradication of lice requires two to three treatment cycles to eradicate lice.[27] Synergized natural pyrethrins (0.3% pyrethrin with 3% piperonyl butoxide) are an over-the-counter product available for the treatment of head lice using the same techniques as permethrin with the exception that the hair is shampooed *after* the 10-minute application. Pyrethrins are natural extracts of the chrysanthemum plant; patients with chrysanthemum allergies should not be treated with pyrethrins. Synergized pyrethrin is less ovicidal than 1% permethrin; therefore, a second treatment one week later is necessary. Itching or mild burning of the scalp may persist for days after the head lice are destroyed, and the persistence of these symptoms is not necessarily an indication for repeat treatment. Topical corticosteroids and oral antihistamines should relieve these symptoms.

Malathion

If treatment with natural pyrethrins or permethrin fails to eradicate the infestation, 0.5% malathion lotion is the treatment of choice.[28] This product is applied to hair and allowed to dry for 8–12 hours before thorough rinsing. The lotions should be reapplied in 7–10 days if live lice reappear. Malathion is ovicidal, and eradication of the lice requires only one or two treatments.

Nit Removal

After insecticidal treatment, nits can be removed with sturdy metal combs and acidic solutions (a 1:1 mixture of 5% acetic acid or vinegar, specialized over-the-counter 8% formic acid preparations). The evidence for the effectiveness of these adjunctive methods remains anecdotal.[29] Acid shampoos (pH 4.5–5.5) are applied along with water to the hair for 15 minutes; then gently combed with a fine-toothed comb (e.g., louse comb). Combing is primarily a cosmetic maneuver because this adjunctive therapy does not increase the efficacy of applied medication (e.g., permethrin cream).[30] Lubrication facilitates combing and removal of lice and eggs from the scalp, but suffocating agents (mayonnaise, oils, hair gels) do not usually kill substantial numbers of lice.

Mechanical removal of head lice by combing does not eradicate an infestation or eliminate the need for a pediculicide.[31] The hair should be checked every 2–3 days with a nit comb to remove nits and lice for the first 2–3 weeks after initial treatment. Mechanical removal of nits from the eyelashes requires the use of the slit lamp. Ophthalmic ointments (erythromycin, physostigmine) have been recommended for local application to the eyelids, but there are few clinical data to confirm the effectiveness of these agents.

Supportive Care

All household contacts and current sexual partners should be examined and treated if evidence of a head lice infestation exists. The US Center for Disease Control and Prevention, but not UK authorities, recommends cleaning of personal and household items touched by infected patients within 2 days prior to treatment.[32] Lice and eggs are destroyed by temperatures above 52 °C (~126 °F) for 5 minutes. Options for destroying lice include washing clothes in hot water (130 °F/54 °C), drying for 20 minutes, ironing, drycleaning, and storage for 2 weeks in plastic bags (life cycle is 30 days). Consequently, all bedding, clothing, pillows, hair items (brushes, combs), and head gear that had contact with an infested patient within 48 hours of treatment should be washed, drycleaned, or stored for 2 weeks in plastic. Floors, play areas, and furniture should be vacuumed thoroughly to remove any shed hairs. However, fumigation is not necessary.

Patients should be reexamined in one week for the continued presence of lice. The incubation period for pubic lice is 5 days to several weeks, and sexual contact should be avoided until the treatment is completed. The incidence of coexisting sexually transmitted diseases is relatively high in patients with pubic lice; therefore, these patients should be evaluated for the presence of sexually transmitted diseases.[33]

Body Lice

The treatment of body lice infestation primarily is supportive consisting of good personal hygiene, calamine lotion for itching, and the laundering of all clothing and bed linen in hot water (130 °F/54 °C). The patient should shower and receive a clean set of clothes. The use of a pediculicide (permethrin, synergized pyrethrin) is optional.

Chapter 173

MOTHS and BUTTERFLIES
(Order: Lepidoptera)

HISTORY

The ancient Greeks attributed some sporadic dermatological disorders to species within the order Lepidoptera. During the Roman era, Galen and Pliny the Elder recorded the irritant potential of species within Lepidoptera. Biting caterpillars were applied as a medicinal treatment during the Middle Ages, and the irritant potential of these caterpillars was recognized again in the 18th century.[1] In Germany during the 1860s, conjunctivitis and iritis were recognized complications of exposure to caterpillar hairs, and the term *ophthalmia nodosa* was applied to the ocular complications of caterpillar hairs during the early 1900s.[2] From 1868 to 1869, the gypsy moth caterpillar (*Lymantria dispar* L.) was intentionally imported from Europe to the Boston area in an attempt to develop an American silk industry. The attempt failed because of the poor quality of silk in their cocoons, but the gypsy moth spread throughout the northeastern United States. White documented the first US case of caterpillar dermatitis from a brown-tail moth (*Euproctis chrysorrhoea* L.) in 1901.[3] In 1914, von Ihering reported the first case of a bleeding diathesis associated with exposure to the South American caterpillars.[4] Caffrey reported the occurrence of a case of occupational asthma (tearing, rhinitis, asthmatic bronchitis) in a biologist studying the New Mexico buck moth caterpillars (*Hemileuca nevadensis* Strech.).[5] During the 1910s and 1920s, outbreaks of caterpillar dermatitis in Texas corresponded to large increases in the caterpillar population, resulting in the closing of public schools for several days in San Antonio during the spring of 1923.[6] During the 1920s, Gilmer published his classic microscopic studies on the urticating hairs of several US caterpillars.[7] Epidemics of caterpillar dermatitis continued sporadically, causing the closing of public schools for several days in Galveston, Texas in 1951.[8] These epidemics occurred primarily in the springtime when aerosolization of the urticating hairs and hemolymph from the first larval instars of the caterpillars cause contact with human skin and mucous membranes. In 1969, Arocha-Pinango first associated a fibrinolysis with exposure to the Venezuelan caterpillars (*Lonomia achelous* Cramer).[9] Human contact with caterpillars from *Lonomia* species causes inflammation at the site of contact, followed by systemic symptoms (e.g., headache, malaise, fever, vomiting). A severe coagulopathy began within 24 hours in some of these patients. Other severe complications include intracranial hemorrhage, acute renal failure, and hemoptysis.

IDENTIFYING CHARACTERISTICS

The order Lepidoptera consists of scaly, winged insects that belong to the large phylum Arthropoda and the class Insecta. Of the estimated 140,000–165,000 butterflies and moths worldwide, most of these insects are harmless. There are at least 11 families [Aganaidae (Hypsidae), Arctiidae, Limacodidae, Lasiocampidae, Lymantriidae, Megalopygidae, Noctuidae, Notodontidae, Saturniidae, Thaumetopoeidae, Zygaenidae] of moths and one family (Nymphalidae) of butterflies that contain about 50–150 venomous species.[10] The four main species involved with human envenomations are

Automeris io Fabricius, *Hemileuca maia* Drury, *Megalopyge opercularis* Smith & Abbot, and *Sibine stimulea* Clemens.[11] Caterpillars are the larval stage of moths and butterflies from the order Lepidoptera.

Common Name: Flannel Moth, Puss Caterpillar (larval form of moth), Woolly Slug, Tree Asp, Italian Asp, El Perrito, Opossum Bug, Asp, Bicho Peludo Negro

Scientific Name: *Megalopyge opercularis* Smith & Abbot

Physical Description: The mature larva has a flat, ovoid, pale yellow to gray-brown body reaching up to 35 mm (~1.4 in.) in length and 20 mm (~0.75 in.) in width. The spines are yellow with black tips. This species has a distinctive posterior tuft of hair that does not occur in other *Megalopyge* species. The female moth is larger than the male moth with a wing span of about 4 cm (~1.5 in.). The yellow-brown adults emerge from cocoons April through June with a second generation appearing September to November.

Common Name: Io Moth, Spiny Caterpillar, Corn Emperor Moth

Scientific Name: *Automeris io* Fabricius

Physical Description: This pale yellow-green caterpillar is 5–6 cm (~2 in.) in length with red true legs and pro-legs. There is a broad white strip on each side surrounded by a maroon stripe above and a thinner red-purple strip below. Each dorsal segment has raised tubercles or scoli containing a whorl of black-tipped green spines.

Common Name: Gypsy Moth

Scientific Name: *Lymantria dispar* L.

Physical Description: This, hairy blue-gray caterpillar is about 20–30 mm (~0.75–1.2 in.) in length with lateral tufts of dull yellow hair and two dorsal white stripes. There are round, raised umps or tubercles on each segment with the first five dorsal tubercles being blue and the remaining seven tubercles being red.

Common Name: Browntail Moth

Scientific Name: *Euproctis chrysorrhoea* L.

Physical Description: This hairy browntail moth caterpillar is 40–50 mm (~1.5–2 in.) long with distinctive dorsal red spots and two dorsolateral white strips.

Common Name: Saddleback Caterpillar

Scientific Name: *Sibine stimulea* Clemens (*Acharia stimulea*)

Physical Description: This brown-red caterpillar reaches 20–30 mm (~0.75–1.2 in.) in length with a green dorsal midsection surrounded by white and dorsal brown-purple centration spot (saddle) also trimmed in white. Adult moths lay eggs during the summer. The cocoon is a brown, oval encasement that retains stinging hairs.[12]

Common Name: Saturniid Caterpillar, Giant Silkworm Moth

Scientific Name: *Lonomia achelous* Cramer, *Lonomia obliqua* Walker

Physical Description: These large, well-camouflaged caterpillars are about 4.5–5.5 cm (~2 in.) in length with background colors ranging from green to brown. They have rows of raised tubercles crowned with whorls of easily detachable spines of different sizes that are present on all larval stages (first–sixth larval stage or instar).

EXPOSURE

Geographic Distribution

Lepidopterism is a common problem in the southern United States, where moths cause symptoms similar to those associated with venomous caterpillars.[13] The habitat of the puss caterpillar (*Megalopyge opercularis* Smith & Abbot) includes areas of the southern coastal states from Texas to Florida as well as Maryland, New York, North Carolina, South Carolina, Virginia, Missouri, Arkansas, and Oklahoma. The io moth ranges from eastern Canada to the Atlantic seaboard and along the Gulf Coast to Texas and northern Mexico. The gypsy moth occurs in the northeastern United States.[14] The browntail moth ranges from southeastern Canada to the northeastern United States. Related species include the Oriental tussock moth (*Euproctis flava* Bremer) from Asia and Siberia, Douglas-fir tussock moth (*Orgyia pseudotsugata* McDunnough) in the Pacific northwest and western Canada, and the mulberry tussock moth (*Euproctis similis* Moore). The saddleback caterpillar lives in the southeastern United States. The processionary caterpillars (*Thaumetopoea pityocampa* Schiffermüller, *Thaumetopoea wilkinsoni* Tams, *Thaumetopoea pinivora* Treitschke) inhabit Europe, Israel, and the Mediterranean coast, particularly in pine forests.[15] The white-stemmed gum moth (*Chelepteryx collesi* Gray) of eastern Australia is a cause of minor skin irritation following contact with many spine-like hairs of the cocoon.

TABLE 173.1. Distribution of Common Envenomating Caterpillars of Moths and Butterflies

Moth/Butterfly Family	Species	Distribution
Arctiidae (moth)	*Arctia* spp.,	Worldwide
	Hyphantria spp.	United States, Europe, Japan
Lasiocampidae (moth)	*Malacosoma* spp.	United States, southern Canada
	Dendrolimus pini L.	Central Asia, north Africa
Limacodidae (moth)	*Euclea delphinii* Boisduval	North America
	Sibine stimulea Clemens	Eastern and southern United States
	Phobetron pithecium Abbot & Smith	North America
Lymantriidae (moth)	*Euproctis chrysorrhoea* L.	United States, United Kingdom, Europe, North Africa
	E. pseudoconspersa Strand	Japan
	E. edwardsii Newman	Australia
	E. flava Fabricius	Asia
	E. similis Moore	Worldwide
	Lymantria dispar L.	Eastern United States, Europe
	Orgyia spp.	North Africa, Europe, Asia, North America
	O. leukostigma J. E. Smith	North America
	O. pseudotsugata McDunnough	United States and Canadian Pacific Northwest
Megalopygidae (moth)	*Megalopyge* spp.	United States, Latin America
Notodontidae (moth)	*Lochmaeus* spp.	New World
(processionary	*Ochrogaster contraria* Walker	Australia
caterpillars)	*Thaumetopoea pityocampa* Schiffermüller	Asia, North Africa, Europe
	Thaumetopoea processionea L.	Europe
	Thaumetopoea wilkinsoni Tams	United States. Asia, Africa. Europe
Nymphalidae (butterfly)	*Nymphalis* spp.	North America, Europe, Asia
Saturniidae (moth)	*Automeris io*	New World (Southern Canada, United States, Mexico
	Hemileuca spp.	Venezuela, French Guyana, Northern Brazil
	Lonomia achelous Cramer	Southern Brazil)
	Lonomia obliqua Walker	
Zygaenidae (moth)	*Neoprocris* spp.	New World
	Zygaena spp.	Central and southern Europe

Table 173.1 lists the taxonomy and distribution of common envenomating species of caterpillars.

Behavior

After the fertilized egg is deposited onto appropriate foliage, the eggs hatch into larval forms (caterpillars) that undergo a series (i.e., usually five to six) of molts and transformations (instars). The last instar pupates into a cocoon. Typically, caterpillars forage in the spring and early summer after winter hibernation, and the adult emerges from the cocoon in late summer.[16] An exception is the Megalopygidae family (e.g., the puss caterpillar or *Megalopyge opercularis* Smith & Abbot), which molt in late summer to early fall and the adults emerge from the cocoons in spring. The habitat of the puss caterpillar includes citrus, sycamore, wild plum, hackberry, plum, elm, oak, and corn, as well as household flowers including rose bushes. The io moth caterpillar (*Automeris io* Fabricius) is a solitary feeder that does not cause significant economic damage. The gypsy moth (*Lymantria dispar* L.) feeds communally on deciduous trees, particularly oaks. The saddleback caterpillar (*Sibine stimulea* Clemens) is a solitary feeder that prefers bushes (oleander, croton) and palm trees, but this caterpillar will eat the leaves of many trees and shrubs including apple, basswood, cherry, chestnut, dogwood, elm, maple, oak, and plum. These caterpillars are most active during the late summer and early fall. Moths from the genus *Hylesia* are native to Central and South America, where these nocturnal creatures are attracted to the lights of ships anchored in ports. The dermatitis associated with this moth is called the *Caripito itch* because of the frequent occurrence of this dermatitis in sailors from ships anchored in Caripito, Venezuela. *Euproctis chrysorrhoea* L. inhabits communal silken nests on blackthorn and hawthorn ornamental shrubs in the eastern United States, but this caterpillar will feed on most fruit and ornamental trees. The mistletoe browntail moth (*Euproctis edwardsii* Newman) of Australia marches down the host tree at dawn to hide under rubbish, bark, or grass until nighttime when the caterpillar returns to the mistletoe to feed.[17] Severe urticarial lesions may result from the handling of this mate-

rial. The processionary tree caterpillars have voracious appetites and cause deforestation. These caterpillars follow a queue, head to tail, often meandering single file following a trailing silk thread like a series of train cars.

PRINCIPAL TOXINS

Venom Composition

The mechanism of action and the composition of secretions from the venomous glands at the base of the specialized hairs are not well defined. The secretions of some caterpillars (e.g., gypsy moth, Oriental tussock moth, browntail) contain histamine, but the use of antihistamines does not usually alter the clinical course of caterpillar dermatitis.[18,19] Fibrinolytic proteases and clotting activators occur in the hemolymph and saliva of the saturniid moth caterpillar (*Lonomia achelous*) from South America.[20] Low molecular weight, basic substances (achelase I, achelase II) activate the fibrinolytic system via plasminogen. These plasmin-like substances are probably activator serine proteinases (Lopap).[21] The hemorrhagic activity of other *Lonomia* species probably differs slightly from the effects of venom from *L. achelous*. The cause of hemorrhage from *Lonomia obliqua* probably results from a consumptive coagulopathy with secondary fibrinolysis rather than primary fibrinolytic activity. An *in vitro* study of venom from *L. obliqua* demonstrated no tissue plasminogen activator-like or fibrinolytic activity as well as no degradation or inhibition of factor XIII.[22]

Venom Apparatus

The skin lesions associated with caterpillar dermatitis result from contact with specialized hollow hairs or spines that are connected to venom glands.[23,24] Hypodermal, glandular epithelial cells produce the venom, which circulates in the hemolymph and collects in external tegument, tubercles (scoli), urticating hairs and spines (setae).[25] Most venomous hairs are straight with sharp ends, although the io caterpillar has a thick, distal chitinous plug.[26] The hairs penetrate the skin and portions of the hairs remain embedded. The poisonous setae or spines may be solid, capped by a distal, detachable tip, or hollow with venom underneath a pigmented plug.[27] Release of the venom occurs when trauma ruptures the poisonous setae or spines, releasing venoms from subapical pores or proximal bases.

Microscopic examination of *Lonomia obliqua* caterpillars indicates that there is no single gland that produces the venom.[28] All spines have hollow internal canals with weak articulations at the tips that allow contact with the venom following rupture of the fragile tips. A secretory epithelium, which underlies the tegument and the spines, secretes the venom. These cells contain vesicles that increase in size and number as they reach the apical region. Deposition of the venom occurs in the subcuticular space and at the tips of the spines. All larval stages (i.e., third to sixth developmental stage or instar) can envenomate, but toxicity increases with each molt (instar) as the size and number of spines increase.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The mechanism of dermal toxicity of caterpillars is not well defined. Potential mechanisms include mechanical irritation, hypersensitivity, and envenomation with toxic secretions. Biopsies of lesions associated with caterpillar dermatitis demonstrate nonspecific pathological changes including hydropic degeneration, spongiosis, edema, and a mixed lymphohistiocytic infiltrate. [29,30] A delayed contact dermatitis may result from exposure to large amounts of caterpillar hairs.[14]

Although the venoms from *Lonomia achelous* and *Lonomia obliqua* produce similar clinical effects, the mechanisms of action are somewhat different. The venom of *L. achelous* has both procoagulant and anticoagulant activity, whereas the venom of *L. obliqua* is primarily procoagulant. The main toxins in the former venom are lonomin II (direct fibrinolytic activity) and lonomin V (degrades coagulation factor XIII).[31] In *L. obliqua* venom, the principal procoagulant toxins are a prothrombin activator, Lopap (*L. obliqua* prothrombin activator protease) and a factor X activator, Losac (*L. obliqua* Stuart-factor activator).[32] Acute renal failure complicates envenomation by *L. obliqua*; potential pathogenic factors causing renal dysfunction include hypotension, renal ischemia, disseminated intravascular coagulation with deposition of fibrin in the glomeruli, and direct nephrotoxic effects.[33] The venom from *L. obliqua* also contains factors, which release kinins from low-molecular-weight kininogen. These substances contribute to the edema and hypotension associated with envenomation.[34]

CLINICAL RESPONSE

Approximately 50–150 species within the order Lepidoptera produce inflammatory lesions of the skin and mucous membranes following direct contact. Most adverse effects involve accidental contact of the skin (caterpillar dermatitis) with the larvae.[35] Rarely, caterpillar dermatitis (rhinitis, pruritic maculopapular rash) results from airborne exposure following the appear-

ance of exceptionally large caterpillar populations and favorable climatic conditions.[14,36] Following ingestion of venous caterpillars, drooling and dysphagia may develop as a result of a local reaction to embedded spines, but systemic symptoms do not usually occur.[37] There are at least five syndromes associated with exposure to caterpillars including erucism, lepidopterism, dendrolimiasis, ophthalmia nodosa, and blood disorders characterized by consumptive coagulopathy with secondary fibrinolysis.[25]

Caterpillar Dermatitis (Erucism)

Erucism is the term applied to the classic lesion of caterpillar dermatitis. The skin lesions associated with exposure to venomous species of Lepidoptera typically develop immediately (i.e., within several hours) after contact with the hairs, but direct contact with the caterpillar is not required to develop the skin lesions. The skin lesions begin as localized or generalized erythematous, pruritic macules that rapidly evolve into urticarial lesions. Small papules or papulovesicles replace the wheals, and occasionally bullae develop.[38] Although most of the lesions are pruritic, some species produce painful lesions including the puss (*Megalopyge opercularis*), io (*Automeris io*),[26] saddleback,[29] and oak processionary caterpillars.[39,40] The puss caterpillar produces characteristic grid-like, hemorrhagic skin lesions within two to three hours following envenomation along with intense, radiating pain and generalized muscle cramps.[41,42] Contact with species of the family Megalopygidae (e.g., puss caterpillar) may produce serous or hemorrhagic bullae as well as the rapid onset of lymphangitis and regional lymphadenopathy, but the skin lesions usually resolve without sequelae.[43,44] The duration of the lesions depends on the species. Most symptoms of envenomation by saddleback and io caterpillars subside within two to eight hours, whereas resolution of the lesions associated with contact by gypsy moths requires up to about two days.[45] Other lesions may require seven to ten days to heal including the dermatitis associated with puss caterpillar, browntail moth,[35] processionary caterpillar,[46] and the yellowtail moth.[10]

Lepidopterism

Lepidopterism is the systemic illness associated with direct or airborne contact with the urticarial hairs or body fluids of caterpillars. In a case series of over 40 patients developing dermal lesions after exposure to the oak processionary caterpillar, only a few patients had direct contact with the caterpillars.[47] Systemic symptoms include paresthesias, vomiting, malaise, headache, generalized urticaria, conjunctivitis, pharyngitis, cough, muscle spasms, and radiating pains.[48,49] Although systemic symptoms are rare, angioedema of the upper respiratory tract, dyspnea, bronchoconstriction, and wheezing may develop in atopic patients, particularly in patients with documented allergies to bees.[18,50] The onset of the contact dermatitis days after exposure secondary to delayed sensitivity complicates the diagnosis of lepidopterism.[51] There are no well documented cases of deaths from lepidopterism other than deaths associated with blood disorders.[52] Complications include secondary bacterial infection, lichen simplex chronicus, and postinflammatory dyschromia.[10] IgE-medicated anaphylactic reactions may occur, particularly in workers chronically exposed to pine processionary caterpillar.[53] The onset of lepidopterism is more common following contact with the gypsy moth (*Lymantria dispar*) or the browntail moth (*Euproctis* spp.) caterpillar rather than the io moth (*Automeris io*) or the saddleback (*Sibine stimulea*) caterpillar.[25,54]

Dendrolimiasis

This syndrome is a chronic form of lepidopterism caused by direct contact with the hemolymph, cocoon, or urticating hairs of the central Asian pine-tree lappet moth or caterpillar (*Dendrolimus pini* L.).[55] Clinical effects include a maculopapular dermatitis, migratory polyarthritis, inflammatory polychondritis, osteoarthritis, and rarely, acute scleritis. The clinical course of this illness suggests an IgE-mediated acute phase secondary to hypersensitivity to foreign proteins followed by an autoimmune-mediated, chronic phase involving the bones and joints. The mean onset of the acute phase is about 1–3 days.

Ophthalmia Nodosa

This disease is a chronic ocular disorder characterized by conjunctivitis followed by panuveitis resulting from the intraocular penetration of urticating hairs from lymantriid caterpillars.[56] However, the most common cause of ophthalmia nodosa is contact with tarantula hairs.[57] Airborne exposure to caterpillar setae usually causes mild, superficial ocular injuries compared with the intraocular injuries associated with application of caterpillars directly to the eye. A 15-year-old male presented to an emergency department 2 days after a caterpillar was rubbed in his eye.[2] Under general anesthesia, 150–250 caterpillar setae were removed from his cornea. Despite repeated removal of caterpillar setae from his eye, he developed persistent iritis and subsequently chorioretinitis from the migration of setae into the interior of his eye. Ultimately, he underwent left pars plana vitrectomy, but his visual acuity remained below normal.

A variety of clinical effects can result from exposure to setae including the following: 1) acute chemosis and conjunctivitis, 2) chronic mechanical keratoconjunctivitis secondary to embedded setae in the conjunctiva, 3) subconjunctival or corneal granulomas, 4) iritis, and 5) chorioretinitis secondary to penetration of the setae into the posterior chamber.[58]

Blood Disorders

In addition to severe local pain, envenomations by *Lonomia* caterpillars of South American produce coagulopathy, bleeding, and renal dysfunction. The venom of the spiny-hair Venezuelan (*Lonomia achelous*) or Brazilian saturniid (*Lonomia obliqua*) caterpillars contains anticoagulant and procoagulant factors that potentially may cause serious bleeding abnormalities. The clinical features of envenomation by these two caterpillars are similar, although renal complications are less common following envenomation by *L. achelous* than by *L. obliqua*.[59] Although there are limited clinical data, case series associate envenomation by these caterpillars with internal bleeding, renal dysfunction, and intracranial hemorrhage,[60] as well as painful skin lesions, nausea, vomiting, lightheadedness, and headache.[61,62] The clinical effects of *L. achelous* envenomation resemble a combination of fibrinolytic activity (plasmin-like, plasminogen activation) and mild disseminated intravascular coagulation (procoagulation activity).[63] *L. obliqua* envenomation results in a consumptive coagulopathy and secondary activation of fibrinolysis.

DIAGNOSTIC TESTING

Radiographic features of dendrolimiasis include epiphyseal separation, initial swelling of small and intermediate joints and adjacent soft tissue, osteoporosis near insertion of tendons and cartilage, osteosclerosis, soft tissue ossifications, and fusion of ankle joints.

Laboratory abnormalities associated with envenomation by *Lonomia obliqua* typically include anemia, prolonged prothrombin time, decreased coagulation factors V, VIII, and XIII, decreased fibrinogen and plasminogen, and increased fibrin degradation products.[33] These abnormalities are consistent with a consumptive coagulopathy with secondary fibrinolysis. In contrast to disseminated intravascular coagulation associated with multisystem failure, the platelet count is relatively normal following envenomation by *L. obliqua*.[64]

TREATMENT

Management of caterpillar dermatitis is supportive (local wound care, elevation, ice). There are few clinical data to guide management. Gently wash the area of the sting with soap and water followed by "no touch" drying of the sting site with a hair dryer rather than a towel. Methods to remove embedded urticating spines include the application of adhesive duct tape, rapidly drying clear fingernail polish, or commercial facial peel solutions. These peeling solutions should dry thoroughly prior to removal. Application of ice packs may improve the pain associated with envenomation. Antihistamines (H_1-, H_2-blockers) are usually effective only in mild cases of lepidopterism. Case reports suggest that high-dose steroids may alleviate severe pain and pruritus associated with caterpillar dermatitis, particularly if a hypersensitivity reaction is suspected.[65] Envenomation by the puss caterpillar may produce intense pain that requires parenteral narcotic analgesics for adequate control.[41] General supportive measures include the use of calamine lotion and soothing soaks (e.g., Epsom salts or Domeboro solution) as needed. The clinical effects of the white-stemmed gum moth (*Chelepteryx collesi* Gray) are generally minor with mild local pain, and complete removal of the hairs is neither possible nor necessary.[66] Treatment of ophthalmia nodosa requires referral to an ophthalmologist for medical and surgical management.

A specific heterologous $F(ab')_2$ antivenom for envenomation by *Lonomia obliqua* is available in Brazil for the treatment of systemic effects associated with envenomation.[67] Animal and human studies suggest that the antivenom (antilonomic serum; Instituto Butantan, Sao Paulo, Brazil) reverses the hemorrhagic syndrome associated with contact by *Lonomia obliqua* caterpillars from Brazil.[67] A randomized, prospective study of 44 patients with grade I (external bleeding only) or II (external and internal bleeding) hemorrhagic syndrome indicated that the administration of 3 vials of this antivenom resolves the coagulation abnormalities within a mean of approximately 15 hours after administration.[67] Early treatment of the consumptive coagulopathy associated with Lonomia caterpillars is important to reduce complications. The administration of whole blood or fresh frozen plasma usually causes thrombocytopenia and renal dysfunction.

Chapter 174

AMPHIBIANS—TOADS, FROGS, SALAMANDERS, and NEWTS
(Class: Amphibia)

TOADS and FROGS

Colorado River Toad

HISTORY

Anthropologists suggest that pre-Columbian peoples used the common marine toad, *Bufo marinus* L., as an intoxicant during ritualistic ceremonies. Toads from genus *Bufo* contain the first hallucinogenic agent documented in the animal kingdom.[1]

IDENTIFYING CHARACTERISTICS

Over 200 species of toads throughout the world produce a wide variety of biologically active substances stored in parotid glands on their backs. The giant marine toad of South and Central America is *Bufo marinus* L., whereas the main European and Asian species are *B. bufo* L. and *B. gargarizans* Cantor, respectively.

Common Name: Colorado River Toad, Sonoran Desert Toad

Scientific Name: *Bufo alvarius* Girard in Baird

Family Name: Bufonidae

Physical Description: Compared with frogs, toads are stout, slower-moving amphibians with short limbs and small webs on their feet. The dorsal skin is rough with numerous dermal protuberances and cryptic coloration. The Colorado River toad is a large amphibian with prominent parotid glands that secrete viscous, milky-white venom. This toad and the cane toad (*Bufo marinus* L.) are morphologically similar except cane toads have a distinctive head and face manifest by a visor extending over each eye and a high, angular boney ridge extending from the eyes to the nose.

Common Name: Cane Toad

Scientific Name: *Bufo marinus* L.

Family Name: Bufonidae

Physical Description: Adult cane toads are relatively large toads with weights up to about 4 pounds (~2 kg) and length of approximately 4–9 in. (~10–23 cm) and their skin is warty. The female is usually bigger than the male. The ventral surfaces of their round flat bodies are yellow-white with darker mottling, whereas their backs and sides vary from olive-brown or reddish-brown to gray and yellow along with light middorsal stripes. The front feet do not have webs between the toes.

EXPOSURE

Geographic Distribution

The Colorado River Toad ranges from southeastern California to Arizona and Northwestern Mexico. The

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

natural habitat of the cane toad (*B. marinus* L.) is the Amazon basin in South America through Central America to Mexico and southern Texas along the Rio Grande River. In 1935, this species was introduced into eastern Australia for pest control. Cane toads were also introduced in many other parts of the world (e.g., Philippines, Florida, Puerto Rico, Caribbean Islands, Venezuela). This tropical toad prefers forested areas with nearby water sources. *Bufo compactilis* Wiegmann ranges from Northern Arizona to Texas and Northeastern Mexico. The Chinese toad is *Bombina maxima* Boulenger (*Bufo bufo gargarizans*). The guttural toad (*Bufo gutturalis* Power) and the raucous toad (*Bufo rangeri* Hewitt) reside in South Africa.[2]

Behavior

The Colorado River toad is a semiaquatic amphibian found only in the Sonoran desert. This toad remains underground in a dormant state from September to April until the breeding season starts. As the summer rains begin, the toads emerge from hibernation, particularly at night. The cane toad (*B. marinus* L.) is primarily nocturnal and ground-dwelling. These toads are particularly attracted to lights at night and feed both on live and dead matter. They have a voracious appetite that includes eating almost any animal (e.g., insects, small lizards, frogs, birds, fish, mice, bees, worms, and beetles) they are capable of ingesting.

Uses

Chan Su is a traditional Chinese medicine that is prepared from the dried white secretions of the auricular and skin glands of Chinese toads including the Chinese cane toad. Other traditional Chinese medicines (e.g., Lin-Shen-Wan, Kyrushin) also contain substantial amounts of Chan Su. These preparations are constituents of traditional expectorants, diuretics, cardiotonic agents, antiarrhythmics, local analgesics (sore throat, tonsillitis, teeth), and detoxifying agents for the blood and skin.[3,4] The West Indian aphrodisiac "Love Stone" and Chan Su are derived from similar sources based on virtually identical gas chromatography/mass spectrometry (GC/MS) profiles.[5] Besides the presence of cardiotonic steroids (bufalin, cinobufagin, bufogenin), these products contain the hallucinogenic substance, bufotenine, which is an isomer of psilocin. Toad licking is a method of drug abuse popularized in the 1980s, particularly in areas where the toads are indigenous.[6]

PRINCIPAL TOXINS

Venom Composition

Toad venoms contain a complex variety of toxins including biogenic amines (epinephrine, norepinephrine), indole alkylamines [bufotenin (bufotenine, cinobufotenine), bufothionine, dehydrobufotenine, serotonin], C24 cardioactive steroids (bufadienolides), and conjugates of bufogenins (bufotoxins).[7] The major bufadienolides in these preparations are bufalin, cinobufagin, cinobufotalin, and bufogenin (resibufogenin).[8] The main toxins in toad venoms are probably these bufadienolides, which have cardiac effects similar to digitoxin; these compounds vary substantially between different species of toads.[9] Bufadienolides are structurally similar to cardiac glycosides (cardenolides), such as digitoxin, digoxin, and oleandrin present in the plant kingdom.[10] Digitoxin is an analog of digoxin with one less hydroxyl group on the steroid part of the molecule. Both bufadienolides and cardenolides have a steroid nucleus; however, bufadienolides have a six-member lactone ring compared with a five-member lactone ring in cardenolides.[11] The cardiac genins (aglycones) in toads do not have the attached sugars present in cardiac glycosides in the plant kingdom. Figure 174.1 demonstrates the structural similarities between bufadienolides (bufalin, cinobufotalin), plant cardenolides (oleandrin, oleandrigenin), and cardiac glycosides (digoxin, digitoxin).

Experimental studies in humans suggest that the psychedelic substance, bufotenin (5-hydroxy-*N,N*-dimethyltryptamine, CAS RN: 487-93-4), does not produce the severe cardiac toxicity associated with toad poisoning.[12] Bufotenin is also a constituent of Cohoba seeds (*Anadenanthera peregrina* (L.) Speg.) from Haiti and some fungi in concentrations up to 1.9% including the fungal species, *Amanita citrina* var. *citrina* (Schaeff.) Pers., *Amanita porphyria* Alb et Schw.:Fr., and *Amanita rubescens* (Pers.:Fr.) Gray.[13] *O*-methyl transferase in the Sonoran desert toad (*B. alvarius* Girard in Baird) catalyzes the conversion of bufotenin to the more potent psychedelic substance, 5-methoxy-*N,N*-dimethyltryptamine. Tropical toads from the genus *Atelopus* contain tetrodotoxin including *Atelopus chiriquiensis* Shreve, *Atelopus oxyrhynchus* Boulenger, *Atelopus peruensis* Gray and Cannatella, *Atelopus subornatus* Werner, and *Atelopus zeteki* Dunn.[14,15]

Venom Apparatus

When threatened, toads secrete venom from parotid-like glands in the skin near their eyes. The cane toad (*B. marinus* L.) has a large, protuberant parotid gland behind each ear. The parotid and tibial glands of the

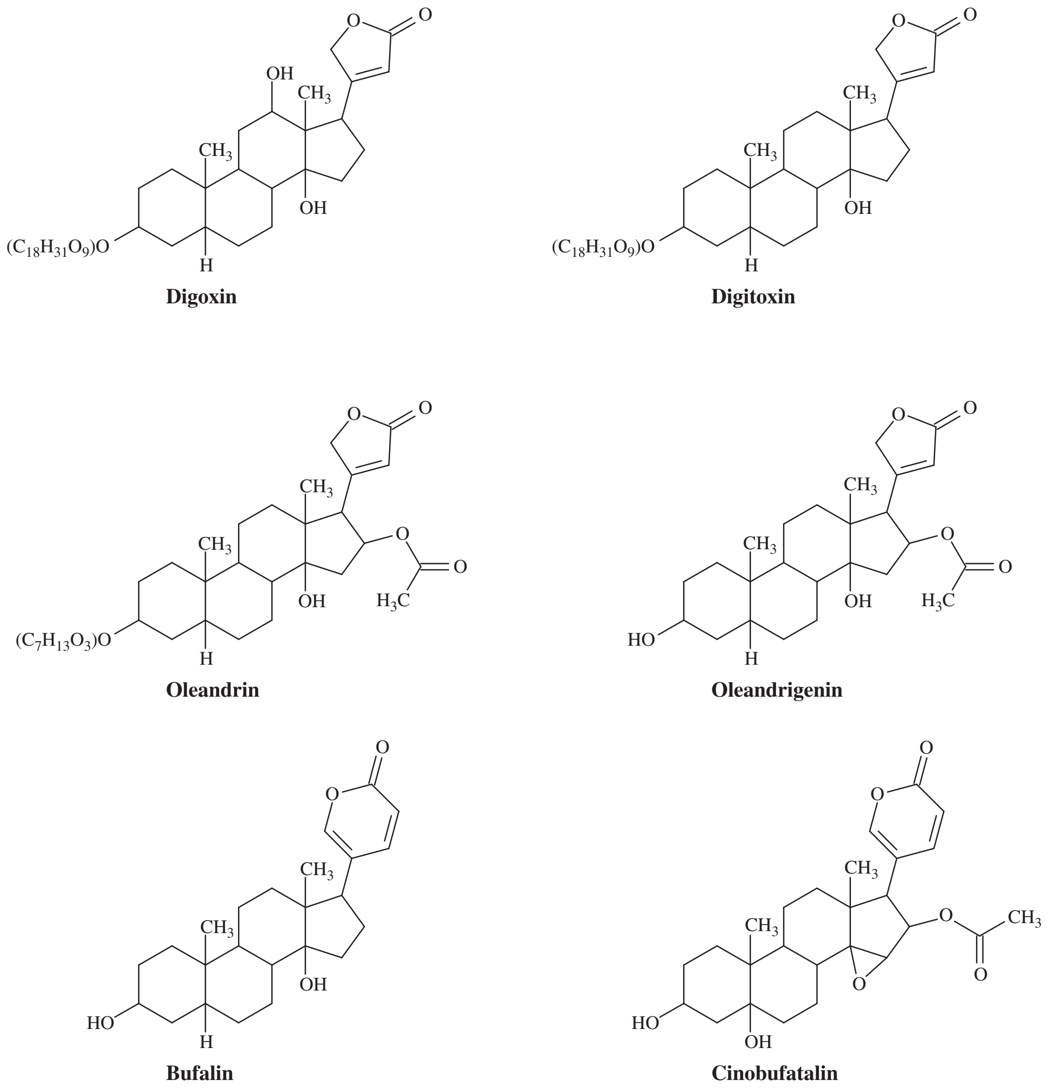

FIGURE 174.1. Chemical structures of bufadienolides and similar cardiac glycosides.

Sonoran desert toad can contain relatively large amounts (i.e., up to 15% by dry weight) of the psychedelic substance, 5-methoxy-*N,N*-dimethyltryptamine, as a result of the *O*-methylation of bufotenin.[16]

Dose Response

The toxicity of the Colorado River toad (*Bufo alvarius* Girard in Baird), the cane toad (*Bufo marinus*) and the Chinese toad (*Bombina maxima* Boulenger) are similar. Substantial variation in sensitivity to digoxin-like compounds and presumably to bufadienolides occurs between animal species. Humans, cats, dogs, and rabbits are highly sensitive, whereas rats, mice, and toads are relatively insensitive to these compounds.[17] In clinical studies on healthy volunteers, intravenous doses of 4–16 mg bufotenin produced hallucination, distortion of time and space, depersonalization, mydriasis, and facial erythema.[12] The higher doses also caused shivering, ataxia, and purple-black visual illusions.

TOXICOKINETICS

Following ingestion of Chinese medications containing toad venom, peak concentrations of bufadienolides in healthy volunteers occur about 1–2 hours after ingestion.[18] The elimination half-lives of bufalin, cinobufagin, and bufogenin (resibufogenin) are approximately 16 hours, 9 hours, and 11½ hours, respectively. Bufalin is strongly bound to serum albumin. Animal studies indicate that cinobufagin is deacetylated to less active metabolites (desacetylcinobufagin, epidesacetylcinobufagin), but there are substantial interspecies variation in the metabolism of cinobufagin.[19]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Although toad secretions contain a variety of toxins, the major toxins are probably the bufadienolides (bufalin, cinobufagin, bufogenin). These compounds are specific inhibitors of the plasma membrane bound Na^+/K^+ ATPase, and this action produces a digoxin-like toxicity. Toxins from the Colorado River toad (*B. alvarius*), African toad (*Bufo regularis* Reuss), common marine or cane toad (*Bufo marinus*), and American toad (*Bufo americanus* Holbrook) also enhance the adenosine 3′, 5′-monophosphate content in mononuclear leukocytes.[20]

CLINICAL RESPONSE

Acute Toxicity

The clinical course of toad poisoning is similar to digoxin toxicity,[21] and the ingestion of high doses of traditional Chinese medicines containing toad venom has been associated with cardiac dysrhythmias, dyspnea, convulsions, and death.[22] In a series of 6 patients ingesting a topical aphrodisiac containing toad venom, all patients developed vomiting and bradycardia.[11] Other clinical features included generalized weakness, salivation, abdominal pain, diarrhea, coldness and numbness of the lower extremities, mental status changes, hypotension, and noncardiogenic pulmonary edema. Four of the 6 patients died following intractable ventricular fibrillation. Within 15 minutes after placing a toad in his mouth, a five-year-old boy developed drooling and generalized tonic-clonic seizures.[23] Additional effects included total left-sided hemiparesis, Babinski sign, slurred speech, tachypnea, tachycardia, systolic hypertension, and hypokalemia. The neurologic deficits resolved within one week. Nausea, vomiting blurred vision, general weakness, perioral numbness, coma, high-grade A-V block, and sudden cardiopulmonary arrest occurred in a 31-year-old male who ingested a bowl of toad soup stewed with rice wine.[24] A 40-year-old man ingested an aphrodisiac containing toad venom, and he developed bradycardia, A-V block, hyperkalemia, respiratory distress, and terminal ventricular fibrillation.[25]

Abuse

"Toad licking" is a colloquial euphemism for the ingestion of the glandular secretions of the bufo toad. This activity was popularized by the lay press in the late 1980s after the publication of a book by Albert Most that explained the use of the bufo toad for ritual and pleasure.[26] One of the constituents of these glandular secretions is bufotenin, which has been classified as a Schedule I drug by the US Drug Enforcement Administration since 1967. There are limited clinical data on the prevalence and the adverse effects of this form of drug abuse.[27] Toad licking can transmit bacterial diseases, such as salmonellosis.

DIAGNOSTIC TESTING

Biomarkers

Postmortem analysis of liver samples from a 30-year-old woman, who died after ingesting a traditional Chinese medicine derived from the skin and parotid venom glands of toad (Chan Su), demonstrated detectable concentrations of several bufadienolides including bufalin, cinobufotalin, and cinobufagin as determined by reversed-phase high performance liquid chromatography and photodiode array detection(RP-HPLC/PDA).[28] Patients ingesting high doses of traditional Chinese medicine (Chan Su, Dan Shen) containing toad venom usually demonstrate positive apparent digoxin concentrations as detected by polyclonal digoxin immunoassays. The apparent digoxin concentration of a woman, who died after the ingestion of a tea brewed from Chan Su, was 4.9 ng/mL as measured by fluorescence polarization digoxin immunoassay.[22] Two hours after the ingestion of toad soap, a 54-year-old man developed vomiting, hypotension, bradycardia, AV block, and hyperkalemia (6.09 mmol/L).[29] His serum dioxin concentration was 1.62 ng/mL. He survived with supportive care despite developing nonsustained ventricular tachycardia 4 hours after ingestion of the soup. These traditional Chinese medications also cross-react with the digitoxin fluorescence polarization immunoassay,[30] but these medications do not cross-react with the digitoxin chemiluminescent immunoassay.[31] The apparent elevation in serum digitoxin immunoassays is much less for cinobufagin and cinobufotalin than for bufalin.

Because of the structural difference between bufadienolides in toad venom and digoxin, the apparent digoxin assays following toad poisoning is relative low even during serious toxicity. Following exposure to bufalin and cinobufotalin, the apparent serum concentrations are much higher for digitoxin than digoxin, as measured by fluorescence polarization immunoassay.[32] The administration of Chinese medications containing toad venom displaces digitoxin from serum protein binding sites causing an increase in free digitoxin concentrations.[33] Consequently, the presence of a positive apparent digoxin or digitoxin immunoassay confirms exposure to bufadienolides, but these concentrations do not correlate to toxicity.[11] A negative apparent digoxin assay does not necessarily exclude exposure to bufadi-

enolides depending on the specificity of the assay; therefore, polyclonal digoxin assays are preferable to monoclonal digoxin assays.

Bufotenin (*N*,*N*-dimethyl-5-hydroxytryptamine) is a dimethylated indoleamine derivative of serotonin that occurs naturally in human urine samples as a result of the biotransformation of serotonin by indolethylamine *N*-methyltransferase.[34]

Abnormalities

The presence of hyperkalemia suggests serious toad poisoning.[35] Although hyperkalemia is a poor prognostic sign in digoxin toxicity and in toad poisoning,[36] ventricular fibrillation and asystole may occur in patients with normal serum potassium concentrations. A 23-year-old man developed noncardiogenic pulmonary edema, ventricular fibrillation, and asystole the day after ingesting a topical aphrodisiac containing dried toad venom.[11] The serum potassium in a blood sample drawn in the emergency department was 4.3 meq/L.

TREATMENT

Gastric emptying is not usually necessary because profuse vomiting often occurs during toad poisoning. The administration of activated charcoal to alert patients who present to the emergency department within 1 hour after ingestion is a therapeutic option, but there are no clinical data to confirm the clinical efficacy of decontamination measures on outcome following the ingestion of bufadienolides. The treatment of toad poisoning is similar to oleander toxicity. The sudden onset of ventricular fibrillation and cardiovascular collapse may occur during serious toad poisoning; therefore, all patients should be monitored for ventricular dysrhythmias at least 6 hours after ingestion. There are limited clinical data on the effectiveness of digoxin Fab fragments for toad poisoning. The structural differences between bufadienolide and digoxin suggest that cross-reactivity between these two compounds may be limited. *In vitro* binding studies indicate that Digibind© (GlaxoSmithKline Pharmaceuticals, Mississauga, Ontario, Canada) is less effective in neutralizing free bufalin than free cinobufotalin.[32] Case reports associate the administration of digoxin Fab fragments with clinical improvement of toad venom poisoning, but these patients did not demonstrate serious ventricular dysrhythmias or hyperkalemia prior to the use of digoxin Fab fragments.[11] The amount of digoxin Fab fragments administered should be based on empiric estimates (i.e., 10 vials for serious intoxication) rather than serum digoxin concentrations because the serum digoxin concentration underestimates the concentration of bufadienolide compounds. Some differences in efficacy may exist between different digoxin Fab preparations (e.g., Digibind®; DigiFab®, Protherics, Inc., Brentwood, TN) as a result of varying cross-reactivity with the cardioactive steroids present in toad venom. In a study of mice receiving digoxin Fab (Digibind®) 30 minutes after the administration of a lethal dose of bufadienolides, digoxin Fab fragments bound to some of the bufadienolides.[37] However, 7 of the 15 treated mice died compared with all 30 controls. All symptomatic patients or patients with laboratory abnormalities (dysrhythmias, conduction disturbances, hyperkalemia) should be admitted for observation in a monitored setting.

Colombian Poison-Dart Frog

HISTORY

Since pre-Colombian times, the Emerá Chocó and the Noanamá Chocó Indians of western Columbia poisoned blow darts with the secretions from three toxic species of the genus *Phyllobates*.[38] Batrachotoxin is the primary toxin in the skin secretions from the three species of Colombian poison-dart frogs (*Phyllobates terribilis* Myers, Daly and Malkin, *Phyllobates bicolor* Duméril and Bibron, *Phyllobates aurotaenia* Boulenger).[39] There is no evidence that other Central or South American Indian tribes used skin secretions from neotropical frogs on poison darts or arrows.

IDENTIFYING CHARACTERISTICS

Common Name: Colombian Poison-Dart Frog

Scientific Name: *Phyllobates bicolor* Duméril and Bibron, *Phyllobates aurotaenia* Boulenger, *Phyllobates terribilis* Myers, Daly and Malkin

Family: Dendrobatidae

Physical Description: The black-legged dart frog (*Phyllobates bicolor*) typically has golden-yellow skin with varying color patterns and black spots on the hind legs. This frog has terminal disks on the digits for climbing plants and trees. The golden poison dart frog (*P. terribilis*) is a small frog ranging in size up to 5 cm (~2 in.). The skin has a uniform metallic golden yellow color, and tiny disks on the end of the digits facilitate climbing as demonstrated in the specimen of *Phyllobates terribilis* in Figure 174.2. A bony plate in the upper jaw separates this frog from other poison dart frogs. The kokoe poison dart frog (*P. aurotaenia*) is the smallest poison arrow frog. They have a black body with

FIGURE 174.2. Golden Poison Frog (*Phyllobates terribilis* Myers, Daly, and Bibron). © 2005 Rune Midtgaard. See color insert.

a green, orange, or gold U-shaped pattern starting at the snout that persists into maturity along with small, light blue spots on a black background.

EXPOSURE

The genus, *Phyllobates*, contains five species of frogs, which live in tropical areas from Costa Rica (*P. vittatus*) through Panama (*P. lugubris* Schmidt) and western Colombia (*P. bicolor*, *P. aurotaenia*, *P. terribilis*). All three poison-dart frogs inhabit the rain forests of western Columbia. *Phyllobates bicolor* lives in tropical rain forests of Central and South America, where the conditions are moist and humid. They live in colonies on the forest floor, particularly near small streams. Like other poison dart frogs, *P. terribilis* inhabits tropical rain forests. The kokoe dart frog is a highly social frog that requires high humidity and cool temperatures in tropical rain forests.

PRINCIPAL TOXINS

Venom Composition

Cutaneous granular glands from the neotropical poison frogs (family: Dendrobatidae) contain biogenic amines, peptides, bufadienolides (bufogenins) and alkaloids.[40] The latter substances are cyclic nitrogen-containing compounds that include water-soluble alkaloids (tetrodotoxins), lipophilic alkaloids, and alkaloids derived from biogenic amines. The major classes of dendrobatid alkaloids are batrachotoxins, histrionicotoxins, indolizidines, pumiliotoxins, and decahydroquinolines.[40] Minor classes include gephyrotoxins, 2,6-disubstituted piperidines, pyrrolidine alkaloids, pyridylpiperidines (noranabasamine), indole alkaloids (frog calycanthine, frog chimonanthine), azatricyclododecenes, and amidine alkaloids. The skin secretions of all species of *Phyllobates* including the Colombian poison-dart frogs contain the highly toxic steroidal alkaloid, batrachotoxin, whereas species of the genus *Dendrobates* secrete pumiliotoxins A, B, and C, histrionicotoxins, and gephyrotoxins.[41] Some species of the family Dendrobatidae of neotropical frogs do not contain significant amounts of toxins in their glandular secretions.[42]

Tetrodotoxin is the primary toxin in the skin of colorful, Central and South American frogs from the genus *Atelopus* (*A. chiriquiensis* Shreve, *A. peruensis* Gray and Cannatella, *A. oxyrhynchus* Boulenger, *A. subornatus* Werner, *A. varius* Lichtenstein and Martens) of the Bufonidae family.[15,43] This toxins also occurs in the Panamanian frog *Colostethus inguinalis* Cope from the Dendrobatidae family as well as an analogue of tetrodotoxin (chiriquitoxin).[44] This latter substance blocks sodium and potassium channels. Batrachotoxins occur in the contour feathers of the belly, breast, and legs of New Guinean birds including the hooded pitohui (*Pitohui dichrous* Bonaparte), variable pitohui (*Pitohui kirhocephalus* Lesson & Garnot), and the blue-capped ifrita (*Ifrita kowaldi* De Vis).[45] Other feathers from these species contain lesser amounts of batrachotoxins. Batrachotoxin (CAS RN: 23509-16-2) and homobatrachotoxin (CAS RN: 23509-17-3) were not detectable in samples of skin from these birds.

Venom Apparatus

Because of a lack of speed and armament, amphibians rely predominately on chemicals to deter predators. The structure of the secretory glands in the skins of poison-dart frogs from the Dendrobatidae family is similar, even though different frogs secrete substances with varying toxicity. Skin secretions from the genus *Phyllobates* contain the highly toxic batrachotoxins, whereas the secretions from frogs from the genus *Dendrobates* are less toxic.

Dose Response

On the basis of LD_{50} experiments in mice, amphibians contain highly toxic substances.[46] The mouse LD_{50} for batrachotoxin is 2 pg/kg compared with 8 pg/kg for tetrodotoxin and 500 pg/kg for curare.[47] Although the concentration of these toxins in amphibians is highly variable, the golden poison frog (*Phyllobates terribilis*) generally contains the highest batrachotoxin concentrations. Analysis of one specimen from this species detected 1.9 mg of batrachotoxin in comparison to the estimated human lethal dose of 0.02 to 0.2 mg.[48]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Batrachotoxin is a potent modulator of voltage-gated sodium channels that can produce dysrhythmias and the depolarization of muscles and nerves. This toxin depolarizes neurons by irreversibly binding to open voltage-dependent sodium channels; continual activation of the receptor results in spastic paralysis. Tetrodotoxin and saxitoxin are sodium channel blockers that bind to a separate and distinct site on the sodium channel protein.[41] The result of the binding of batrachotoxin is a stabilization of the sodium channel in an open conformation. Batrachotoxin also modulates the voltage-gated sodium channel Na(v)1.8, which is an important part of nociception. Alteration of these channels produces altered sensation (i.e., paresthesias).[49] Other natural toxins (e.g., aconitine, veratridine, grayanotoxin) interact at the same site as batrachotoxin, but these compounds are less potent than batrachotoxin.[50] Batrachotoxin does not bind to the calcium or potassium channels.[51]

Target Organs

In guinea pig atria, batrachotoxin demonstrates positive chronotropic and inotropic properties. Dysrhythmias and atrial arrest develop after the application of batrachotoxin to isolated cardiac muscle preparations. Morphologically, batrachotoxin produces swelling of the axon at the node of Ranvier and extracellular fluid accumulation along the axon.[52]

CLINICAL RESPONSE

Case reports of poisoning by the poison dart frogs and batrachotoxin are not well described in the medical literature. Based on similarity in the mechanism of toxicity between batrachotoxin and veratridine, intoxication by batrachotoxin and the poison dart frog would be expected to produce vomiting, bradycardia, and hypotension. Massive poisoning could produce serious cardiac abnormalities including atrioventricular block, junctional and idioventricular escape rhythms, atrial dysrhythmias, ST abnormalities, T wave inversions, QT prolongation, and ventricular fibrillation.

DIAGNOSTIC TESTING

There are no commercially available laboratory tests to detect poisoning by neotropical poison frogs.

TREATMENT

Treatment is supportive. Atropine is the initial drug of choice for symptomatic bradycardia, but the effect of atropine on hypotension is usually limited. Fluids and vasopressors may be necessary to correct hypotension. Cardiac monitoring and electrocardiograms should be instituted in severely poisoned patients because of the potential for the development of conduction blocks and ventricular dysrhythmias.

SALAMANDERS and NEWTS

IDENTIFYING CHARACTERISTICS

The order Caudata contains over 500 species of primitive salamanders, advanced salamanders, newts, and sirens as outlined in Table 174.1.[53] Salamanders have slender bodies, four short legs of equal size, and long tails that are typically as long as their bodies. Some salamanders do not have legs, but all members of this order have tails (tailed amphibians). The primitive salamanders include members of the Cryptobranchidae and Hynobiidae families. The former family contains the largest salamanders (*Andrias davidianus* Blanchard), which grow up to 1.6 m (~5.3 ft.) in length. Members of the other family of primitive salamanders (Hynobiidae) are small- to medium-sized salamanders. These two families of primitive salamanders contain only three species each, whereas the family of lungless salamanders (Plethodontidae) contains over one-half of the species in this order. Salamanders from the genus *Onychodactylus* in this family do not possess lungs. Advanced salamanders comprise the largest number of salamander species, and these salamanders have fused angular and prearticular bones in the lower jaw in contrast to primitive salamanders. Terrestrial mole salamanders (family: Ambystomatidae) have prominent, protruding eyes, thick arms, prominent costal grooves, thick arms, and round tails. Skin colorations range from dark blue patches to large yellow bars on dark backgrounds.

Newts are members of the true salamander family, Salamandridae. Newts are salamanders with a unique pattern of teeth in the roof of their mouths, whereas

TABLE 174.1. Members of the order Caudata

Family	Common Names of Members	Primary Habitat
Ambystomatidae	Mole salamander, axolotl	North America
Amphiumidae	Amphiuma	Southeastern US
Cryptobranchidae	Giant salamander	America, Asia
Dicamptodontidae	Pacific giant salamander	Western US, southwestern Canada
Hynobiidae	Asiatic salamander	Asia, Russia, Middle East
Plethodontidae	Lungless salamander	North, Central, South America
Proteidae	Mudpuppy, olm, waterdog	North America
Rhyacotritonidae	Torrent salamander, seep salamander	Northern California, Oregon, Washington
Salamandridae	True salamander, newt	North America, Europe, Russia, Middle East
Sirenidae	Siren	Midwestern and eastern US, northeastern Mexico

other salamanders have teeth in the upper and lower jaws. Figure 174.3 displays a specimen of the red-spotted newt (*Notophthalmus viridescens* Rafinesque). Unlike salamanders, newts have no costal grooves and their skin is rough in contrast to the moist, mucoid secretions on the skin of most salamanders. The absence of hind legs separates sirens from other species in the order Caudata. Although they have forelimbs, these appendages are reduced in size compared with other species in this order. They also retain their larval gills and one to three gill slits.

EXPOSURE

There are only six living species of primitive salamanders, and these amphibians live in Asia and America with isolated species in the Middle East and Russia. Most advanced salamanders and newts inhabit the cooler regions of the northern hemisphere with the exception of some species in the Plethodontidae family that inhabit tropical areas of Central and South America. Most members of the order Caudata begin as aquatic larvae, but adults may be aquatic, semi-aquatic, or terrestrial. The Plethodontidae family contains a variety of salamander species, which inhabit aquatic, terrestrial, and arboreal habitats. Salamander species in the Amphiumidae family are aquatic, and these species live in swamps and ponds with dense vegetation in the southeastern United States. Species in the Dicamptodontidae and Rhyacotritonidae families inhabit conifer forests, particularly along streams and creeks during the mating season. Many newts inhabit aquatic areas. In general, species in the order Caudata prefer to walk or run rather than leap like frogs or toads.

*Primary toxin definitely identified as tetrodotoxin.

alkaloids, biogenic amines, vasoactive peptides, and cardenolide-like steroids. The skin, internal organs and embryos of newts contain tarichatoxin, which is structurally identical to tetrodotoxin. Tetrodotoxin is a colorless amino perhydroquinazoline compound with a pKa of 8.5. This substance rapidly degrades in alkaline media to several quinazoline compounds. The concentration of tetrodotoxin in newts varies between different newt species, sex (i.e., female > male), and specific organ.[43] Table 174.2 lists the relative toxicity of newt species. In general, the skin and muscle contain a higher concentration of tetrodotoxin than the liver, stomach, intestines, and gonads. In a study of the Japanese newt (*Cynops pyrrhogaster* Boie) from western Japan, the concentration of tetrodotoxin in tissues ranged between 5–370 mouse units (MU)/g.[54]

Certain genera of salamanders from the Salamandridae family (*Taricha*, *Notophthalmus*, *Cynops*, *Triturus*) contain tetrodotoxin and related toxins (6-epitetrodotoxin, 11-deoxytetrodotoxin, 11-oxotetrodotoxin) in their skin secretions, muscle, and eggs.[55,56] Tetrodotoxin is uniformly distributed in the dorsal skin of the newt.[57] The concentration of tetrodotoxin varies substantially between individual specimens from the same species.[58] In a study of 12 adult specimens of the red-spotted newt (*Notophthalmus viridescens* Rafinesque), the tetrodotoxin concentration ranged between 0.15 μg/g and 23.5 μg/g as measured by postcolumn fluorescent HPLC with mass spectrometry in selected ion monitoring mode.[59] The tetrodotoxin concentration of specimens of newts from *Taricha torosa* Rathke in Eschscholtz ranged between 2–36 μg/g body weight, whereas specimens of *Taricha granulosa* Skilton contained higher concentrations of tetrodotoxin, ranging between 8–328 μg/g body weight.[60] Although 6-epitetrodotoxin was detectable in all specimens, the concentration of this substance was minor. Young newts (efts) also contain substantial amounts of tetrodotoxin as well as some analogues (11-oxotetrodotoxin).[61] The analogue, 6-epitetrodotoxin, is usually a minor constituent of these newts.

Tetrodotoxin occurs in a wide range of marine and terrestrial animals, and this neurotoxin is the cause of puffer fish poisoning. Although the ingestion of livers from certain species of puffer fish is the most common cause of tetrodotoxin poisoning, a variety of animals other than puffer fish, salamanders, and newts contain tetrodotoxin including Goby fish, frogs (*Atelopus*, *Brachycephalus*, *Colostethus* species from South and Central America), horseshoe crab, xanthid crabs, blue-ringed octopus, gastropods trumpet shell, arrow worms, and annelids.[62] These studies indicate that these species contain tetrodotoxin as well as tetrodotoxin analogs including 6-epitetrodotoxin, 4-epitetrodotoxin, 4,9-anhydro-6-epitetrodotoxin, and 4,9-anhydrotetrodotoxin. In general, the concentration of tetrodotoxin is higher in the skin, muscles, and blood of newts (e.g., *Taricha torosa* Rathke in Eschscholtz) compared with tetrodotoxin-containing fish.[63] The origin of tetrodotoxin in salamanders and newts remains controversial. Experimental studies did not detect the *de novo* synthesis of tetrodotoxin after the feeding of radiolabeled metabolites to captive newts. These studies suggest that tetrodotoxin is synthesized following infection by bacteria similar to the presence of tetrodotoxin in other marine animals.[60] However, subsequent testing of newts with polymerase chain reaction (PCR) primers suggests that symbiotic bacteria in newts are not the source of the tetrodotoxin.[64]

Venom Apparatus

Newts do not possess a venom apparatus. Intoxication results from the ingestion of tetrodotoxin from the skin or muscles of these animals.

Dose Response

An average adult newt contains about 250 µg tetrodotoxin.[65] Ingestion of ethanol and a 20-cm (~8 in.) newt (*Taricha granulosa* Skilton) produced paresthesias within 15 minutes and a fatal cardiopulmonary arrest within 2 hours.[66] However, patients have survived the consumption of five newts. Variations in the presence of the neurotoxin probably account for differences in clinical presentation. The East Coast species of newt found in the Carolinas (*Notophthalmus* spp.) contains less tetrodotoxin compared with West Coast newts (*Taricha* spp.).[56,65]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Tetrodotoxin blocks the sodium ion channels with subsequent inhibition of nerve and muscle activity. This toxin produces rapid, reversible flaccid paralysis of skeletal muscle, primarily by blockade of nerve transmission as a result of the inhibition of sodium channels.

CLINICAL RESPONSE

Certain species of newts contain tetrodotoxin and the ingestion of these reptiles produces classical tetrodotoxin poisoning similar to puffer fish. Clinical features include headache, perioral paresthesias, weakness, vomiting, diarrhea, excessive salivation, and lightheadedness. During severe tetrodotoxin poisoning, fixed and dilated pupils, ascending paralysis, bradycardia, hypotension, respiratory depression and cardiovascular collapse may occur.[66] Alteration of consciousness does not usually develop unless hypotension or respiratory failure occurs. Contact with the skin of a newt usually produces an immediate burning sensation.[67]

DIAGNOSTIC TESTING

Commercial laboratory tests for the detection of tetrodotoxin are not available. Methods to detect tetrodotoxin in biological specimens include postcolumn fluorescent HPLC and GC/MS.[59] In a study of four hospitalized victims of an unknown fish poisoning, blood samples were analyzed 10 hours after the ingestion of the fish by HPLC/MS with electrospray ionization interface.[68] The limit of detection was 15.6 nM. The blood tetrodotoxin concentrations in two patients requiring assisted ventilation were 344 ± 17 nM and 325 ± nM. Two other patients had neurological symptoms and respiratory distress, but they did not require intubation and assisted ventilation. Their blood tetrodotoxin concentrations were 47 ± 5 nM and 190 ± 16 nM.

TREATMENT

Treatment is supportive. Gut decontamination measures are usually unnecessary. The administration of activated charcoal to alert patients who present to the emergency department within 1 hour after ingestion is a therapeutic option, but there are no clinical data to confirm the clinical efficacy of decontamination measures on outcome following the ingestion of newts. Hypotension should be treated with intravenous saline and vasopressors if the patient fails to respond to fluid infusions. Symptomatic patients should be observed for 24 hours for signs of respiratory depression and hypotension. There are no antidotes.

Chapter 175

GILA MONSTER and BEADED LIZARD

IDENTIFYING CHARACTERISTICS

Of about 2,000 species of lizards, only two species of lizard previously were considered venomous. These lizards included the Gila monsters (*Heloderma suspectum* Cope) and the Mexican beaded lizards (*Heloderma horridum* Wiegmann). Recent evidence suggests that the lace monitor lizard (*Varanus varius* White) and the iguanian lizard (*Pogona barbata* Cuvier) also possess venom.[1] The taxonomic order Squamata contains both venomous snakes and the family of venomous lizards called Helodermatidae. Construction of gland complementary-DNA libraries and phylogenetic analysis of transcripts suggest that the venom from lizards and snakes contain nine similar toxin types. The shared lineages possessing toxin-secreting oral glands suggest a single early origin of the venom system in lizards and snakes.

Common Name: Gila Monster

Scientific Name: *Heloderma suspectum*

Infraspecies: *H. s. cinctum* Bogert and Martin del Campo (Banded Gila monster), *H. s. suspectum* Cope (Reticulate Gila monster)

Family: Helodermatidae

Physical Description: These large (25-50 cm/~10–12 in.), stout creatures possess sharp claws on short, stout legs, and flat, relatively large heads with blunt snouts and thick, black, forked tongues. The skin contains thick, beaded (bone-impregnated) scales on the dorsal surfaces that range in color from yellow and orange to pink and brown.

Common Name: Beaded Lizard

Scientific Name: *Heloderma horridum* Wiegmann

Infraspecies: H. *h. exasperatum* Bogert and Martin del Campo (Rio Fuerte beaded lizard), *H. h. alvarezi* Bogert and Martin del Campo (Black beaded lizard), *H. h. horridum* Wiegmann (Mexican beaded lizard)

Family: Helodermatidae

Physical Description: This large, heavy bodied lizard has scales resembling black and yellow beads. Features distinguishing the beaded lizard from the Gila monster include a larger size (70–100 cm/~2–3 ft.), longer tail, pink tongue, and finer speckles. The beaded lizard grows 1 m (~3 ft.) in length and weighs up to 2 kilograms (~2 lbs). Figure 175.1 displays a specimen of the beaded lizard (*Heloderma horridum* Wiegmann).

EXPOSURE

Geographic Distribution

The two species of Gila monsters inhabit arid regions of the southwestern United States and western Mexico from sea level to over 5,000 ft (1,500 m). The Gila monster appears primarily in the Great Sonoran Desert. Two infraspecies are the banded Gila monster (southeastern California, southern Nevada, Arizona, Mojave Desert) and the reticulate Gila monster (Sonoran and Chihuahua deserts in southern Arizona and northern Mexico). The habitat of the Mexican beaded lizard is Sonoran Mexico, the Pacific coast of Mexico from the

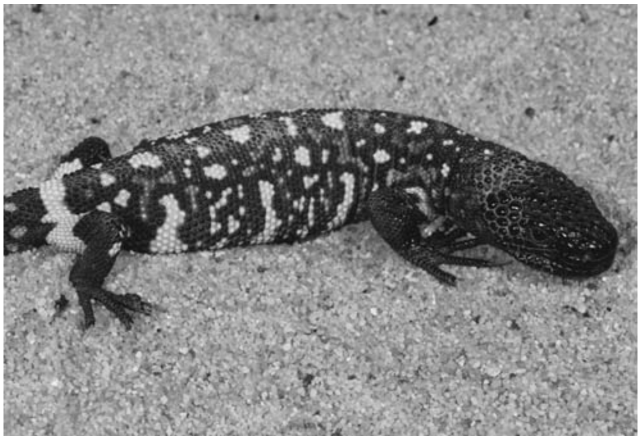

FIGURE 175.1. Beaded lizard (*Heloderma horridum* Wiegmann). © 2006 Rune Midtgaard. See color insert.

Isthmus of Tehuantepec to southern Sonora, and Guatemala.

Behavior

These large, slow-moving lizards live 10–25 years. The skin of the Gila monster is more permeable to water than the skin of many other lizards; therefore, these shy creatures retreat into burrows and rocky shelters during the hot daytime sun. Although they are primarily nocturnal during the warm summer months, they are diurnal in the cooler temperatures during the spring and winter. When threatened, these lizards display an open mouth while moving venom in preparation of envenomation. Gila monsters are binge feeders, consuming very large meals (i.e., up to one-third body weight) at infrequent intervals. They prey upon the eggs, newborn, and the young of many species of small mammals, reptiles, and birds.

PRINCIPAL TOXINS

Venom Composition

Helodermatidae venom is a complex mixture of proteins and enzymes (phospholipase A_2, hyaluronidase, L-amino acid oxidase, proteolytic enzymes, serotonin) with diverse biological activities.[2] The venom of the Gila monster and Mexican beaded lizard are similar.[3] Unique substances in this venom include gilatoxin (CAS RN: 77641-30-6), *N*-benzoyl-L-arginine ethyl ester hydrolase, exendin-3 (*H. horridum*) exendin-4 (*H. suspectum*), and helothermine (CAS RN: 127670-24-0). Exendin-4 (exenatide) is 39-amino acid peptide isolated from the saliva of the Gila monster (*H. suspectum*) that is structurally similar to glucagon-like peptide-1.[4] This compound stimulates glucose-induced insulin secretion in animal models,[5] and exendin-4 is a potential treatment for type II diabetes mellitus.[6] Rapid increases in the plasma concentration of exendin-4 occur in the Gila monster after feeding, primarily as a result of mechanical stimulation.[7] Helothermine (CAS RN: 127670-24-0) is a 25.5 kDa serine protease that inhibits Ca^{2+} channels in cerebellar granule cells of newborn rats.[8] These experiments suggest that helothermine produces a high-potency blockage of at least three pharmacologically distinct Ca^{2+} current components (i.e., ω-conotoxin GVIA-sensitive, ω-Aga-IVA-sensitive, dihydropyridine-sensitive). Additionally, *in vitro* experiments suggest that helothermine inhibits the intracellular ryanodine receptor, which is associated with the release of intracellular calcium stores in response to voltage or inotropic agents.[9] Whole-cell voltage-clamp experiments on cerebellar granule neurons also suggest that helothermine inhibits at least two different potassium current components similar to an IA-type current and a classical delayed-rectifier current.[10] Helothermine has kallikrein-like properties.[11]

Gilatoxin is a serine protease with kallikrein-like and thrombin-activating activity.[12] There are a variety of phospholipase A_2 (PLA) enzymes in animal venoms including at least five anionic phospholipases in the venom of the Gila monster.[13] The acidic PLA in the venom of the beaded lizard (*Heloderma horridum*) differs from snake PLA by specifically inhibiting thromboxane-induced platelet aggregation *in vitro*.[14] *N*-benzoyl-L-arginine ethyl ester hydrolase stimulates the release of vasoactive kinins and causes hypotension in animal models.[15] Horridum toxin (i.e., a purified glycoprotein from the crude venom from the Mexican beaded lizard) is hemorrhagic toxin with 210 amino acid residues that produces exophthalmia, internal hemorrhage, and paralysis when injected into experimental animals.[16,17] In contrast, gilatoxin has 245 amino acid residues and does not cause exophthalmia in experimental animals.

Venom Apparatus

The primitive injection apparatus of the Gila monster and the Mexican beaded lizard involves, but is not necessarily limited to, grooved teeth that are connected by a duct to the lower mandibular venom glands. Located subcutaneously in the lower anterior jaw, these glands deliver venom via ducts to openings located at the base of the enlarged, central mandibular teeth. Glandular compression during chewing motions moves the venom along the ducts. Alongside each mandible, dental sacs serve as reservoirs for the secreted venom. The venom diffuses primarily by simple capillary action up the rudimentary grooves present on the sharp, recurved teeth.

In contrast to Gila monsters, most venomous snakes have compressive muscular tissue surrounding the venom glands. Envenomation by these venomous lizards requires prolonged contact and a grinding motion. The teeth of the Gila monster are poorly anchored and frequently are shed during envenomation. Bites may be tenacious, requiring minutes to several hours to disengage. Bites in humans are rare and usually result from the careless handling of captive lizards; lizards use their venom primarily for defensive purposes.

Dose Response

The rat LD_{50} of lizard venom (10.3 mg/kg) is comparable to that of rattlesnake venom (10.6 mg/kg), but lizard venom has much lower enzymatic activity. The severity of the envenomation depends on several factors including the size of the lizard, the duration of contact, the location and depth of the bite, and the aggressiveness of the lizard. The amount of venom in the gland of a Gila monster exceeds the estimated lethal dose for humans, but the above factors limit the amount of venom injected during a human evenomation.[18]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

In experimental animals, *Heloderma* venom produces lethal changes in cardiopulmonary parameters without obvious effects on coagulation. Although some local bleeding occurs from puncture sites following human envenomation, animal studies indicate that the injection of lethal doses of Gila monster venom does not alter clotting or prothrombin time (PT).[19]

CLINICAL RESPONSE

Medically significant envenomations by members of the Helodermatidae family are rare. Most envenomations by Gila monsters cause local effects manifest by erythema and pain along with minor systemic complaints (weakness, lightheadedness, nausea, diaphoresis, chills).[20] A case report associated envenomation by the Mexican beaded lizard with the immediate onset of excruciating pain, nausea, and vomiting that resolved within 24 hours.[3] Tissue edema begins about 15–45 minutes after envenomation and progresses slowly up the extremity over the next 4–8 hours. Local pain may be severe during the first few hours after envenomation, but the pain usually resolves within 6–10 hours. In contrast to rattlesnake envenomation, local edema is usually minimal and skin necrosis is absent.[18] Neurovascular compromise of the involved extremity does not usually develop. Paresthesias, muscle fasciculations, and diaphoresis may also occur after envenomation, and some local hyperesthesia typically persisting for several days after the swelling resolves. The presence of hypotension, decreased vascular resistance, and tachycardia indicate a serious envenomation.[21] A 23-year-old herpetologist with a prior history of cocaine use developed changes suggestive of an anterolateral myocardial infarction (increased serum creatine kinase with positive MB band and electrocardiographic changes of right bundle branch block and ST-segment elevation) after a Gila monster envenomation.[22] A stress test demonstrated decreased contractility in the apex of the heart, but the patient refused a cardiac catheterization. Case reports associate bites from the Gila monster[23] and Mexican beaded lizard[24] with the occurrence of an anaphylactic-like reaction involving hypotension, dyspnea, drooling, dysphagia, angioedema, diaphoresis, and lightheadedness. There were no laboratory abnormalities or sequelae. These injuries occurred in patients with prior exposure and previous envenomations by these lizards.

Sequelae are rare except mild local hyperesthesia.[25] Lymphangitis may complicate the envenomation.[21] The wound may remain tender for several weeks. Fatalities following envenomation by the Gila monster or by the Mexican beaded lizard are not well documented in the modern medical literature with the last death recorded in 1930.[26]

DIAGNOSTIC TESTING

Laboratory abnormalities are usually minimal with leucocytosis and hypokalemia occurring occasionally. Coagulation studies are typically normal, although a case report documented the presence of hypofibrinogenemia, thrombocytopenia, elevated fibrin split products, and increased PT and partial thromboplastin time (PTT) following an envenomation by a Gila monster.[27] Transient intraventricular conduction defects and T-wave inversions may occur.[27,28] Serum cardiac enzymes are usually normal. Teeth shed into the wound during envenomation are often radiopaque, and the absence of teeth on radiographs does not exclude the presence of foreign bodies in the wound.[21]

TREATMENT

The most important first-aid measure is detachment of the tenacious lizard from the victim with the best available method (e.g., pliers, crowbar, strong stick placed in near posterior teeth, submerging the lizard in cold water, hot water on the head of the lizard, placing an open flame under jaw). A cast spreader is appropriate if the lizard remains attached during arrival to the emergency department. Pulling the reptile by the tail should be

avoided because of the potential for increased tissue destruction. After removal of the lizard, the affected extremity should be placed in a neutral position and the patient transported to a medical facility as soon as possible. The wound should be cleaned with 1% povidone-iodine, irrigated with saline, and débrided to remove all embedded teeth. If a foreign body is suspected, appropriate radiographs should be obtained. Prophylactic antibiotics are usually unnecessary unless there is evidence of lymphangitis. Other measures of supportive care include tetanus prophylaxis as indicated and analgesics (i.e., opiates, fentanyl, hydromorphone, nonsteroidal anti-inflammatory agents) for pain relief. There are theoretical concerns about the use of nonsteroidal anti-inflammatory drugs because of their antiplatelet properties, but there are no documented clinical complications associated with the use of these drugs following Gila monster envenomations. Peripheral nerve blocks are occasionally necessary to relieve pain.

Serious toxicity following Gila monster envenomations is rare. Hypotension usually responds to fluid replacement (10–20 mL saline/kg). Laboratory studies should include complete blood count, serum chemistry panel (electrolytes, blood urea nitrogen [BUN], creatinine, glucose), serum creatine kinase, PT, PTT, fibrinogen, fibrin degradation products, and D-dimer. Bleeding secondary to clotting abnormalities is rare, but outpatients should be instructed to return if abnormal bruising or bleeding develops. The platelet count rarely decreases below 100,000/mm^3; thrombocytopenia usually resolves within several days without complications.

Chapter 176

TERRESTRIAL SNAKES
(Suborder: Serpentes)

All snakes belong to the order Squamata and the suborder Serpentes that is characterized by scaly skin, absence of movable eyes, and elongated bodies without appendages. Venomous snakes inhabit all continents *except* Antarctica and some islands (Ireland, New Zealand). Approximately 15% of over 3,000 snake species are venomous, and the two main families of venomous snakes are **Elapidae** (elapids) and **Viperidae** (vipers).[1] The family **Atractaspididae** contains side-fanged snakes (stiletto vipers, mole vipers) that live in subterranean areas of Africa and the Middle East. The **Colubridae** family (colubrids) contains only a few species that are venomous to humans.

Elapids are characterized by short-fixed fangs that inject venom during a series of chewing movements. The smooth scales, large head shields, and mostly terrestrial habitat are similar to species in the Colubridae family. The main subfamily of elapids is Elapinae, which contains cobras (*Naja* spp.), kraits (*Bungarus* spp.), mambas (*Dendroaspis* spp.), and coral snakes (*Micrurus* spp., *Micruroides* spp.). Marine snakes were formerly classified as a separate family (**Hydrophiidae**), but now these snakes belong to the other two subfamilies of **Elapidae**, Hydrophiinae (sea snakes), and Laticaudinae (sea kraits).[2] The two main subfamilies of **Viperidae** are Crotalinae (pit viper) and Viperinae (true viper). The pit vipers (e.g., rattlesnakes, water moccasins, copperheads) possess heat-sensing foramen or pits, whereas true vipers (e.g., small adder [*Vipera berus* L.], large puff adder [*Bitis arietans* Merrem]) do not possess this heat-sensing organ. The third subfamily of **Viperidae** consists of only one ancient viper, Fea's viper (*Azemiops feae* Boulenger). The large family of **Colubridae** (colubrids) contains a majority of snake species, but most of these species are not venomous to humans. Several species of this family including the African boomslang (*Dispholidus typus* Smith) and the twig snakes (*Thelotornis* spp.) have back-fangs that inject potent venom.[3]

ATRACTASPIDS

Species of Atractaspidal are usually small, innocuous snakes. Most venomous members of this family are side-fanged, mole or burrowing vipers including *Atractaspis bibronii* Smith (Bibron's burrowing adder), *Atractaspis congica* Peters (Congo burrowing adder), and *Atractaspis engaddensis* Haas (burrowing asp). *Atractaspis bibronii* inhabits most of sub-Saharan Africa and arid regions extending northeast into Saudi Arabia and Jordan, whereas *A. engaddensis* inhabits Jordan and Israel. These snakes burrow into the ground, expose their frontal fangs protruding from the side of their partially closed mouth, and hook nearby prey. Bites frequently involve only one fang, and the envenomation is usually mild compared with other venomous snakes.[4] The venom of *A. engaddensis* contains 21-amino acid residue peptides called sarafotoxins that are structurally similar to the vasoactive peptides, endothelins.[5] Endothelins modulate the cardiovascular system including the regulation of blood pressure through smooth muscle contraction.[6] Although these snakes possess unique

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD

venoms, envenomation by these snakes is an uncommon cause of mortality and morbidity in these regions.[7] Clinical features of these envenomations usually involve localized pain, hemorrhage and swelling, regional lymphadenopathy with occasional discoloration, and blistering or necrosis at the bite site.[8] Less common complaints include headache, myalgias, dry mouth, and hoarseness. Neurological symptoms are usually absent, and systemic symptoms are uncommon. Hematological abnormalities are minimal, and cardiovascular effects (i.e., P-R prolongation, nonspecific ST-T wave changes, T-wave inversions as noted on the electrocardiogram) do not usually produce clinically significant hemodynamic effects.[9] Treatment is supportive with analgesics, wound care, and fluids as necessary. There is no commercially available antivenom for envenomation by these snakes.

VIPERS

The family Viperidae consists of folding-fanged snakes that are the most important cause of serious snake envenomations globally.[10] Taxonomically, this family is divided into the following subfamilies: 1) Azemiopinae containing only the ancient Fea's viper (*Azemiops feae* Boulenger), 2) Viperinae or true vipers (e.g., European asp, common viper, puff adders, Russell's viper), 3) Crotalinae or pit vipers (e.g., rattlesnakes, fer-de-lance, Asian lance-headed vipers, tree vipers), and Causinae containing only species of the genus *Causus*. Species within the Viperidae family are wide-ranging snakes that live in many different habitats with the exception of New Guinea and Australia. Members of this snake family include the Malayan pit viper, Gaboon viper, Asian habu, Chinese mamushi, Brazilian pit viper, North American rattlesnakes, Central American bushmaster, European adder, and the African puff adder. In Europe, species in the genus *Vipera* account for most snake envenomations. These vipers include *V. aspis* L. (asp viper or European asp), *V. ammodytes* L. (sand viper), *V. berus* L. (common viper), and *V. latastei* Bosca (Lataste's viper).[11] Mortality from these envenomations is very low. In the Middle East, the most common species involved in snakebites belong to the genera *Vipera* (*V. palaestinae* or Palestine viper, *V. xanthina* Gray), *Macrovipera* (*M. lebetina* L. or Lavantine viper), and *Cerastes* (*Cerastes vipera* L. or Cleopatra's asp). The annual incidence of snakebite in the United States and Europe is similar, and most US snake envenomations result from bites by rattlesnakes (*Crotalus* spp.), copperheads (*Agkistrodon contortrix* L.), or cottonmouths (*Agkistrodon piscivorus* Lacépède). The prevalence of snakebites is significantly higher in Central and South America than in the United States. Pit vipers account for most of the serious bites in this region (e.g., *Bothrops* spp. in Brazil, *Crotalus durissus* subsp. *terrificus* Laurenti in the savanna areas of South America, and *Crotalus durissus* subsp. *durissus* L. in Central America). The prevalence of snakebites in Africa is probably underestimated because of inadequate reporting systems, but existing evidence suggests that envenomations by species from the Viperidae family account for most deaths from snakebites. The common species involved in snake envenomations depend on the following locations: banana plantations (*Causus maculatus* Hallowell or spotted night adder), palm tree and rubber plantations (black cobras or *Naja melanoleuca* Hallowell, green mambas from the *Dendroaspis* species), forests and rice fields (*Bitis* spp. such as Gaboon viper), and savanna (*Echis* spp.). There is wide variation in the prevalence of snakebites in Asia. The majority of snakebites in Southern Japan and south China involve *Trimeresurus* species or *Protobothrops flavoviridis* Hallowell (habu or *Trimeresurus flavoviridis*). Dangerous snake species in Southeast Asia include *Calloselasma rhodostoma* Boie (Malayan pit viper), *Daboia russelii* Shaw & Nodder (Russell's viper, *Vipera russelii*), and *Naja naja* L. (Asian cobra). Almost all deaths from snakebites in Australia occur from envenomations by Elapidae species (*Pseudonaja, Notechis, Oxyuranus*). Figure 176.1 compares the mortality from snakebites across the world.

Old World Vipers (Viperinae)

Table 176.1 includes the African, European, and Middle Eastern vipers (adders, asps, vipers) that are venomous species of the Viperinae subfamily of the family Viperidae (viper). Viper venom contains a wide variety of components including pre- and postsynaptic neurotoxins, myotoxins, and toxins directed at the coagulation system and blood vessels, depending on the specific viper species.

EUROPE

EXPOSURE

Table 176.2 lists the common European venomous vipers. Indigenous venomous snakes in Europe belong

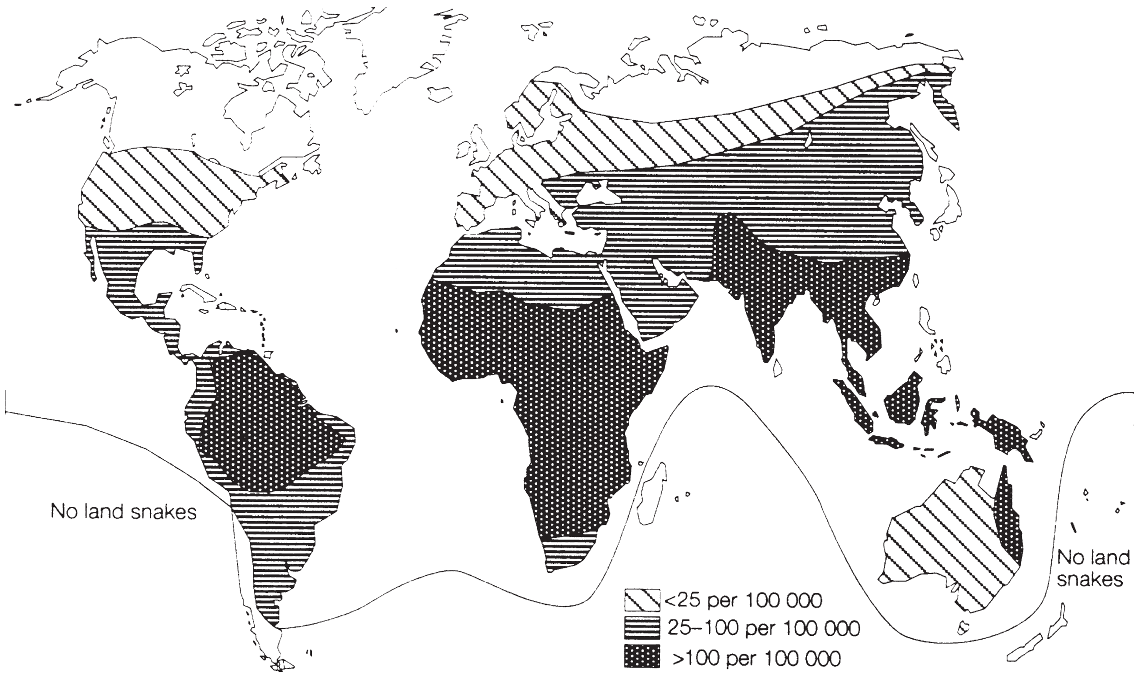

FIGURE 176.1. Global distribution of morbidity from snakebites. From Chippaux J-P. Snake-bites: appraisal of the global situation. Bull World Health Organ 1998;76:520. Reproduced with permission from the World Health Organization.

almost exclusively to the family Viperidae, subfamily Viperinae. *Vipera berus* L. (common viper) inhabits most parts of Europe, whereas *Vipera aspis* L. (asp viper) is found in France, Italy, and the Alpine region of Southern Germany, Austria, and Switzerland. Other important venomous viper species in Europe include the nose-horned or sand viper (see specimen in Figure 176.2) in the Balkans and the Orsini's viper (*Vipera ursinii* Bonaparte) in Eastern Europe (see Table 176.2). The adder is the only venomous snake indigenous to the United Kingdom.

FIGURE 176.2. Nose-horned Viper (*Vipera ammodytes* L.). © 2000 Rune Midtgaard. See color insert.

VENOM

The venom from European vipers is similar to the composition of venom from tropical vipers. These venoms contain proteases, esterases, L-amino acid oxidases, and hyaluronidase, but the concentration of myotoxic phospholipases A_2 and hemorrhagic factors are usually clinically insignificant.[12] Venom from the sand viper (*Vipera ammodytes* L.) does contain neurotoxic phospholipase A_2, which occasionally causes presynaptic neuromuscular blockage (i.e., ptosis ophthalmoplegia, generalized weakness) following envenomation.[13,14]

CLINICAL RESPONSE

Table 176.3 lists the gradation of envenomations by European vipers as outlined by Audebert et al. In a series of 147 cases of envenomations by *V. ammodytes* presenting to a Greek hospital, the most common clinical features of envenomation were pain, swelling, and ecchymosis with only 3% of cases presenting with blurred vision.[15] There were only two cases of severe envenomation (grade 3). The clinical features of envenomation by European vipers (e.g., *V. berus*) primarily involve cytotoxic and slight hemorrhagic effects resulting in mild local edema and pain, gastrointestinal symptoms (nausea, vomiting, diarrhea, abdominal pain), and

TABLE 176.1. Scientific and Common Names of Venomous Species of the Viperinae Subfamily[a]

Group	Scientific Name	Common Name
Adders		
	Bitis arietans Merrem	Puff adder
	Bitis atropos L.	Berg adder
	Bitis caudalis Smith	Horned puff adder
	Bitis cornuta Daudin	Horned adder
	Bitis gabonica Schmidt	Gaboon adder/viper
	Bitis inornata Smith	Plain mountain adder
	Bitis nasicornis Shaw	Rhinoceros or horn-nosed adder/viper
	Bitis peringueyi Boulenger	Peringuey's adder
	Causus defilippii Jan	Snouted night adder
	Causus lichtensteinii Jan	Lichtenstein night adder
	Causus rhombeatus Lichtenstein	Common night adder
	Vipera kaznakovi Nikolsky	Caucasus adder
	Vipera superciliaris Peters	African lowland adder
Asps		
	Cerastes vipera L.	Cleopatra's asp
	Vipera aspis L.	European asp, asp viper
Vipers/Other Adders		
	Atheris species	African bush vipers
	Atropoides nummifer Rüppell	Jumping viper
	Bothriechis schlegelii Berthold	Eyelash viper
	Cerastes cerastes L.	Horned viper
	Cerastes vipera L.	Sahara sand viper
	Daboia russelii Shaw & Nodder	Russell's viper
	Echis carinatus Schneider	Saw-scaled viper
	Echis coloratus Günther	Saw-scaled or Arabian viper
	Echis pyramidum Geoffroy Saint-Hilaire	Egyptian carpet viper
	Macrovipera lebetina L. (*Vipera lebetina*)	Desert adder, blunt-nosed viper, Levantine viper
	Porthidium nasutum Bocourt	Hognose viper
	Pseudocerastes persicus Duméril, Bibron & Duméril	Palestine or Persian horned viper
	Vipera ammodytes L.	Long-nosed or nose-horned viper
	Vipera aspis L.	Asp viper
	Vipera berus L.	European or common adder, common viper
	Vipera latastei Bosca	Lataste's or snub-nosed viper
	Vipera ursinii Bonaparte	Meadow adder or meadow viper, Orsini's viper
	Vipera xanthina Gray	Near East viper
	Vipera palaestinae Werner	Palestine viper

[a]Source: Adapted from Ref 1.

occasionally, hypovolemia.[16,17] In a case series of 231 *Vipera berus* bites, about 11% of the bites did not result in envenomation, while 13% of the bites produced severe envenomation (grade 3).[18] In a study of 99 bites by *Vipera aspis* L. presenting to a Swiss regional hospital, there were no cases of neurotoxicity or hemolysis.[19] The percentages of dry bites (grade 0) and severe envenomation (grade 3) were 8% and 10%, respectively. Rarely, case reports associate the development of severe local swelling and elevated compartment pressures with envenomation by *V. berus* L.[20] or *V. aspis* L.[21] The composition of the venom and the clinical presentation following envenomation are similar for both the asp and the adder with clinical effects ranging between local edema and rare cases of severe hypotension and bleeding.[22,23] Although ptosis occurs occasionally following envenomation by the European vipers,[24] flaccid paralysis and clinically significant coagulopathies are unusual. Severe envenomations are uncommon and these envenomations produce rapidly progressive edema, angioneurotic edema of face and pharynx similar to anaphylaxis, severe gastrointestinal symptoms, hypotension, shock, renal failure, coma, and death.[25,26] Rare case reports associate European viper bites with myocardial infarction,[27] cerebrovascular bleeding, and thrombosis of the iliac vessels with intestinal infarction.[28]

TABLE 176.2. Most Common European Venomous Vipers[a]

Species	Common Name	Description	Distribution	Habitat
Vipera ammodytes L.	Sand viper, nose-horned viper	Males; light-gray to gray with well developed black vertebral zig-zag strip; females: reddish brown to yellow with brown or gray bands. Distinct fleshy horn on snout and 60–80 cm length	Austria, Italy, Balkan States, Turkey, Transcaucasia	Dry, rocky slopes 200–600 m up to 2000 m (~6,500 ft)
Vipera aspis L.	Asp viper	60–75 cm (~25–30 in.) with variable coloration (light gray to gray-brown with black zig-zag strips). Snout slight upturned, but not erect	West, Central, Southern Europe	Sunny, dry, rocky hillsides up to 3,000 m (~10,000 ft)
Vipera berus L.	Adder, common viper	Thick-bodied 50–65 cm (~20–25 in.) in length with pale gray color and zig-zag stripes. Y- or X-pattern on distal head	England, France, Central and Northern Europe up to about 1,000 km.	Cool, moist habitats (dunes, marsh, meadows, forest edges up to polar circle)
Vipera latastei Bosca	Lataste's viper	50–60 cm (~20–25 in.) with coloration similar to asp viper, except darker edges, black tail tip and distinct nose-horn	Central and Eastern Spain, Southern Portugal	Rocky hillsides, open forest up to 1,500 m (~5,000 ft)
Macrovipera lebetina L.	Blunt-nosed viper	Largest (80–100 cm/~30–40 in.) European viper with yellow-, gray-, or red-brown coloration and vertebral zig-zag stripe	Cyprus, Greek Islands, Near East, North Africa	Rocky, dry hillsides with some vegetation up to 1,500 m
Vipera ursinii Boneparte	Meadow viper, Orsini's viper	Smallest (40–50 cm/~15–20 in.) European viper with yellow, brown, gray or dark green coloration and vertebral zig-zag stripes	Southern France, Italy, Austria, Balkan States	Dry meadows, hillsides up to 2,000 m (~6,500 ft)
Vipera xanthina Gray (*Montivipera xanthina*)	Ottoman viper	Large (80–100 cm/~30–40 in.) viper with light gray or brown coloration with dark brown or olive vertebral zig-zag stripes	Greece, West Turkey Islands, Turkey	Hillsides, rocky meadows up to 2,500 m (~8,000 ft)

[a]Source: Adapted from Ref 2.

TABLE 176.3. Grading of European Viper Envenomations[a]

Grade	Envenomation	Clinical Features
0	None	Fang marks without edema
1	Minimal	Local edema around bite with systemic symptoms
2	Moderate	Regional edema involving major portion of limb with moderate systemic symptoms (mild hypotension, vomiting diarrhea)
3	Severe	Extensive edema spreading to trunk with severe systemic symptoms (persistent hypotension, shock, bleeding)

[a]Source: Adapted from Ref 22.

DIAGNOSTIC TESTING

Laboratory abnormalities following envenomation by European vipers include leukocytosis and hemoconcentration, as well as anemia and thrombocytopenia in severe envenomations. Coagulopathy, internal bleeding, and rhabdomyolysis are rare.[29,30] Enzyme-linked immunosorbent assays (ELISA) can detect European viper venom antigens (*Vipera aspis*, *Vipera berus*, *Vipera ammodytes*) for at least 24 hours in serum samples from moderately envenomated patients.[31] This test does not cross-react with venom from *Vipera russelii, Bothrops jararaca* Wied, or *Crotalus durissus* subsp. *terrificus* Laurenti.

TREATMENT

Therapy for European viper envenomation is primarily supportive. Antivenom administration (e.g., ovine ViperaTAb® [Protherics PLC, Macclesfield, Cheshire, UK] administered intravenously) is often restricted to cases of moderate to severe envenomation with rapidly progressive edema and persistent hypotension depending on availability.[32] A few patients with the clinical appearance of minor or moderate viper envenomation during initial evaluation can develop severe envenomation. In general, early use of antivenom reduces both morbidity and mortality. Web databases (http://www.toxinfo.org/antivenoms/Index_Indication.html) are available for locating antivenom in Europe for vipers and other venomous snakes. Monitoring of laboratory data in these cases involves complete blood count, coagulation parameters (fibrinogen, fibrin split products, prothrombin time, activated partial thromboplastin time), serum electrolytes, and renal function. Supportive care includes tetanus immunization as needed, elevation, splinting in a position of rehabilitation, daily cleansing and wound dressings, and early, gradual mobilization with physical therapy.

MIDDLE AND NEAR EAST/AFRICA

EXPOSURE

Table 176.4 lists important venomous vipers in this area of the world. *Vipera palaestinae* Werner (Palestine viper) accounts for most of the serious venomous snakebites in Israel,[33] whereas the desert horned vipers (*Cerastes* species) are the most abundant venomous snakes of the great deserts of North Africa and the Middle East. The genus *Cerastes* comprises three species of desert vipers including the Saharan sand viper (*C. vipera* L.), Gasperetti's horned viper (*C. gasperettii* Leviton & Anderson), and the Saharan horned viper (*C. cerastes* L.). In contrast to the Saharan horned viper, the Saharan sand viper lacks the distinctive supraocular horns. In Israel and southwestern Asia, envenomations by venomous snakes from the subfamily Viperinae produce both hemorrhagic and neurotoxic effects depending on the particular species.[34] Most of these snakes exhibit warning sounds (e.g., puff adders hiss, saw-scaled vipers produce a rasping sound by rubbing their scales together). Nocturnally active species include the carpet vipers (*Echis* spp.) and night adders (*Causus* spp.). Important causes of morbidity and mortality from African vipers include carpet and saw-scaled vipers (*Echis* spp.), night adders (*Causus* spp.), and puff adders (*Bitis* spp.).[35] Vipers possess erectile fangs that may reach 3 cm (~1 in.) in length in large vipers (e.g., Gaboon viper, *Bitis gabonica* Duméril Bibron & Duméril). In contrast to crotaline snakes (i.e., pit vipers), non-crotaline vipers (e.g., *Bitis* spp.) do not possess the ability to strike prey with thermal sensors.[36]

VENOM

Viper venoms produce local tissue damage and coagulation abnormalities as a result of endothelial damage, platelet aggregation and dysfunction, increased capillary permeability, and inhibition of thrombin and thromboplastin along with some fibrinolysis and hypofibrinogenemia. The venom of snakes from the genus *Cerastes* contains a variety of toxins that affect coagulation including serine proteases (cerastotin),[37] hemorrhagic protease (cerastase F-4), fibrinogenases (afaâcytin),[38] protein C activator, and other thrombin-like enzymes (cerastocytin).[39] *Echis* venoms from the saw-scaled and carpet vipers contain an enzyme, ecarin, which directly activates prothrombin and initiates a consumption coagulopathy by forming fibrin after the splitting of fibrinopeptide A and B from fibrinogen. These venoms produce severe local signs of envenomation (edema, vesiculation, ecchymosis, necrosis) along with coagulopathy. *Bitis* (puff adder) venoms produce local hemorrhage and necrosis, but these venoms do not cause clinical significant coagulation disorders with the exception of venom from the Gaboon viper (*Bitis gabonica*)[40] and the puff adder (*Bitis arietans*).[41] The venom of tree vipers (*Atheris* species) can produce a consumptive coagulopathy because of platelet-aggregating and fibrinogen-converting activity.[42]

CLINICAL RESPONSE

Local Tissue Damage

Symptoms and signs of envenomation usually begin within a few minutes to approximately 1 hour after the bite.[43] With the exception of the Gaboon viper (*Bitis gabonica*), puff adder (*Bitis* spp.) envenomations produce local edema and hemorrhage with vesiculation around the bite site, but systemic and hematological complications are usually mild. Occasionally, severe envenomations may cause hypotension, respiratory failure, thrombocytopenia, severe coagulopathy, and necrosis. Envenomation by the puff adder (*Bitis arietans*) may cause extensive local tissue destruction.[44] Severe envenomation manifests by progressive swelling and local necrosis. Prolonged coagulation times may

TABLE 176.4. Important African, Middle Eastern, and Near Eastern Venomous Vipers[a]

Species	Common Name	Description	Distribution	Habitat
Echis Species	Carpet and saw-scaled vipers	Small (50–60 cm), slender snakes with variable coloration ranging from red, brown to olive gray with light dorsal spots	Near East: *E. carinatus*, (*E. multisquamatus, E. sochureki*); *E. pyramidum* Middle East: *E. coloratus* East/North Africa: *E. megalocephalus, E. jogeri, E. pyramidum* West Africa: *E. hughesi, E. leucogaster, E. ocellatus*	Dry areas (savannah, deserts), agricultural areas (West Africa)
Bitis Species	Puff adders	Largest African vipers up to 2 m length with triangular head and variable coloration from light brown and white/yellow strips to highly diverse coloration (green, purple, brown)	*B. arietans:* Africa to Arabian Peninsula *B. gabonica:* Forests of West/Central/East Africa *B. nasicornis:* West/Central Africa *B. caudalis:* Southern Africa	*B. arietans*—dry habitats and river beds, *B. gabonica* and *B. nasicornis*—forest floors
Cerastes and *Pseudocerastes* Species	Horned vipers, sand vipers	Thick-bodied vipers up to 70 cm in length with yellow or gray background, marked serrated scales, and irregular dorsal coloration; most have distinctive horn above eyes	North Africa, Sahara, Middle East to Pakistan	Sandy deserts, dry rock areas with sparse brush
Atheris, Montatheris, Proatheris Species	Bush or tree vipers	Small to medium vipers up to 80 cm with overlapping scales and variable coloration ranging from gray brown to yellow green	West/East Africa to Angola	*Montatheris, Proatheris* species—terrestrial; *Atheris* species—arboreal
Causus Species	Night adders	Medium sized vipers up to 1 m with gray brown or olive background and dark spots resembling a rhomboid	Southwest Africa below the Sahara	Forests and lowlands near water

[a]Source: Adapted from Ref 2.

occur after envenomation by the Gaboon viper; death may occur in envenomated patients unable to obtain medical care.[45] Envenomations by *Causus* species (night adders) usually cause mild local edema and vesiculation with occasional necrosis, but systemic symptoms are usually mild.[46] Envenomations by *Cerastes* species (horned or sand vipers) and European vipers are similar. Local edema, vesiculations, and hemorrhage occur, but impairment of coagulation and systemic symptoms are usually minimal to mild.[47] However, case reports suggest that severe *Cerastes* envenomations may produce clinically significant coagulopathy, increased fibrinolysis, thrombocytopenia, microangiopathic hemolytic anemia, and acute renal failure.[48,49] Envenomations by *Pseudocerastes* species (horned vipers) usually result in mild local effects without systemic complications.

Local Tissue Damage and Coagulopathy

Because carpet vipers (*Echis* species) may bite during the night, envenomation may not be recognized until the following day when slight local swelling and bleeding from the mouth or wounds occur. Complications include thrombocytopenia, severe consumption coagulopathy, massive hematomas, intracerebral hemorrhage, gastrointestinal bleeding, hematuria, renal failure, and death.[50,51] Envenomation by tree and bush vipers (*Atheris* species) can produce severe coagulopathy, systemic symptoms (drowsiness, respiratory impairment, vomiting, diarrhea), and hypotension. However, internal bleeding is not well documented following *Atheris* envenomations.

TREATMENT

Local treatment for viper envenomations is similar to the treatment for crotaline envenomations. Initially, the envenomated extremity should be immobilized at or below the level of the heart in a position of rehabilitation. The wound should be cleansed and dressed with sterile dressings, and tetanus immunization updated as necessary. Systemic antibiotics are usually necessary only for secondary infections. Victims should be evaluated for hypovolemia, respiratory depression, and coagulopathy. Antivenom is indicated in life-threatening conditions (e.g., coagulopathies, respiratory depression, refractory hypotension) or marked progressive local signs including envenomation by the common viper (*Vipera berus*)[52] or *Vipera palaestinae*.[53] The recommended dose of the equine *Vipera palaestinae* antivenom (Felsenstein Medical Research Institute, Rabin Medical Center, Petah Tikva, Israel) starts with a very slow test dose over 10 minutes followed by a fixed dose of 50 mL infused over 2 hours intravenously Additional intravenous doses (30–50 mL) may be administered as dictated by the progression of symptoms. Envenomations by carpet and saw-scaled vipers (*Echis* species),[54] Gaboon viper (*Bitis gabonica*), and tree and bush vipers (*Atheris* species) usually require antivenom (South African polyvalent antivenom). Specific monovalent antivenom is preferable to polyvalent antivenom because of the interspecies variation of venom composition, particularly for *Echis* species. However, there are limited supplies of antivenom for African vipers. For African viper species, only the South African polyvalent antivenom is available. This antivenom has limited efficacy for North African viper species. Antivenom for other vipers (*Bitis, Causus, Cerastes, Pseudocerastes*) is usually necessary only for severe envenomations. Supportive care in viper envenomation is similar to crotaline envenomation.

ASIA

EXPOSURE

Russell's viper (*Daboia russelii,* a.k.a. *Vipera russelii*) is the most dangerous viper in Southeast Asia[55] with the following two main subspecies: a western species (India, Pakistan, Sri Lanka, Bangladesh) named *Daboia russelii* subsp. *russelii* Shaw, and an eastern species (China, Taiwan, Thailand, Burma, Indonesia) named *Daboia russelii* subsp. *siamensis* Smith. *Echis carinatus* Schneider, *Echis carinatus* subsp. *multisquamatus* Cherlin, *Echis carinatus* subsp. *sochureki* Stemmler, and related species (*E. coloratus* Günther, *E. ocellatus* Stemmler, *E. leucogaster* Roman, *E. pyramidum* Geoffroy Saint-Hilaire) are distributed over Africa and Asia as listed in Table 176.5.[56]

VENOM

The venom from Russell's viper (*Daboia russelii*) contains protease inhibitors, hemorrhagins (i.e., factors that increase vascular permeability or damage vascular endothelium), phospholipase A_2, and procoagulant factors that activate factor X to factor Xa and initiate the coagulation cascade. There is substantial geographical variation in venom composition and clinical manifestations of envenomation by Russell's viper with neurotoxicity less common in the western (Indian) species of Russell's viper.[57] Saw-scaled vipers (*Echis carinatus*) range between the Middle East and India, and their venom

TABLE 176.5. Venomous Asian Vipers[a]

Species	Common Name	Description	Distribution	Habitat
Daboia russelii (subsp. *russelii* and *siamensis*)	Russell's viper	Large snake up to 2 m (~7 ft) with background coloration from gray to light yellow and brown and dark spots surrounded by white	6 species in Indian subcontinent, Burma, Thailand, South China, Taiwan	Open terrain with dense grass or low bushes up to 3,000 m
Echis carinatus Complex	Saw-scaled viper	Small, thin snakes up to about 80 cm (~300 in.) in length with red, brown, grey or olive colorations and small light spots on the dorsum. The flanks contain V-shaped markings	*E. multisquamatus:* Uzbekistan, Turkmenistan, Iran, Afghanistan and Pakistan *E. sochureki:* northern India, Pakistan, Afghanistan, Arabian Peninsula	

[a]Source: Adapted from Ref 2.

contains an enzyme, ecarin, which directly activates prothrombin and initiates a consumption coagulopathy. The presence of hemorrhagins in addition to procoagulant factors in *Echis* species frequently produces clinically significant bleeding. Local tissue damage and coagulopathy (i.e., defibrination) are the most common complications of envenomations by Asian vipers with low fibrinogen concentrations and thrombocytopenia being the most common laboratory abnormalities.[58] The massive consumption of clotting factors following serious envenomations typically results in clinical anticoagulation rather than thrombosis and embolic disease.

CLINICAL RESPONSE

Clinical features of envenomation usually develop within a few hours, and delay of the onset of signs of envenomation beyond 6 hours postenvenomation is rare.[59] Acute tubular necrosis, renal failure, coagulopathy (prolonged prothrombin time with depletion of factors V and X, thrombocytopenia, hypofibrinogenemia, increased D-dimer), disseminated intravascular coagulation, hypotension, flaccid paralysis, and hemolysis are the major complications of severe envenomation by Russell's viper (*Daboia russelii* subsp. *russelii*).[60] Neurological effects are variable with the most common neurological signs of envenomation including ptosis, bulbar palsy, and weakness in neck flexors.[61] Rhabdomyolysis is rare. Sheehan's syndrome may result from pituitary infarction and panhypopituitarism following envenomation by Russell's viper. Some regional variation occurs following envenomation by Russell's viper with the Formosan Russell's viper (*Daboia russelii* subsp. *siamensis*) producing more systemic thrombosis and little neurological symptoms compared with the eastern variety (*D. russelii* subsp. *russelii*).[62]

TREATMENT

Treatment of Asian viper envenomation is similar to crotaline envenomation, particularly supportive care (cleansing wound, sterile dressing, immobilization, early physical therapy) for local tissue damage. Antibiotics are usually reserved for secondary infections. Studies of snake flora indicate that the mouth of Asian vipers contains enteric organisms (i.e., Gram-negative rods, *Enterobacter* and *Pseudomonas* species) as well as *Staphylococci* and *Clostridia* species.[63] Most envenomations require the use of antivenom. The specificity and efficacy of antivenom varies with individual localities and species. The administration of polyvalent antivenom produced for the Russell's viper in India causes mixed results following envenomations by Russell's vipers in Sri Lanka.[64] A new, monovalent ovine Fab antivenom (Polonga TAb Therapeutic Antibodies, Inc., London, UK) has been developed against the venom of Russell's viper from Sri Lanka. An open, randomized clinical trial comparing the two venoms suggests that the monovalent Fab antivenom is more effective against species of Russell's vipers from Sri Lanka.[65] However, this antivenom is available primarily for research purposes, and a polyvalent antivenom is imported from India for the treatment of envenomation by the Russell's viper in Sri Lanka. A polyvalent antivenom for the eastern species of Russell's viper (*Daboia russelii siamensis*, Formosan Russell's viper) is available in Taiwan, as well as monospecific antivenom raised against the Formosan Russell's viper.[66] The polyvalent antivenom effectively reverses the coagulation disorder (disseminated intravascular coagulation with secondary fibrinolysis and thrombocytopenia), but administration of the antivenom may not reverse the acute renal failure associated with severe envenomations.[67] Coagulation profiles and complete blood count should be followed serially until the parameters substantially improve. The presence of dark urine indicates the need to evaluate for the presence of myoglobinuria, hematuria, and renal dysfunction. Generous intravenous fluid replacement should be given to maintain adequate urine flow if myoglobinuria occurs. The efficacy of urine alkalinization for the prevention of myoglobin-induced renal disease remains unclear.

Pit Vipers (Crotalinae)

Table 176.6 lists some members of the *Crotalinae* (pit vipers) subfamily of the Viperidae family that includes the Asian (e.g., Okinawan and Chinese habu of the genus *Trimeresurus*) and the North American pit vipers (rattlesnake, copperhead, cottonmouth), as well as the Central and South American bushmaster (*Lachesis* spp.) and fer-de-lance (*Bothrops* spp.).[68,69] There are no native vipers in the New World. The hump-nose viper (*Hypnale hypnale* Merrem) is a pit viper native to Southeast Asia, and envenomation by this snake usually produces only local effects (pain, swelling, hemorrhagic vesicles, regional lymphadenopathy).[70] However, occasionally coagulopathy, spontaneous hemorrhage, acute renal failure, and respiratory failure can develop following envenomation by the hump-nose viper.[71]

NORTH AMERICA

Of about 120 species of snakes in the United States, approximately 20 are venomous.[72] At least one species

TABLE 176.6. Scientific and Common Names of Venomous Pit Vipers (Crotalinae) Subfamily[a]

Group	Scientific Name	Common Name
American		
	Agkistrodon bilineatus bilineatus Günther	Common cantil
	Agkistrodon bilineatus taylori Burger and Robertson	Taylor's cantil
	Agkistrodon contortrix contortrix L.	Southern copperhead
	Agkistrodon contortrix laticinctus Gloyd and Conant	Broad-banded copperhead
	Agkistrodon contortrix mokasen Palisot de Beauvois	Northern copperhead
	Agkistrodon contortrix phaeogaster Gloyd	Osage copperhead
	Agkistrodon contortrix pictigaster Gloyd and Conant	Trans-Pecos copperhead
	Agkistrodon piscivorus conanti Gloyd	Florida cottonmouth
	Agkistrodon piscivorus piscivorus Lacépède	Eastern cottonmouth
	Agkistrodon piscivorus leucostoma Troost	Western Cottonmouth
American Lanceheads		
	Atropoides nummifer Rüppell	Jumping viper
	Bothriechis lateralis Peters	Yellow-lined pit viper
	Bothriechis nigroviridis Peters	Black spotted pit viper
	Bothriechis schlegelii Berthold	Eyelash viper
	Bothriopsis bilineatus bilineatus Wied-Neuwied	Amazonian tree-viper
	Bothriopsis peruviana Boulenger	Peruvian pit viper
	Bothrops alternatus Duméril & Bibron	Urutu or Yarara
	Bothrops andianus Amaral	Andean pit viper, Terciopelo (Fer-de-lance)
	Bothrops asper Garman	Barba amarilla (Fer-de-lance)
	Bothrops atrox L.	Caissaca (Fer-de-lance)
	Bothrops barnetti Parker	Barnett's pit viper
	Bothriechis bicolor Bocourt	Bocourt's pit viper
	Bothrops brazili Hoge	Brazil's pit viper
	Bothrops caribbaeus Garman	St. Lucia pit viper
	Bothrops cotiara Gomes	Cotiara
	Bothrops fonsecai Hoge and Belluomini	Fonseca's *pit* viper
	Bothrops insularis Amaral	Island jararaca
	Bothrops jararaca Wied-Neuwied	Jararaca
	Bothrops jararacussu Lacerda	Jararacussu
	Bothrops lanceolatus Bonnaterre	Fer-de-lance
	Bothrops lojanus Parker	Lojan lancehead
	Bothrops neuwiedii Wagler	Jararaca pintada or Wied's lancehead
	Bothrops pirajai Amaral	Piraja's pit viper, Jararacucu
	Cerrophidion barbouri Dunn	Barbour's montane pit viper
	Cerrophidion godmani Günther	Godman's pit viper
	Ophryacus melanurus Müller	Black-tailed pit viper
	Porthidium dunni Hartweg and Oliver	Dunn's pit viper
	Porthidium lansbergii Schlegel	Lansberg's hog nose viper
	Porthidium nasutum Bocourt	Hog-nosed pit viper
	Porthidium ophryomegas Bocourt	Western hog-nosed pit viper
	Porthidium yucatanicum Smith	Yucatan pit viper
Rattlesnake		
	Crotalus adamanteus Palisot de Beauvois	Eastern Diamondback rattlesnake
	Crotalus atrox Baird and Girard	Western Diamondback rattlesnake
	Crotalus basiliscus Cope	Mexican west-coast rattlesnake, Oaxacan rattlesnake
	Crotalus catalinensis Cliff	Santa Catalina Island or rattleless
	Crotalus cerastes cerastes Hallowell	Mojave Desert sidewinder
	Crotalus cerastes cercobombus Savage and Cliff	Sonoran Desert sidewinder
	Crotalus cerastes laterorepens Klauber	Colorado Desert sidewinder
	Crotalus durissus durissus L.	Central American rattlesnake
	Crotalus durissus culminates Klauber	Northwestern neotropical rattlesnake

TABLE 176.6. *Continued*

Group	Scientific Name	Common Name
	Crotalus durissus terrificus Laurenti	South American rattlesnake
	Crotalus durissus totonacus Gloyd and Kauffeld	Totonacan rattlesnake
	Crotalus enyo enyo Cope	Baja California rattlesnake
	Crotalus enyo cerralvensis Cliff	Cerralvo Island rattlesnake
	Crotalus enyo furvus Lowe and Norris	Rosario rattlesnake
	Crotalus horridus atricaudatus Latreille in Sonnini and Latreille	Canebrake rattlesnake
	Crotalus horridus horridus L.	Timber rattlesnake
	Crotalus intermedius intermedius Troschel	Totalcan small-headed rattlesnake
	Crotalus lepidus klauberi Gloyd	Banded rock rattlesnake
	Crotalus lepidus lepidus Kennicott	Mottled rock rattlesnake
	Crotalus lepidus morulus Klauer	Tamaulipan rock rattlesnake
	Crotalus mitchellii mitchellii Cope	San Lucan speckled rattlesnake
	Crotalus mitchellii pyrrhus Cope	Southwestern speckled rattlesnake
	Crotalus mitchellii stephensi Cope	Panamint rattlesnake
	Crotalus molossus molossus Baird and Girard	Northern black-tailed rattlesnake
	Crotalus molossus nigrescens Gloyd	Mexican black-tailed rattlesnake
	Crotalus polystictus Cope	Mexican lance-headed rattlesnake
	Crotalus pricei pricei Van Denburgh	Twin-spotted rattlesnake
	Crotalus ruber lucansensis Van Denburgh	San Lucan diamond rattlesnake
	Crotalus ruber ruber Cope	Red diamond rattlesnake
	Crotalus scutulatus scutulatus Kennicott	Mojave rattlesnake
	Crotalus scutulatus salvini Günther	Huamantlan rattlesnake
	Crotalus stejnegeri Dunn	Long-tailed rattlesnake
	Crotalus tigris Kennicott in Baird	Tiger rattlesnake
	Crotalus tortugensis Van Denburgh and Slevin	Tortuga Island diamond rattlesnake
	Crotalus unicolor Lidth de Jeude	Aruba Island rattlesnake
	Crotalus vegrandis Klauber	Uracoan rattlesnake
	Crotalus viridis abyssus Klauber	Grand Canyon rattlesnake
	Crotalus viridis caliginis Klauber	Coronado Island rattlesnake
	Crotalus viridis cerberus Coues in Wheeler	Arizona black rattlesnake
	Crotalus viridis concolor Woodbury	Midget faded rattlesnake
	Crotalus viridis helleri Meek	Southern Pacific rattlesnake
	Crotalus viridis lutosus Klauber	Great Basin rattlesnake
	Crotalus viridis nuntius Klauber	Hopi rattlesnake
	Crotalus viridis oreganus Holbrook	Northern Pacific rattlesnake
	Crotalus viridis viridis Rafinesque	Prairie rattlesnake
	Crotalus willardi silus Klauber	Chihuahuan ridge-nosed rattlesnake
	Crotalus willardi willardi Meek	Arizona ridge-nosed rattlesnake
	Sistrurus catenatus catenatus Rafinesque	Eastern massasauga
	Sistrurus catenatus edwardsi Baird and Girard	Desert massasauga
	Sistrurus catenatus tergeminus Say in James	Western massasauga
	Sistrurus miliarius barbouri Gloyd	Southeastern pygmy rattlesnake
	Sistrurus miliarius miliarius L.	Carolina pygmy rattlesnake
	Sistrurus miliarius streckeri Gloyd	Western pygmy rattlesnake
	Sistrurus ravus Cope	Mexican pygmy rattlesnake
Bushmaster	*Lachesis muta* L.	Bushmaster
Asian		
	Calloselasma rhodostoma Boie	Malayan pit viper
	Deinagkistrodon acutus Günther	Hundred-pace snake
	Gloydius halys Pallas	Mamushi (Japan and Korea)
	Gloydius himalayanus Günther	Himalayan pit viper
	Gloydius intermedius Strauch	Central Asian pit viper
	Hypnale hypnale Merrem	Hump-nosed viper
	Ovophis okinavensis Boulenger	Himehabu

TABLE 176.6. *Continued*

Group	Scientific Name	Common Name
	Protobothrops elegans Gray	Japanese lace-headed viper, Sakishima-habu
	Protobothrops flavoviridis Hallowell	Habu
	Trimeresurus albolabris Gray	White-lipped tree viper
	Trimeresurus gramineus Shaw	Green tree viper
	Trimeresurus mucrosquamatus Cantor	Chinese or Taiwan habu
	Trimeresurus popeorum Smith	Pope's tree viper
	Trimeresurus purpureomaculatus Gray	Mangrove pit viper
	Trimeresurus stejnegeri Schmidt	Chinese green tree viper
	Tropidolaemus wagleri Wagler	Wagler's pit viper

[a]Source: Adapted from Ref 1.

of venomous snake resides in every state of the United States except Hawaii, Alaska, and Maine. The vast majority (95%) of poisonous snakebites involve members of the subfamily Crotalinae (pit viper). Eastern and Western Diamondback rattlesnakes are dangerous species because of their large size and potential for large envenomations.[73] The only venomous species of the Elapidae (cobra) family indigenous to the United States are the Northern coral snakes (*Micrurus fulvius* L.), Texas coral snakes (*Micrurus tener* Baird & Girard), and the Western or Sonoran coral snakes (*Micruroides euryxanthus* Kennicott). These elapids account for less than 3% of US snakebites.

American pit vipers belong to the subfamily Crotalinae of the Viperidae family, and this subfamily includes 25 species divided into the following three genera: *Crotalus* (true rattlesnakes), *Sistrurus* (pygmy rattlesnake, massasauga), and *Agkistrodon* (copperhead, cottonmouth). The rattle, which functions as a warning device to predators, is the main characteristic common to species in the genera *Crotalus* and *Sistrurus*; hence, these snakes are called rattlesnakes. The rattle consists of a series of interlocking horny rings that vibrate to produce a buzzing sound following stimulation of the rattlesnake. *Agkistrodon* species do not possess rattles. The following four characteristics separate poisonous American pit vipers (subfamily Crotalinae) from most of the other nonpoisonous American snake species (See Figure 176.3):

1. Triangular or arrow-shaped head due to the temporal location of the venom glands
2. Facial pits between the nostril and eye that contain heat-sensing organs
3. Vertical-oriented, elliptical pupils ("cat's" eyes)
4. Single row of subcaudal scales rather than a double row

Coloration and diamondback patterns do not reliably identify rattlesnakes because nonpoisonous snakes mimic these markings for defensive purposes. Furthermore, the characteristics of nonvenomous species in Figure 176.3 do *not* separate poisonous Elapidae species from nonpoisonous snakes. Coral snakes have round pupils rather than elliptical pupils and smooth tapered bodies with narrow heads. All pit vipers have movable fangs, whereas Elapidae species have fixed fangs.

Reactions to snakebite are not reportable in the United States; therefore, there are limited data on the actual incidence of snakebites in the United States. During the 1950s and 1960s, there were approximately 45,000 snakebites annually in the United States with about 7,000–8,000 venomous bites and an estimated 10–15 fatalities.[74,75] Currently, rattlesnake-induced fatalities, which usually result from prolonged hypotension and multiple organ system failure, are rare.[76] Although pediatric patients sustain more serious envenomations than adults because the relative higher amount of venom per kilogram, the case-fatality rates are similar between children and adults.[77] Improved supportive care and the aggressive use of antivenom significantly reduced mortality and morbidity (e.g., limb and skin necrosis) since the 1960s when the use of antivenom was less common.[78] In the United States, fatalities from allergic reactions to *Hymenoptera* (bees, wasps, ants) stings are at least 10 times greater than the fatalities resulting from snakebites.[79,80]

The majority of rattlesnake bites in California occur in the warm, highly populated regions of southern California, whereas the highest incidence of venomous snakebite occurs in the southern areas of the United States (i.e., North Carolina, Texas, Arkansas, Mississippi, Georgia, West Virginia, Louisiana, Oklahoma).[81] Not all rattlesnake bites result in envenomation because rattlesnakes fail to inject venom in approximately 20% of bites.[82]

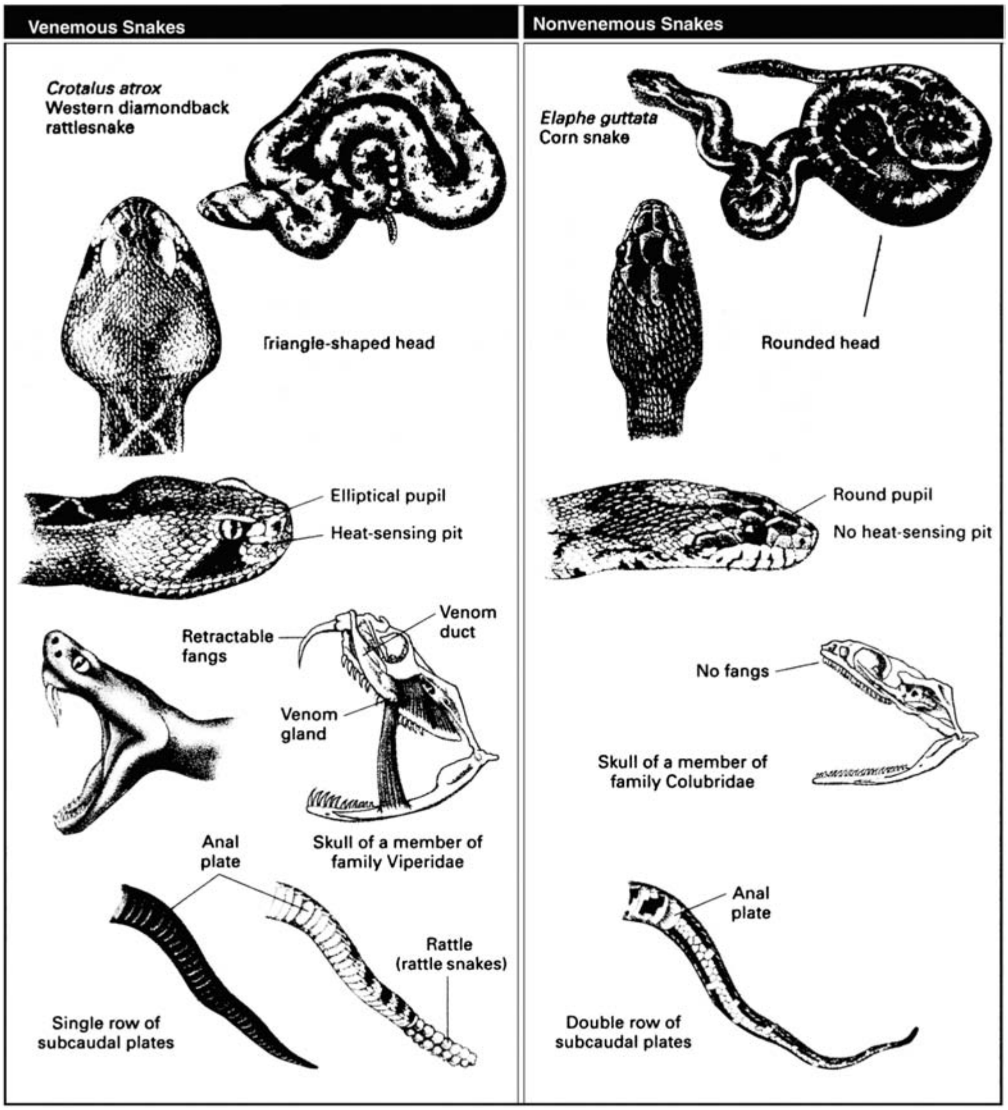

FIGURE 176.3. Characteristics of venomous and nonvenomous American snakes. From Gold BS, et al. Bites of venomous snakes. N Engl J Med 2002;347:350.

Because of the inactivity of snakes during the winter, most snakebites occur from April through October depending on the temperatures in specific localities. Nearly three-quarters of the rattlesnake bite victims are men. The typical victim of a pit viper envenomation is a young man bitten on the hand while handling the snake. Illegitimate bites (i.e., failure to move away from the snake, snake handling) represent a substantial portion of snakebites, particularly in association with the use of alcohol. In a study of 86 consecutive rattlesnake bites in patients presenting to a central Arizona medical center, 56% of the victims had illegitimate (i.e., provoked) bites.[83] In a study of 36 patients hospitalized in New Mexico for rattlesnake envenomation, about 28% of the patients were envenomated while consuming alcohol and handling the snake.[84] Most accidental (i.e., legitimate) snakebites occur in the afternoon or early evening of the summer months (July, August) during recreational activities. Although most bites occur during daytime hours, the intense heat of southwestern deserts and the nocturnal habits of some rattlesnakes result in nighttime bites.[85] Bites to the lower extremity are usually legitimate.

True Rattlesnake (*Crotalus spp.*)

Although some species differences occur in the coloration and body of rattlesnakes, all pit vipers share the four main characteristics demonstrated in Figure 176.3. Almost all rattlesnakes (genus *Crotalus*) have a set of interlocking, terminal horny segments known as rattles.

The exception is *Crotalus catalinensis*, which is found only on Santa Catalina Island in the Sea of Cortez off Baja, California. A characteristic buzzing similar to the sound of escaping steam usually, but not always, occurs before a rattlesnake strike. Each molting (one to four times per year) adds a rattle, but trauma or congenital abnormalities may reduce the expected number of rattles. This genus represents some of the most biologically advanced of all snakes.

EXPOSURE

Geographic Distribution

Of the 32 species of rattlesnakes comprising 65–70 subspecies, 21 species inhabit the United States. Rattlesnakes appear in every state on the US mainland except Maine and Delaware including areas above the timberline (i.e., 10,000 ft/~3000 m) during the summer. Most rattlesnake bites result from the Western Diamondback (*C. atrox*), the Southern Pacific (*Crotalus viridis helleri*), Northern Pacific (*Crotalus viridis oreganus*), the prairie (*C. viridis viridis*), the Eastern Diamondback (*C. adamanteus*), the timber (*C. horridus horridus*), and the pygmy (*Sistrurus miliarius*) rattlesnakes. In the eastern United States, the latter three species inflict most of the rattlesnake bites.[86] The Mojave rattlesnake (*Crotalus scutulatus scutulatus*) is a clinically important species because its venom typically produces less tissue damage and substantial neurotoxicity compared with most other rattlesnake bites. Proper treatment of neurological sequelae requires recognition of envenomations by this species. The range of this species includes southeastern California, southern Nevada, Arizona, New Mexico, and southwestern Texas (Figure 176.4). Although components of the venom from some specimens of *Crotalus lepidus lepidus* (Mottled rock rattlesnake) resemble the neurotoxin (Mojave toxin) present in the venom of the Mojave rattlesnake, rare case reports of envenomation by *C. lepidus lepidus* do not document neurological complications.[87] The distribution of *C. lepidus lepidus* includes southwest Texas, southeastern New Mexico, and the Mexican Plateau to San Louis Potosi. Rattlesnake bites may occur in areas distant (e.g., Europe) to the natural habitat because of the importation of species from the Crotalinae subfamily.[88]

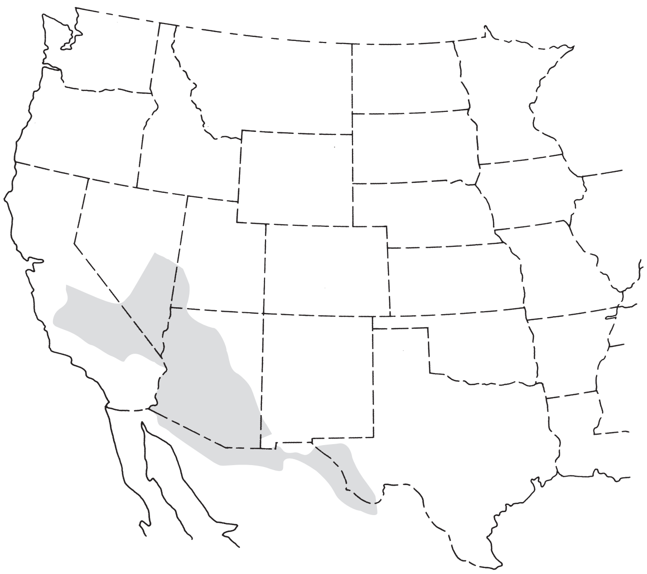

FIGURE 176.4. Geographic distribution of Mojave rattlesnake. Adapted from Ellenhorn MJ, Barceloux DG. Medical Toxicology: Diagnosis of Human Poisoning. 1st Edition, New York: Elsevier, 1988:1117.

Species Differences

Variations between rattlesnake species occur in size, coloring, and distribution as well as in venom potency. Figure 176.5 displays a picture the Red Diamondback rattlesnake (*Crotalus ruber ruber Cope*). The Eastern Diamondback rattlesnake (*Crotalus adamanteus*) is the largest rattlesnake with a maximum length up to 7 ft (~2 m). The highly specialized sidewinder species uses a peculiar type of lateral motion (i.e., side winding). This motion is well designed for rapid movement across smooth, hot desert terrain because this movement requires less contact with the hot ground than crawling. Venom from sidewinders is substantially less potent than venom from the Eastern and Western Diamondback rattlesnakes.

Identification of the Mojave rattlesnake (Figure 176.6) is important because this venom from this species possesses more neurotoxicity and less tissue toxicity than the venom from the similar appearing Western

Diamondback species (Figure 176.7). The Mojave rattlesnake favors flat grassland or scrub-covered desert. These snakes rarely inhabit rocky, hilly terrain. Rhomboid markings are found on a brownish yellow to green background, with a tail characterized by white rings up to twice the size of the black rings. The basal rattle is yellow or white. The Western Diamondback has white and black tail rings of equal width and a black basal rattle. This snake is the largest rattlesnake in the western United States.

Table 176.7 lists the distinguishing characteristics of the Mojave and Western Diamondback rattlesnakes. Coloration alone does not distinguish these two rattlesnake species because at least some hybrids of the Western Diamondback and the Mojave rattlesnakes probably exist in the overlapping ranges of these species.[89]

FIGURE 176.6. Mojave Rattlesnake (*Crotalus scutulatus scutulatus* Kennicott). In contrast to the Western Diamondback Rattlesnake, specimens of the Mojave Rattlesnake often have a greenish tinge, a diagonal facial stripe behind their eye that usually does not touch their mouth, two to three enlarged scales between their eyes on top of their head, and white bands on the tail that sometimes are wider than the black bands. Photograph Courtesy of Arizona Poison and Drug Information Center. See color insert.

Behavior and Senses

Pit vipers are carnivores that use their venom primarily as an offensive weapon to obtain food. The pit vipers' keen sense of smell and their ability to sense the temperature of their prey and surrounding areas allows them to track their prey effectively. The potency of the venom allows the prey several minutes to withdraw from the scene before its death. The snake cannot accurately follow prey more than 20 ft (~6 m); consequently, the snake usually stays within that distance following envenomation. Rattlesnakes usually, but not always, strike from the coiled position. The strike averages 8 ft (~2.5 m)/s and is in a slightly downward position. A rattlesnake rarely strikes accurately over a distance exceeding one-half their body length (i.e., about 3–4 ft/~1 m maximum). Hence, a safe distance is 10–15 ft (~3–5 m) from the snake. Reflex actions produce envenomation up to 1 hour after the death of the snake despite decapitation.

The facial pit contains a unique thermal sensory organ that detects temperature changes as small as 0.003 °C.[90] These organs efficiently collect infrared photons to map the environment, similar to visual cues. Consequently, pit vipers simultaneously receive cues

TABLE 176.7. Distinguishing Characteristics of Mojave (*C. scutulatus scutulatus*) and Western Diamondback (*C. atrox*) Rattlesnakes

Characteristic	Mojave	Western Diamondback
Body size	Heavy-bodied	Heavy-bodied
Dorsal Markings	Single row of large dark diamond-shapes on lighter background with light margins	Single row of large dark diamond-shapes on lighter background with light margins
Facial strips	Bilateral with postocular light strip extending backwards above the angle of the mouth	Bilateral with postocular light strip intersecting mouth
Tail rings	Alternating circumferential black and white rings with white rings wider than black rings	Circumferential black rings encircling the tail about equal width as white rings
Intersupraocular scales	Less than 4 scales (usually 2–3)	4–7 scales (usually 4–5)

from both the visible and infrared parts of the electromagnetic spectrum. However, the maximum range of thermal detection using this organ is short (~1 ft). Sensitivity to changes in radiant temperature allows pit vipers to direct strikes at warm-blooded prey within a close range or to identify appropriate areas for thermoregulation. The presence of humans probably overwhelms the sensory mechanism because of our relatively large size. Consequently, the strike is defensive rather than offensive, and the rattlesnake does not usually inject the whole contents of the venom gland. The vision of rattlesnakes is poor because rattlesnakes lack a fovea and color receptors. Although pit vipers are deaf, they are quite sensitive to ground vibrations at distances up to 100 ft. Most rattlesnakes crawl at maximum speeds of about 3 miles/h, which is equivalent to a moderately paced walk by a man.

Venom Apparatus

Fangs and Bite Marks

Pit vipers have retractable, canalized fangs that retract into the roof of the mouth and rotate forward during a strike. In a study of 48 Western Diamondback snakes (*C. atrox*), the mean distance between fangs was about 11 mm (~0.4 in.) with a range between 4–24 mm (~0.15–1 in.).[91] At least three pairs of replacement fangs lie behind each functional fang. These replacement fangs are in various stages of development, and they move forward after the loss of the functional fang. Adult snakes shed their fangs every 6–10 weeks. Most envenomations involve the subcutaneous deposition of venom. Although subfascial injections are uncommon, intramuscular penetration is theoretically possible, especially in children. The pattern of fang marks depends on the strike. The most common pattern is two marks, 2 mm to 4 cm (~0.1–1.5 in.) apart, depending on the size of the snake. Because of the presence of reserve fangs, bite marks may contain one, two, three, or more fang marks in the case of multiple bites. Bite patterns alone do not adequately discriminate between venomous and nonvenomous snakes because of the variability in the presence of functional and replacement fangs. In general, nonvenomous snakes produce horseshoe-shaped bite marks characterized by four rows of small abrasions (upper jaw) separated from two rows of small abrasions (lower jaw). A definitive diagnosis of envenomation requires identification of the snake and/or classic clinical signs of envenomation.

Venom Gland and Envenomation

Venom glands are modified parotid glands that are surrounded by a muscle (compressor glandulae) in rattlesnakes. The amount of venom excreted from the venom gland varies depending on a number of circumstances, but the amount of venom extruded from the gland is not necessarily under neuronal control of the rattlesnake. In a study of the Western Diamondback rattlesnake (*C. atrox*), the amount of venom injected by the snake correlated to the pressure created by the compressor glandulae, the peripheral resistance of the target tissue, and compression of the fang sheath during the strike.[92] Contraction of the compressor glandulae accounted for approximately 30% of the variation in venom flow. The venom sac contains a lethal adult dose of venom, but the rattlesnake usually injects less than the full contents of the venom gland. There are variations in the amount of venom available for envenomation as a result of seasonal variation, previous strikes, and the size of the snake. Rattlesnakes are venomous from birth, but some changes occur in the composition of the venom during maturation.

PRINCIPAL TOXINS

Venom Composition

Venom is a complex mixture of proteins and polypeptides that is highly stable and resistant to drying and temperature fluctuations. The venom contains a lethal component (toxins) designed to immobilize the prey while digestive enzymes circulate through the prey to enhance subsequent digestion. Rattlesnake venom is a complex mixture of 5–15 enzymes, metal ions, biogenic amines, lipids, free amino acids, large and small proteins, and polypeptides. Lethal proteins and peptides consist of 20–80 amino acids that damage endothelial cells and plasma membranes. Polypeptides are low-molecular-weight proteins that lack enzymatic activity and are 5–20 times more lethal in animal models than crude venom. The weight of these polypeptides ranges from 6,000–30,000 daltons, and the concentration of these lethal proteins is higher in cobra (Elapidae) than in rattlesnake (Crotalinae) venom. Digestive enzymes include the following: 1) phospholipase A_2 that hydrolyzes the ester bond of lecithin and damages fatty molecules in cell membranes, 2) hyaluronidase that decreases the viscosity of connective tissue, 3) amino acid esterase that promotes fibrin formation, and 4) proteolytic enzymes and 5′ nucleotidase that damage proteins in muscle fibers.

Phospholipases A, B, C, and D hydrolyze lipids with subsequent disruption of neurotransmission at both the presynaptic and postsynaptic areas. Hyaluronidase allows the rapid spread of venom through tissue by hydrolyzing connective tissue hyaluronic acid. Proteases produce damage by dissolving proteins and peptides in

the tissues. Hemolysis results from the destruction of lecithin in the cell membranes. L-Amino acid oxidase produces local tissue destruction by catalyzing the oxidation of amino acids. Other enzymes include transaminases, ribonuclease, L-arginine ester hydrolases, deoxyribonuclease, phosphomonoesterase, phosphodiesterase, DNAse, ATPase, alkaline phosphatase, acid phosphatase, and endonuclease. The venom from the Mojave rattlesnake (*C. scutulatus scutulatus*) contains few digestive enzymes compared with other rattlesnake species, and therefore envenomations by Mojave rattlesnakes produce less tissue destruction than envenomation by other true rattlesnakes. The venom from *Crotalus* species does not contain acetylcholinesterase enzymes.

Dose Response

There is substantial interspecies, intraspecies, and seasonal variation in rattlesnake venom composition and toxicity.[93] The intraperitoneal LD_{50} in mice exposed to the venom of *Crotalus* species ranges from 0.23 mg/kg (*C. scutulatus scutulatus*) to 6.69 mg/kg (*C. ruber ruber*).[94] Seasonal variation in venom potency results from changes in feeding patterns and physiological responses (e.g., hibernation).[95] Factors producing intraspecies variation include age and time from last feeding. Rattlesnakes are venomous from birth.

TOXICOKINETICS

Crotalus venom is a complex mixture of substances with varying molecular weights and activities. There are very limited data on the toxicokinetics of these components. Detection of whole venom depends on the time since envenomation, the administration of antivenom, and the sensitivity of the analytical method. Case reports and case series of rattlesnake envenomations suggest that coagulopathic components of rattlesnake venom may remain active up to 1–2 weeks.[96,97] In a study of the urine from a patient envenomated by the bite from the Western Diamondback rattlesnake (*C. atrox*), venom was detectable by ELISA from days 3–6 postenvenomation.[98] The duration of detectable venom was not determined. As measured by enzyme-linked immunosorbent assay, whole venom from the South American rattlesnake (*Crotalus durissus durissus*) was not detectable in plasma when the time elapsed between the bite and hospital admission was over 8 hours.[99] Crotoxin was not detectable in most of the patients, who were admitted to the hospital at times ranging between 4 hours and 8 hours after the snakebite. Rattlesnake venom does not penetrate the blood–brain barrier.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Venom affects almost every organ system because of the increased permeability of capillary membranes that results in the extravasation of albumin, electrolytes, and red blood cells. However, the brain is relatively resistant to the direct toxic effects of rattlesnake venom. The primary effects of venom include local tissue damage, edema, hypoalbuminemia, coagulopathy, thrombocytopenia, hypovolemia, and, in a few pit viper species, neurotoxicity. Snake venom metalloproteinases are a series of zinc-dependent proteins that disrupt the interaction between the basement membranes and endothelial cells leading to increased capillary membrane permeability, extravasation of fluid, electrolytes, proteins, and erythrocytes.[100] Rarely, pulmonary edema and renal failure result from multiorgan failure and the transudation of fluid into alveoli. The venom of the Mojave rattlesnake contains a fraction of fluid that produces flaccid paralysis by blocking presynaptic neuromuscular transmission.

Target Organs

Neurotransmission

Most rattlesnake envenomations cause relatively minor changes in neuromuscular transmission as compared with coral snake envenomations. The major exception is envenomation by the Mojave rattlesnake (*C. scutulatus scutulatus*), which can produce respiratory paralysis. Experimental studies suggest that the neurotoxic component results from calcium channel blockade of presynaptic neurons and the noncompetitive inhibition of the release of acetylcholine.[101] Neurotoxicity requires the synergistic action of phospholipase and an acidic, inert component.[102] The venom from some *Crotalus* species (e.g., *C. lepidus lepidus*) contains this neurotoxin, but neurological complications are rare because the amount of this component is substantially less than the Mojave rattlesnake.

Skin and Soft Tissue

Crotalus envenomation produces serious local damage due to the action of proteases and hyaluronidases. Venom metalloproteinase activates tumor necrosis factor alpha, which is a mediator of the inflammatory response that causes neutrophil degranulation, leukocyte migration, and the release of mediators of inflammation (e.g., interleukins, human metalloproteinase).[103] The venom from some *Crotalus* species (e.g., *C. viridis,*

C. atrox) contains phospholipases A_2-type enzymes, called myotoxins (e.g., myotoxin-a).[104] Myotoxin-a produces increased intracellular calcium concentrations that ultimately cause muscle necrosis.[105]

Blood

The most common coagulation abnormality following *Crotalus* envenomation is hypofibrinogenemia and thrombocytopenia due to venom-induced consumption of fibrinogen and platelets. The injection of thrombin-like enzymes in rattlesnake venom converts fibrinogen to an unstable fibrin clot that is subsequently lysed by the fibrinolytic system. A consumptive coagulopathy may develop following the excessive activation of the fibrinolytic system. Amino acid esterases and thrombin-like enzymes (e.g., crotalase) promote clotting of fibrinogen by the hydrolytic splitting of fibrinopeptide A or B from fibrinogen.[106,107] The incomplete splitting of fibrin inhibits the release of clot-stabilizing factor, and crotaline venom may enhance anticoagulation by reversibly binding to prothrombin. Factor XIII is not activated and the unstable clots trap platelets. Crotalase acts at a different fibrinogen recognition site than thrombin, and crotalase does not directly activate platelets. Plasmin and proteolytic enzymes in the venom readily lyse the clot, and a consumptive coagulopathy develops characterized by excessive consumption of fibrin, thrombocytopenia, and increased fibrin split products. The destabilizing action of phospholipase on erythrocyte membranes contributes to the hemolysis associated with venom-induced coagulopathies. However, intravascular coagulation (disseminated intravascular coagulation [DIC]) does not usually occur as reflected in normal concentrations of antithrombin III, factor XIII, and D-dimer. A venom fraction of *C. horridus horridus* (timber rattlesnake) causes platelet aggregation, and this effect contributes to the severe thrombocytopenia often seen after envenomations by this species.[108] Decreased platelet survival results from local consumption of the platelets at the site of injury.[109]

Cardiovascular System

Although some rattlesnake venoms (e.g., Mojave, Southern Pacific rattlesnakes) contain a direct cardiotoxin, hypotension usually results from fluid extravasation caused by intimal injury as well as changes in vascular resistance. Large volumes of fluid may diffuse across injured capillaries. Consequently, hypotension usually results from hypovolemia. In experimental animal models, rattlesnake venom produces myocardial necrosis and ischemia as demonstrated by elevation of cardiac enzymes and histological changes in the heart.[110] However, clinical evidence of myocardial injury in humans following envenomation by rattlesnakes is rare. The venom damages the endothelial cells of the vascular walls as manifest by endothelial blebs, dilation of the perinuclear space, and deterioration of the plasma membranes.

Pulmonary System

Pulmonary edema may result from extravasation of proteins through damaged alveolar membranes. Pulmonary hemorrhage and intraalveolar edema may cause hypoxia.

Kidney

Renal dysfunction may result from hypoperfusion, intravascular hemolysis with hemoglobinuria, myoglobinuria, disseminated intravascular coagulation, and/or a direct nephrotoxicity.[111]

CLINICAL RESPONSE

The clinical presentation of rattlesnake envenomation varies substantially depending on a variety of factors including the potency of the venom, the amount of venom injected, and patient-related factors. The latter factors involve age, health, and individual susceptibility of the patient as well as the use of protective clothing. Consequently, the clinical features of a rattlesnake bite range from an asymptomatic, "dry" bite to skin necrosis, weakness, lethargy, paresthesias, fasciculations, and life-threatening coagulopathy. About 20% of *Crotalus* bites do not result in envenomation, and therefore no toxic effects develop. The lack of burning pain and edema over 2 cm from a fang mark more than 1 hour after the snakebite suggests that either no or minimal envenomation occurred, whereas the absence of edema and erythema at the bite site more than 6–8 hours after the snakebite indicates a lack of evenomation for most rattlesnake bites.

The most common response to a snakebite is fear, which may cause cold, clammy skin, tachycardia, nausea, vomiting, or syncope. In general, children have more severe responses because of the increased amount of venom per kilogram of body weight compared with adults, but serious morbidity other than restricted range of motion and muscle weakness following rattlesnake bites is uncommon.[112] Topical exposure or ingestion of rattlesnake venom does not usually cause systemic envenomation. Contact of rattlesnake venom to the eye often produces transient irritation without systemic effects, and the local irritation usually responds to standard first-aid measures.[113] *Salmonella* species (e.g.,

Salmonella arizonae) are part of the normal intestinal flora of reptiles including rattlesnakes.[114] In parts of the southwestern United States, *Salmonella* gastroenteritis is a complication of the use of rattlesnake meat as a folk remedy by individuals with normal and compromised immune systems.[115,116] The ingestion of rattlesnake capsules produced *Salmonella* sepsis in two immunocompromised, elderly patients.[117]

Local Effects

Crotalus envenomation classically presents with visible fang marks (one or more), immediate burning without severe pain, and localized edema beginning about 5 minutes after the bite. The number of fang marks depends on a number of factors including the number of strikes, the accuracy of the strike, and the number of reserve fangs. *Crotalus* bites that produce superficial abrasions and lacerations do not usually cause envenomation because the orifice of the fang lies slightly proximal to the tip of the fang. Local findings after envenomation are usually obvious within 30–60 minutes, and the edema continues to worsen during the first several hours after envenomation. Swelling progresses over 6–8 hours depending on the severity of the envenomation, and pain correlates to the amount of edema. Mild cyanosis commonly occurs at the site of injury without the presence of ischemia. Ecchymosis typically appears within several hours because of the extravasation of blood into subcutaneous tissue from damaged vessels. Clear or hemorrhagic vesicles and petechiae may appear distant to the fang marks on the same extremity. However, generalized petechiae and purpura appear rarely, and these findings are usually associated with thrombocytopenia, especially in previously damaged skin (e.g., sunburn).[118] Necrosis is usually localized following the use of adequate doses of antivenom, but return to full function of the envenomated extremity typically requires approximately 1 month despite the use of antivenom. The amount of local tissue damage and edema is species-dependent ranging from minimal changes following some Mojave rattlesnake envenomations to the severe swelling produced by the Eastern Diamondback. Pressures in muscle compartment are usually normal in the absence of muscle necrosis from a subfascial envenomation. Despite significant discoloration and swelling of extremities, arterial perfusion generally increases after envenomation. Decreased skin temperature in the extremity suggests the possibility of ischemia. Tender regional lymph nodes may develop in the absence of infection and signs of lymphangitis usually reflect the proximal diffusion of venom rather than a local infection.

Systemic Effects

Minty, rubbery, or metallic taste is a frequent symptom following envenomation by prairie (*C. viridis viridis*), Northern Pacific (*C. viridis oreganus*), and Southern Pacific (*C. viridis helleri*) rattlesnakes. Weakness, diaphoresis, lightheadedness, and nausea occur commonly. However, the development of perioral paresthesias, muscle paralysis, or facial fasciculations suggests a moderate to severe envenomation. Muscle fasciculations may involve the head and neck in addition to the extremities, and these fasciculations can persist for a few days despite the use of antivenom.[119] Paralysis and respiratory insufficiency may develop following envenomation by the Eastern Diamondback, Mojave, or Southern Pacific rattlesnakes,[120] but these findings are relatively rare except following envenomation by the Mojave rattlesnake. Other neurological effects of envenomation by this rattlesnake include dysphagia, ptosis, diplopia, and respiratory failure. Myokymia is a fine, spontaneous, involuntary, undulating movement of muscle fibers that occurs in some demyelinating diseases (Guillain-Barré syndrome, multiple sclerosis). Myokymia can also result from envenomation by a few rattlesnake species (e.g., timber rattlesnake—*C. horridus horridus* and midget faded rattlesnake—*C. viridis concolor*).[121,122] These low-amplitude muscle movements occur in muscle groups close to the bite and the face, but muscle fibers in nonbitten extremities also can develop myokymia. Convulsions do not usually develop following rattlesnake envenomations. Severe systemic effects (hypotension, respiratory distress, angioedema of the oropharynx) can occur with minimal local effects following the intravenous injection of venom.[123]

During severe envenomation, pulmonary edema secondary to adult respiratory distress syndrome (ARDS) may develop from the extravasation of fluid across damaged alveolar membrane. Most fatalities occur within 48 hours of envenomation due to ARDS, persistent hypotension unresponsive to fluid administration, and disseminated intravascular coagulation. Renal dysfunction usually results from hypoperfusion, myoglobinuria, or multisystemic failure. Although rare except following severe envenomations from intravascular injection of rattlesnake venom, a consumptive coagulopathy may develop as characterized by petechiae, diffuse bleeding from puncture sites, hematomas, melena, epistaxis, and hematuria. Intracerebral hemorrhage, intracardiac bleeding, retinal hemorrhage, and bowel infarction are infrequent complications of rattlesnake envenomation.

Classical Grading of Envenomation

Classification of the severity of rattlesnake envenomation involves separating the clinical features of envenomation into four categories (none, minimal, moderate, severe). Typical snakebites produce one or more fang marks with puncture wounds circumscribed by ragged edges. Envenomation produces local subcutaneous edema and variable amounts of pain that correlate to the extent of the edema. Slight bleeding often occurs at the puncture site that later is associated with subcutaneous hemorrhage. Common systemic signs of envenomation include muscle fasciculations and paraesthesia. The presence of cranial nerve signs (drooling, diplopia, dysphagia) suggests envenomation by the Mojave rattlesnake. Without antivenom administration, minimal envenomations may progress to severe envenomations over several hours. Consequently, the severity of envenomation is frequently determined by the time to definitive intervention (i.e., antivenom).

- *None*: A dry bite produces a puncture wound without surrounding edema, significant local pain, systemic complaints, or laboratory abnormalities.
- *Minimal*: A minimal envenomation results in the presence of fang marks with local swelling confined to the bite area. Systemic symptoms and laboratory abnormalities are absent or clinically insignificant.
- *Moderate*: A moderate envenomation causes local swelling, which progresses beyond the immediate bite area, but the edema does not involve the entire extremity. Significant systemic symptoms (paresthesias, fasciculations) develop along with moderate laboratory changes including mild thrombocytopenia ($<80{,}000/m^3$), decreased fibrinogen (<80 mg/dL), and mildly increased fibrin split products. There is no bleeding from remote sites. Nausea and vomiting may be present.
- *Severe*: Severe envenomations involve fang marks with rapidly progressive edema, subcutaneous hemorrhage along with severe generalized symptoms and signs, particularly hypotension. Subcutaneous changes extend over the entire extremity. Marked laboratory abnormalities include decreases in all coagulation factors, proteinuria, hematuria, and increased serum creatine kinase. Envenomation by large, highly toxic rattlesnake species (e.g., Eastern or Western Diamondback) usually produces this type of clinical presentation.

Anaphylaxis

Anaphylactic responses to *Crotalus* envenomation are extremely rare. A 22-year-old man with a history of rattlesnake envenomation one year earlier developed urticaria, hypotension, and bronchospasm within 30 minutes of an unidentified rattlesnake bite.[124] He responded to subcutaneous (SQ) epinephrine, intravenous (IV) diphenhydramine, and fluid administration. The administration of antivenom was terminated after he developed wheezing and shortness of breath following the administration of 60 mL of a 100 mL solution containing 5 vials of Wyeth (Wyeth Pharmaceuticals, Collegeville, PA) antivenom. Hypersensitivity responses are common in snake handlers who sustain multiple bites.[125] Severe anaphylaxis developed in a professional snake handler who had a prior history of snake venom sensitivity.[126]

DIAGNOSTIC TESTING

Analytical Methods

Double diffusion technique is a simple, rapid method of identifying snake venom, but the test is qualitative rather than quantitative with detection limits of about 1 μg for *C. atrox*, whereas the ELISA is more sensitive (1-nanogram range).[127] However, an ELISA test for the detection of rattlesnake envenomation is not commercially available. Although these tests are available in some experimental laboratories, the low concentration of venom in urine and plasma samples frequently limits detection in clinical settings.[128] Potentially, such assays can differentiate snakebites from other injuries and envenomations, determine the genus and occasionally the species involved, and detect the presence of specific antibodies in human populations.

Abnormalities

Bleeding abnormalities following rattlesnake envenomation include defibrination, venom-induced thrombocytopenia, and disseminated intravascular coagulation (see Table 176.8). The most common coagulopathy following envenomation by North American rattlesnakes is defibrination without DIC, particularly following envenomation by Eastern and Western Diamondback, timber, blacktail, or Mojave rattlesnakes.[129] Early hematological changes include coagulopathy, hypofibrinogenemia, and venom-induced thrombocytopenia.[130] Case series indicated that hypofibrinogenemia and thrombocytopenia may develop without other evidence of a significant coagulopathy, particularly after timber rattlesnake envenomations.[131] Thrombocytopenia reaches a nadir 2–4 days after envenomation and may persist for 10–14 days. A rebound thrombocytosis typically occurs approximately 36 hours after envenomation.

A consumptive coagulopathy may occur during the first few days manifest by prolonged clotting times

TABLE 176.8. Abnormalities Separating Defibrination (DF), Venom-Induced Thrombocytopenia (VIT), and Disseminated Intravascular Coagulation (DIC) during Rattlesnake Envenomation[a]

Test	Defibrination (DF)	Venom-Induced Thrombocytopenia (VIT)	DF and VIT	Disseminated Intravascular Coagulation (DIC)
Fibrinogen	Low	Normal	Low	Low
Fibrin Split Products	Elevated	Normal	Elevated	Elevated
Prothrombin Time	Prolonged	Normal	Prolonged	Prolonged
Activated Partial Thromboplastin Time	Prolonged	Normal	Prolonged	Prolonged
Platelet Count	Normal	Low	Low	Low
Hemolysis[b]	Absent	Absent	Absent	Present
Diffuse Bleeding	Absent	Severe only	Severe only	Present
Organ Infarction	Absent	Absent	Absent	Present

[b]Microangiopathic

(partial thromboplastin time [PTT] > prothrombin time [PT]), hypofibrinogenemia, elevated fibrin split products, and thrombocytopenia, but hemorrhagic complications and DIC are uncommon except in severe cases (e.g., multiorgan failure, intravascular envenomation).[132] The presence of DIC is indicated by intravascular fibrin deposition with subsequent fibrinolysis, hemolysis, thrombocytopenia, reduced coagulation factors, and bleeding from diffuse sites. D-dimer is a direct measure of cross-linked fibrin derivatives from intravascular fibrin deposition and plasmin degradation. The thrombin-like enzymes in rattlesnake venom do not form cross-linked fibrin, and therefore D-dimer concentrations remain normal after envenomation unless DIC occurs.

Anemia occurs primarily during severe envenomations and results from internal bleeding or intravascular hemolysis secondary to DIC.[133] Laboratory manifestations of rhabdomyolysis include elevated serum creatine kinase (CK) and myoglobinuria. Case reports suggest that increased serum concentrations of the CK-MB fraction following an envenomation do not necessarily reflect myocardial damage, particularly following bites by the canebrake rattlesnake.[134] Urine abnormalities include hematuria, glycosuria, proteinuria, or myoglobulinuria. These abnormalities are transient and usually resolve within 2 weeks unless renal damage develops.[135]

TREATMENT

First-Aid

There are limited data regarding the efficacy of various first-aid measures following crotalid envenomation. Tourniquets, incision, electric shock therapy,[136,137] and cryotherapy are ineffective and potentially dangerous first-aid measures for rattlesnake bites.[138] Most authorities advise against the use of ice packs, cold packs, ice water soaks, ethanol, and stimulants.

General recommendations for first aid in the field are as follows:

1. Retreat from the snake at least 10–15 ft (~3–5 m) and remain calm. Arrange to move the victim to a medical facility as soon as possible to begin the administration of antivenom.
2. Remove all constricting items, such as rings, watches, and restrictive clothing immediately.
3. Put the victim at rest, give reassurance, and keep him or her warm. Excessive activity may increase the spread of venom. However, keeping the victim at rest should not delay the transport of the patient to the nearest medical facility.
4. Lightly immobilize the injured part below the heart in a position of rehabilitation (e.g., full extension of phalangeal joints, 90° flexion of metacarpal-phalangeal joints, wrist in neutral position). Typically, the extremity is elevated in the hospital when antivenom is available. Identification of the snake is not usually necessary for the proper treatment of *Crotalus* envenomation, unless more than one dangerous species of rattlesnake exists in the area (e.g., Mojave rattlesnake). The snake should not be handled directly because the snake's reflexes remain intact 30–60 minutes after death and bites may occur even after decapitation of the snake.[139]

Although the use of pressure dressings has been a common first-aid recommendation for rattlesnake snakebites, there are no clinical data validating the efficacy of this modality and there are theoretical disadvantages to restricting the venom to the area of the bite.[140]

Application of a lightly constricting band above the swelling that admits a finger beneath it is commonly recommended *only* when definitive treatment will be delayed 1–2 hours, such as occurs in remote locations. Available experimental data suggest that a constrictive band limits systemic spread of the venom, but there is no clinical evidence that the use of a constrictive band improves outcome.[141,142] Clinical experience suggests that previously applied tourniquets should *not* be removed in the emergency department until intravenous lines are established, a blood pressure cuff is inflated proximal to the tourniquet, and antivenom therapy is available. The blood pressure cuff should be deflated gradually as the patient receives antivenom and fluids.

The use of incision and drainage is discouraged because of potential contamination of the wound and the lack of clinical evidence regarding a clear benefit for this first-aid measure. Suction is potentially useful *only* in the unusual circumstance where 1) medical help is over 1–2 hours away, and 2) the procedure begins within 5 minutes of the bite. Use of a commercial suction device (e.g., Sawyer Extractor Vacuum Pump; Sawyer Products, Inc., Safety Harbor, FL) is preferable to suction by mouth based on theoretical concerns about contaminating the wound with human oral flora. However, there are inadequate experimental and clinical data to support the efficacy of this device.[143,144] If an extractor pump is present and contains fluid, the pump should be left in place until arrival in a health care facility. Otherwise, the extractor pump may be removed during transport.

Stabilization

Life-threatening local edema may result from airway obstruction following intraoral or facial snakebites.[145,146] Anaphylactic responses to snakebites are rare, except in those patients, such as snake handlers, who sustain snakebites on multiple occasions. A case report documented the development of life-threatening glossal and epiglottic edema in a 36-year old man envenomated on the thumb by the head of a decapitated timber rattlesnake.[147] Hypotension should be treated by starting two intravenous lines for the administration of crystalloid solution. Large volumes may be required. Vasopressors should be reserved as a short-term measure, and necessity of using vasopressors indicates the need to monitor pulmonary wedge or central venous pressures. Pulmonary edema usually results from adult respiratory distress syndrome. Respiratory depression is uncommon except as a complication of shock and Mojave rattlesnake envenomations. Vital signs including oxygen saturation initially must be monitored every 15 minutes in the acute care setting with direct, continuous observation.

Elimination Enhancement

There are no clinical data to support the use of methods to enhance the elimination of venom as a treatment for rattlesnake envenomation.

Antivenom

Two antivenoms approved for use following *Crotalus* envenomations include Crotalidae polyvalent antivenom produced in horses and Crotalidae polyvalent Fab fragments (CroFab™; Protherics, Inc., Brentwood, TN) produced in sheep. There are limited supplies of the former antivenom, and the use of the latter antivenom may completely replace the use of the former depending on the resolution of issues on the incidence of hypersensitivity responses and the efficacy of treatment of delayed coagulopathies. Although both antivenoms reduce systemic symptoms following North American Crotalinae envenomation, the efficacy of these antivenoms to reduce postenvenomation edema remains unclear, in part because of the lack of large, controlled clinical trials.[148] The antivenom, Antivipmyn, is a polyclonal antivenom $F(ab')_2$ fragment produced in horses and available from the Instituto Bioclon, Mexico City, Mexico.[149,150]

Crotalidae Polyvalent Immune (Ovine) Fab (CroFab™)

Formulation. Crotalidae Polyvalent Immune Fab (Ovine) is a lyophilized powder produced in sheep as a monospecific, polyvalent antivenom for the treatment of North American Crotalinae envenomations. Flocks of sheep are immunized with one of four crotaline venoms (Eastern Diamondback, Western Diamondback, Mojave, Cottonmouth). Ovine immune serum from each flock is digested by papain to separate the Fab and Fc fragments. After an affinity-purification process to remove the Fc fragments, the four individual monospecific Fab preparations are mixed to form the final product. The advantages of CroFab™ compared with the Wyeth antivenom include faster and easier administration and fewer allergic responses.[151,152] However, the shorter elimination half-life of CroFab™ requires more frequent administration compared with the equine antivenom.

Mechanism of Action. CroFab™ is a polyvalent antivenom that is a specific antidote to North American pit viper venom. This antivenom neutralizes the whole pit viper venom rather than specific components. Consequently, the antivenom may be more effective against some components. The administration of antivenom

does not reverse local tissue injury caused by snake venom prior to the use of antivenom. Antivenom limits the progression of local swelling and reverses coagulopathy. The effect on thrombocytopenia is variable.

Indications. The indications for the administration of CroFab™ to victims of snakebites are similar to the indications for antivenin (Crotalidae) polyvalent. Antivenom is indicated in patients who demonstrate progressive signs of envenomation during the first hour after envenomation. Progression of swelling and pain in a digit suggests the need for antivenom, particularly in children. Although premarketing and postmarketing studies of the use of CroFab™ have excluded children, retrospective studies indicate that the use of this antivenom in pediatric patients with crotalid envenomations is safe.[153] The antivenom is most effective when administered within 4 hours of the bite. Although CroFab™ production uses the venoms of four snake species (Western and Eastern Diamondback rattlesnakes, Mojave rattlesnake, water moccasin), clinical experience suggests that CroFab™ is effective against envenomation by other rattlesnakes (e.g., Southern Pacific rattlesnake or *Crotalus viridis helleri*).[154]

Cautions. Sensitization potentially may occur in patients administered a foreign protein, such as CroFab™. Therefore, patients receiving repeat courses of CroFab™ should be evaluated carefully for the development of allergic responses. Occasionally, fasciculations, muscle weakness, and respiratory insufficiency persist despite the administration of adequate doses of antivenom and cessation of the spread of extremity edema.

Administration. Each vial should be reconstituted with 10 mL sterile water and mixed by gentle, continuous swirling. The initial dose of antivenom is diluted in 250 mL normal saline, and the total dose is infused intravenously over 1 hour with the initial infusion beginning at 25–50 mL/h to observe for signs of any allergic response. The antivenom is relatively stable to heat and to motion.[155]

Dosage. The initial dose of CroFab™ is 4–6 vials and this dose should be repeated if signs of envenomation progress as defined by continued progression of edema or lack of improvement in coagulation abnormalities and systemic signs. An additional 2-vial dose is recommended 6 hours, 12 hours, and 18 hours after the initial control of the envenomation to prevent recurrence of local and systemic signs (e.g., coagulopathy) of envenomation. The typical *Crotalus* envenomation involves the administration of 14–18 vials of CroFab™. Although ideally CroFab™ should be administered as soon as possible after envenomation, case reports suggest that the administration of antivenom may be effective up to 2 days after envenomation, particularly for the venom-induced coagulopathy.[156] Recurrence of signs of envenomation following CroFab™ treatment results from the pharmacokinetic mismatch between the receptors for the venom components and the antivenom.[157] This situation occurs because the clearance is faster for unbound antivenom than for some venom components. In general, the distribution times and the elimination half-lives increase as the size of the molecule increases. The prolonged absorption of nonneutralized venom from deposition sites near the bite enhances the phenomena of recurrence. Consequently, recurrence occurs more frequently following the administration of CroFab™ than Wyeth antivenom because of the relatively smaller size of the Fab molecules compared with the IgG molecules present in the Wyeth antivenom. The clinical significance of recurrent coagulopathy is unclear. Table 176.9 lists suggested recommendations for the treatment of recurrent coagulopathy.[158] Standard treatment regimens for CroFab™ usually limit the recurrence of local symptoms and signs. However, fasciculations may persist despite the use of adequate doses of CroFab™.

Sensitivity Testing. The affinity-purified Crotaline antivenom ovine Fab does not usually contain the immunogenic Fc and IgG molecules present in the Wyeth antivenom (Crotalidae) polyvalent. Because of the lack of immunogenicity and allergic responses following the use of the ovine Fab antivenom, sensitivity testing is not recommended prior to the administration of this antivenom.[159]

Adverse Reactions. Both anaphylactoid reactions, immediate hypersensitivity, and serum sickness may occur after the administration of CroFab™, but the

TABLE 176.9. Recommendations for Repeat Treatment of Recurrent Coagulopathy with CroFab™[a,b]

Test	Lab Value
Fibrinogen	<50 µg/mL
Platelet count	<25,000/mm^3
INR[c]	>3.0
aPTT[d]	>50 s

[a]Source: Adapted from Ref 158.
[b]Additional indications for repeat treatment include high-risk for trauma, recurrence of coagulopathy in patient with history of severe coagulopathy, comorbid conditions that increase the risk of internal hemorrhage, and multicomponent coagulopathy.
[c]INR = international normalized ratio.
[d]aPTT = activated partial thromboplastin time.

immune responses are usually mild without sequelae.[160,161] Serious anaphylactic reactions may occur in patients allergic to sheep. In a case series of 31 patients given CroFab™, 6 patients developed acute responses ranging from transient urticaria to mild cough and wheezing.[162] Of the 4 patients requiring treatment, all responded promptly. Over a one-month follow-up period, 6 of 26 patients developed serum sickness ranging from mild (two cases) to severe (two cases). All patients were asymptomatic 28 days after treatment. Persistent, recurrent, or late coagulopathy (thrombocytopenia, hypofibrinogenemia) may occur 2–14 days after rattlesnake envenomation despite the administration of CroFab™.[163] Although these abnormalities are not usually associated with spontaneous bleeding, monitoring the coagulation should continue during the first week and elective surgical procedures should be avoided at least for several weeks. As a result of platelet-aggregating constituents of venom (e.g., crotalocytin) and platelet sequestration in areas of vascular damage, thrombocytopenia may persist 5–7 days after envenomation despite the use of antivenom. Following evenomation by *Crotalus ruber ruber* (Red Diamond rattlesnake), a 42-year-old man developed severe thrombocytopenia (platelet count 5,000–10,000/mm^3) within 4 days that did not respond to 46 vials of CroFab™ and 10 vials of antivenin (Crotalinae) polyvalent (Wyeth) despite the normalization of other coagulation factors (fibrinogen, prothrombin time).[164] Despite receiving large amounts of antivenom, the patient did not develop serum sickness.

Follow-up Care. Patients with thrombocytopenia or hypofibrinogenemia should be reevaluated for evidence of delayed coagulopathy within 4 days of initial therapy or whenever signs of coagulopathy (e.g., hematuria, petechiae, bleeding) develop. If the patient developed an abnormal coagulation profile during the first 36 h, the patient should be reexamined for recurrent coagulopathy 48 hours after antivenom administration. Redosing with CroFab™ is appropriate when the platelet count is <25,000/mm^3 and the fibrinogen level is below 50 mg/dL.

Antivenin (Crotalidae) Polyvalent (Equine by Wyeth)

Formulation. Antivenin (Crotalidae) polyvalent (antivenom) is a lyophilized powder produced by the immunization of horses with the venoms of *Crotalus atrox* (Western Diamondback), *Crotalus adamanteus* (Eastern Diamondback), *Crotalus durissus terrificus* (South American rattlesnake), and *Bothrops atrox* (fer-de-lance). Because of the common antigens shared by pit vipers, the antivenom is effective against poisonous American pit vipers, including rattlesnakes, pygmy rattlesnakes, cottonmouth, and copperhead as well as the fer-de-lance, cantil, and Central and South American bushmaster. This antivenom also provides protection against the habu (*Protobothrops flavoviridis* Hallowell) and *Agkistrodon* species in Japan and Korea. Commercial venom is freeze-dried and must be reconstituted in sterile water. One vial of antivenom yields 10 mL of concentrated serum.

Mechanism of Action. Antivenom neutralizes pit viper venom, but the administration of antivenom does not reverse local tissue injury caused by snake venom prior to the administration of antivenom. The use of antivenom limits the progression of local swelling, reverses coagulopathy and thrombocytopenia, and improves muscle strength in patients with generalized weakness. The persistence of DIC after the administration of antivenom suggests the presence of organ infarction.[129]

Indications. Antivenom is indicated in patients who demonstrate progressive signs of envenomation during the first hour after envenomation unless the risks outweigh the benefits (e.g., horse serum-sensitive patients). Progression of swelling and pain in a digit suggests the need for antivenom, particularly in children. The antivenom is most effective when administered within 4 hours of the bite. Early administration of antivenom is necessary to prevent local and systemic injury before vascular destruction restricts the delivery of antivenom to the tissues. Antivenom is less effective when administered over 12 hours after envenomation, but some reversal of coagulation defects occurs 24 hours after envenomation. Thrombocytopenia frequently improves after antivenom therapy, but the response is usually partial and platelet counts often remain below normal 7–10 days.[165]

Cautions. The only absolute contraindication to antivenin (Crotalidae) polyvalent use is the lack of signs of envenomation. Another contraindication is horse serum sensitivity and the option to use CroFab™. The use of antivenin (Crotalidae) polyvalent in sensitized patients requires careful consideration of the risks and potential benefits. Consultation, when time permits, is advisable to decide the need for antivenom and the best method of administration (e.g., desensitization or simultaneous administration of diphenhydramine and epinephrine with diluted antivenom). Pregnancy is not a contraindication to the administration of antivenom and the use of antivenom may prevent envenomation-induced abortions that are common in untreated, pregnant women.[166,167]

ADMINISTRATION. Antivenin (Crotalidae) polyvalent should be administered only by the intravenous route because of the superior delivery of antivenom to the tissues using this route, and antivenom should not be injected into the area of the bite. Ten mL of diluent or normal saline is added to each vial, and the solution is mixed by rolling the vial between the hands rather than shaking. For adults, the appropriate number of antivenom vials is added to 250–500 mL of normal saline (about 1:5 dilution) and then infused into the main intravenous line, ideally via a four-way stopcock located near the catheter site. For children, the volume is decreased proportionally so that the reconstituted vials may be diluted 1:1 in normal saline and added to a microdrop set. Because of the false-negative results (i.e., up to about 20%) of hypersensitivity testing, the initial infusion begins at a rate of 0.25–1 mL/min during the first 10–15 minutes. If allergic symptoms (pruritus, urticaria, flushing) develop, the infusion is stopped and the main line started to give fluid and diphenhydramine. If no reaction occurs within the first 10–15 minutes, the infusion rate should be increased to administer the entire dose of antivenom over the next 1 to 2 hours. The initial dose of antivenom should be repeated every 2 hours if local or systemic signs of envenomation continue to progress. Antivenin (Crotalidae) polyvalent is less effective 8–12 hours after envenomation and of questionable value after 24 hours, except in reversing coagulation defects (e.g., thrombocytopenia).

If a reaction occurs, stop the infusion and give 50 mg (1.25 mg/kg) of both diphenhydramine (50–100 mg, 1.25 mg/kg) and ranitidine (50 mg, 1–2 mg/kg) intravenously and, if needed, epinephrine subcutaneously (0.01 mL/kg of a 1:1,000 dilution to a maximum of 0.3–0.5 mL in adults). Epinephrine must be given in more severe anaphylactic responses because of the inability of antihistamines to inactivate leukotrienes during anaphylaxis.[168] For anaphylactic shock, an initial intravenous epinephrine dose of 0.1 mg (0.1 mL of a 1:1,000 solution diluted in 10 mL of normal saline) infused over 5–10 minutes is recommended. For poor adult responders, a constant infusion of a 4 μg/mL solution (1 mg of a 1:1,000 solution added to 250 mL of 5% dextrose in water [D_5W]) may be infused at a rate of 1–4 μg/min.[169] Subcutaneous epinephrine may not be adequately absorbed when the patient is severely hypotensive. Myocardial ischemia is a potential complication in patients with coronary artery disease. Vasopressors, oxygen, and intubation equipment should be available for immediate use. There are no well-documented anaphylaxis-related fatalities in the medical literature from the administration of Wyeth antivenom.

Dosage. The clinical grading of the severity of envenomation determines the initial amount of antivenom. Children typically have more severe reactions to a given envenomation because of the greater amount of venom per body weight; therefore, children usually require more antivenom (i.e., up to 50%) than adults on a weight per weight basis. However, the use of clinical grading accounts for the difference in size between children and adults. The total dose of antivenom depends on the initial clinical presentation, the progression of edema, and systemic symptoms after the administration of antivenom. The typical average *initial* dose of equine antivenin (Crotalidae) polyvalent is 5 vials for minimal, 10–12 vials for moderate, and 15–20 vials for severe rattlesnake bites. If local or systemic signs progress after 2 hours, infuse an additional 5-vial incremental dose diluted in 500 mL saline. The circumference of the bitten extremity should be measured at a distance 10 and 20 cm above the bite every 30–60 minutes to monitor of effectiveness of the antivenom. The neurovascular status of the affected extremity should be evaluated regularly until swelling ceases. If signs of a compartment syndrome develop, the compartment pressures should be measured directly.

Mojave rattlesnake envenomation can produce respiratory paralysis 8–12 hours after envenomation despite the initial absence of local pain or systemic symptoms. If an envenomation by the Mojave rattlesnake is strongly suspected, the administration of 10 vials of antivenom should be considered despite the initial lack of local or systemic symptoms. All patients with suspected Mojave rattlesnake bites should be observed in an intensive care unit and additional doses of antivenom administered if neurological symptoms develop.[170] In patients receiving antivenom for coagulopathy after a crotaline envenomation, a retrospective analysis of 354 consecutive cases of North American crotaline snake envenomation suggests that coagulopathy may recur within several days after the administration of antivenom.[171] Repeat administration of antivenom is usually unnecessary unless clinical evidence of internal hemorrhage develops.

Sensitivity Testing. The decision to use hypersensitivity testing prior to the administration of Antivenin (Crotalidae) polyvalent depends on physician judgment. The efficacy of skin testing prior to antivenom therapy is questionable because of the insensitivity of the test to predict which patients will develop anaphylactic reactions. In a study of 26 patients receiving skin testing prior to antivenom administration, 3 of 6 patients with positive skin tests and 2 of 20 patients with negative skin tests developed anaphylaxis.[172] Therefore, skin testing prior to the administration of Crotalidae antivenom (equine) is not necessary, particularly when life-

threatening symptoms are present. Sensitivity testing should not be administered to patients unlikely to receive antivenom because hypersensitivity testing may complicate future antivenom administration by producing sensitivity to horse serum. Before testing, a history should be obtained about horse serum sensitivity because patients with a history of horse serum reactions are at higher risk of anaphylactic responses during antivenom administration.

The protocol for hypersensitivity testing for patients without horse serum sensitivity involves the injection of 0.02 mL of horse serum diluted 1:10 (Wyeth antivenom kits contain this 1:10 dilution of horse serum) intradermally at a site contralateral from the bite and the injection of 0.02 mL of normal saline in the opposite extremity as a control. A wheal and erythema indicate a positive reaction. Occasionally, patients may develop generalized urticaria, pruritus, or bronchospasm. Along with intravenous access, epinephrine and diphenhydramine should be immediately available prior to the skin testing. While awaiting skin test results, the initial doses of antivenom may be reconstituted with saline from the infusion bag. No reaction by 20–30 minutes indicates a negative reaction. For patients suspected of horse serum sensitivity, the horse serum should be diluted 1:100 (10 times weaker) and administered in the same acute care setting under direct observation. Not all patients with positive skin tests will have immediate hypersensitivity reactions when antivenom is given slowly.

Adverse Reactions. The most common acute reaction to antivenom administration is urticaria, which usually responds to slowing the infusion and intravenous antihistamines.[173] Although rare, the most serious response is a type I anaphylactic response to the horse serum, especially in patients with a history of horse serum sensitivity. During the production process, ammonium sulfate precipitation destroys up to one-half of the neutralizing IgG antibodies while most antigenic material remains. A majority of patients, who receive antivenin (Crotalidae) polyvalent, develop serum sickness (type III) within 3 weeks (on average within 7–14 days) of antivenom administration. In a retrospective chart review of 181 rattlesnake envenomations receiving antivenin (Crotalidae) polyvalent, 56% developed serum sickness.[174] For patients receiving <20 vials and ≥40 vials the incidence of serum sickness was 34% and 100%, respectively. Clinical manifestations of serum sickness include fever, headache, myalgias, arthralgias, lymphadenopathy, and urticaria. Patients who receive more than 7 vials invariably develop serum sickness.[175] These patients usually respond to a 7- to 10-day, tapering course of prednisone beginning at 60 mg/day.

Skin Test-Positive Patients. The use of antivenom in a patient with a positive skin test requires careful clinical evaluation because withholding antivenom in severe envenomations may result in serious morbidity unless CroFab™ is immediately available.[176] Pretreatment with diphenhydramine and careful, slow titration of antivenom, as well as the use of subcutaneous epinephrine for reactions, may avoid a serious response. The patient should be monitored in an intensive care setting. Highly allergic patients may respond to antivenom infusions and simultaneous epinephrine infusion in a separate line, but this method requires considerable clinical judgment. Patients have survived serious envenomation with only supportive care; permanent sequelae in these patients may be limited despite severe initial swelling of the involved extremity. The option of using CroFab™ should be seriously considered in these patients.

Supplemental Care

The management of rattlesnake envenomation depends, in part, on the patient population and the type of local venomous snakes. All asymptomatic patients suspected of being envenomated should be observed for at least 6–8 hours.[177] Before the release of asymptomatic patients, all laboratory studies should be repeated at least 4 hours after the first tests to confirm the absence of a coagulopathy. Severe thrombocytopenia and defibrination may occur in the absence of significant local swelling.[129] Suspected Mojave rattlesnake envenomations should be observed for 24 hours. All envenomated patients require observation in an intensive care setting. Smoking and drug use should be discouraged during the first few days following envenomation, and dental work, contact sports, and elective surgery should be avoided for the first few weeks. All patients should be reevaluated in 1–2 days. Repeat laboratory tests (complete blood count [CBC], PT/aPTT, fibrinogen) should be done within the first 2 to 3 days, and then repeated within the first 2 weeks if abnormalities develop. The patient should be instructed to return to the Emergency Department if recurrent swelling/pain, abnormal bleeding/bruising, wound infection, rhabdomyolysis (decreased urination, dark-colored urine), or serum sickness develops.

Ancillary Tests

Depending on severity, the following routine laboratory tests should be obtained on admission and monitored daily unless the clinical picture dictates more frequent intervals: CBC, urinalysis, serum electrolytes, creatinine, blood urea nitrogen, creatine kinase, coagulation profile (platelet count, PT, aPTT, fibrin split products), and chest x-ray for envenomations with pulmonary symptoms.

Most mild to moderate envenomations require only CBC and a coagulation profile unless the envenomating rattlesnake species (e.g., canebrake rattlesnake, *Crotalus horridus atricaudatus*) are associated with rhabdomyolysis., Electrolytes, kidney function, and serum creatine kinase should be monitored closely if there is evidence of rhabdomyolysis. Type and cross-match is necessary only for patients with severe envenomation and signs of active bleeding. For patients over 40 years of age or for severe envenomations, cardiac monitoring and an electrocardiogram are indicated. Transient hyperkalemia may develop due to cell lysis.

Wound Care

Circumferential measurements of the bitten extremity should be repeated every 30–60 minutes initially, and then as needed to monitor the effectiveness of antivenom therapy. There are few clinical data on the efficacy of varying methods of wound care during rattlesnake envenomation. The envenomated area should be cleaned by gentle irrigation with saline. The wound may be gently covered with nonadherent, hydrophilic dressings (e.g., Adaptic™, Johnson & Johnson, Inc., New Brunswick, NJ; Xeroform™, Kendall Company, Mansfield, MA). For the first 3 days, the extremity should be immobilized with a padded splint in a position that facilitates rehabilitation below the heart. Edema usually resolves about 7–10 days after a moderate envenomation. Local treatment includes sterile whirlpool baths and cleansing with 1:20 aluminum acetate soaks (Burow's solution) for 15 min. Hemorrhagic blebs and necrotic tissue should not be débrided until hemostasis returns to normal (i.e., after the third to fifth days postenvenomation).[178] Rehabilitation should start after the first surgical débridement (i.e., after the first 3 days) with aggressive passive and active range of motion exercises. Skin grafting may be necessary to cover large areas of skin necrosis.

In general, observational studies indicate that the incidence of wound infections is low following envenomation by both North American and South American rattlesnake species.[179,180] Prophylactic antibiotics may be considered for high-risk wounds (e.g., severe envenomations, first-aid measures involving incision and drainage, puncture wounds on the hand or foot). Abrasions and mild envenomations do not require antibiotic coverage. The presence of gram-negative organisms in the mouth of the North American pit viper requires broad-spectrum coverage (e.g., quinolones). Studies of the bacterial flora of North American pit vipers indicate that *Proteus vulgaris, Escherichia coli, Corynebacterium* spp. (diphtheroids), *Streptococcus*, and *enterobacteria* are the most common organisms.[181] Diphtheria-tetanus prophylaxis is similar to other puncture wounds (i.e., every 5 years).

Coagulation Disorders

Monitoring of coagulation defects requires the determination of the complete blood count with platelet count, PT, activated PTT [aPTT], fibrinogen concentration, and fibrin degradation products as well as serum electrolytes, serum creatinine, and blood typing as necessary. Laboratory coagulation parameters should be repeated every 4–6 hours until the patient stabilizes. All patients with serious clinical bleeding should receive antivenom as well as platelet packs, cryoprecipitate, and fresh frozen plasma as needed.[182] However, multiple coagulation defects (i.e., international normalized ratio [INR] > 3, aPTT >50, fibrinogen <75 mg/dL, *and* platelet count <50,000) suggest the potential for serious clinical bleeding, and the administration of antivenom is an option when these multiple coagulation defects develop. If adequate amounts of antivenom have been administered to control local tissue abnormalities and systemic effects, close observation is an option to further administration of antivenom as long as there is *no* evidence of internal or external bleeding.[183] Consequently, the administration of more antivenom is not necessary to correct laboratory evidence of *isolated* coagulation defects.

The consumptive coagulopathy is not responsive to the replacement of coagulation factors (i.e., fresh-frozen plasma) until there is sufficient antivenom to neutralize circulating snake venom. Furthermore, isolated coagulation defects are not usually associated with clinically significant bleeding because thrombin generation usually remains intact.[184] The infusion of platelet packs is not usually necessary when the platelet count exceeds 20,000/m^3 and the rest of the coagulation profile is normal. Marked reduction in platelet count is common. An increase in the platelet count usually begins within a few hours after the administration of CroFab™, but the platelet count may not return to normal for 7 days. In the presence of clinically significant bleeding, cryoprecipitate is indicated when the fibrinogen concentration decreases below 100 mg/dL. Hypofibrinogenemia is relatively resistant to the infusion of CroFab™.[185] Heparin is not effective for venom-induced coagulopathy because the thrombin-like glycoproteins in crotaline venom are not inhibited by antithrombin III (heparin cofactor).

Analgesia

Mild sedatives and analgesics (e.g., acetaminophen, codeine) are appropriate for anxiety and pain. More potent analgesics may be necessary (e.g., fentanyl, hydromorphone). Aspirin is contraindicated because of the effect of aspirin on platelet aggregation.

COMPARTMENT SYNDROME AND FASCIOTOMY

Most envenomations result in superficial rather than subfascial swelling, and muscle necrosis usually results from the direct toxic effects of venom on muscle rather than elevated muscle compartment pressure.[186,187] The blood flow usually increases in most envenomated extremities, and there are inadequate data to determine if the use of fasciotomy improves clinical outcome. The clinical diagnosis of a compartment syndrome is difficult because rattlesnake envenomation produces tense facial compartments and loss of two-point discrimination without the presence of a compartment syndrome. The presence of painful passive stretching of the involved compartment, distal and localized paresthesias, or persistent pain despite the use of parental analgesics and antivenom suggest the possibility of a compartment syndrome, particularly following the cessation of antivenom therapy.[188] The presence of muscle compartment pressures >30 mm Hg indicates the need for continued limb elevation and additional therapy. The use of additional doses of antivenom (e.g., 3–5 vials of CroFab™) and 1–2 g mannitol/kg is an option to fasciotomy if the compartment pressures are slightly elevated (i.e., 40–50 mm Hg). Surgical incisions and fasciotomies are treatment options *only* when there is objective evidence (i.e., compartment pressures >30 mm Hg for over 1 h, reduced Doppler flow) of vascular compromise that does not respond to adequate doses of antivenom and mannitol.[189] The effect of mannitol infusion on the enhancement of CroFab™ clearance has not been evaluated. Commercial compartment pressure monitors (e.g., Stryker, Kalamazoo, MI) are available for measurement of elevated compartment pressures in the arm, but there is no practical method for measuring compartment pressures in the digits. Measurement techniques include the use of needle manometer, slit catheter, or wick catheter. Variation in oxygen saturation as measured by pulse oximetry is not a sensitive measure of elevated compartment pressures.[190] Long-term complications of rattlesnake envenomations are rare with the exception of joint stiffness and muscle weakness.[191]

STEROIDS

Steroids should be reserved for those patients who develop serum sickness. No clinical data document an improvement in the clinical course of rattlesnake envenomation after the administration of steroids. Clinical features of serum sickness include malaise, fever, headache, gastrointestinal upset, arthralgias, myalgias, lymphadenopathy, skin lesions, and, less commonly, peripheral neuritis, meningismus, and renal dysfunction. Symptoms typically begin 7–14 days after the administration of antivenom, beginning with urticaria. Prednisone, 40–60 mg daily (1–1.5 mg/kg in children) in four divided doses for 2 to 3 days and then tapered over 7–10 days. Antihistamines are not usually effective.

Pygmy Rattlesnake and Massasauga

The *Sistrurus* genus (pygmy rattlesnakes, a.k.a. pigmy rattlesnakes) contains more primitive snakes compared with true rattlesnakes (*Crotalus*). The pygmy rattlesnake (*Sistrurus miliarius*) has a small, slender body that seldom exceeds 75 cm (~30 in.) in length. Like the massasauga, the pygmy rattler displays the characteristic dorsal head scales. The massasauga is distinguished from true rattlesnakes (*Crotalus* spp.) by nine large shields arranged in rows across the crown of the head, whereas rattlesnakes from the genus *Crotalus* have small crown scales. These shy and highly secretive snakes (*Sistrurus catenatus*) are the most gentle of the rattlesnake species. Generally, the massasauga inhabits bogs or swamps except during the summer when these snakes move to drier habitat. The desert massasauga (*S. catenatus* subspecies *edwardsi*) lives in the Sonoran desert region of the southwestern United States.

EXPOSURE

Geographical Distribution

The pygmy rattlesnake (*Sistrurus miliarius*) comprises three subspecies distributed over the southeastern United States from Texas to Florida (See Figure 176.8). The western pygmy (*Sistrurus miliarius* subsp. *streckeri*) rattlesnake ranges over Texas, Louisiana, and parts of Missouri, Arkansas, Tennessee, and Alabama. The Carolina pygmy rattlesnake (*Sistrurus miliarius* subsp. *miliarius*) is found from the Carolinas to Alabama. The southeastern pygmy (*Sistrurus miliarius* subsp. *barbouri*) appears in the Deep South. The massasauga (*Sistrurus catenatus*) species comprises three subspecies, which range from the Great Lakes to desert regions of the southwestern United States (see Figure 176.9). These ranges of these three subspecies include the following: from the desert to the Southwest (*Sistrurus catenatus* subsp. *edwardsi*); the western seaboard to the middle Midwest (*Sistrurus catenatus* subsp. *tergeminus*); the eastern seaboard to the Great Lakes region in marshy habitats and flood plains (*Sistrurus catenatus* subsp. *catenatus*).

Habitat/Characteristics

Generally, the snakes of this genus avoid human contact and these snakes are much more reclusive than the true

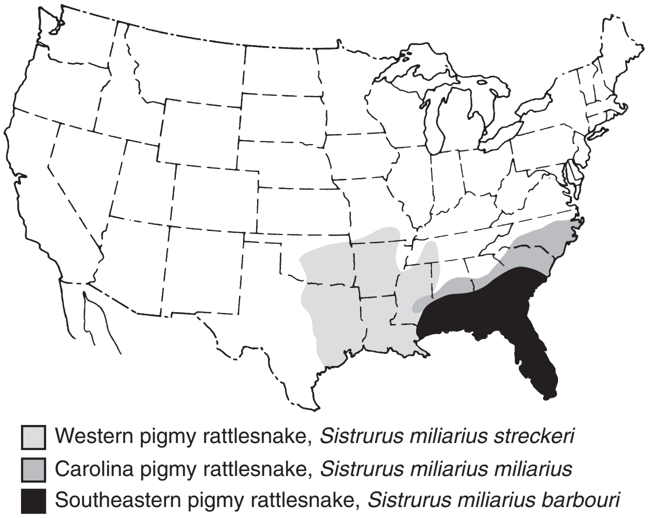

FIGURE 176.8. Distribution of pygmy rattlesnake. Adapted from Ellenhorn MJ, Barceloux DG. Medical Toxicology: Diagnosis of Human Poisoning. 1st Edition, New York: Elsevier, 1988:1124.

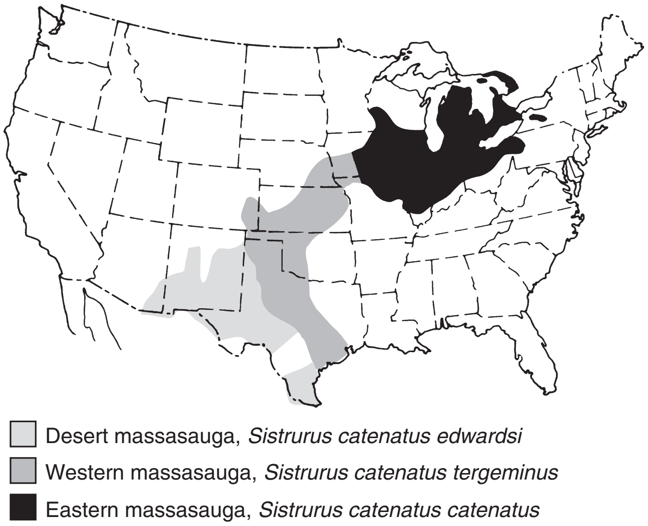

FIGURE 176.9. Distribution of the massasauga. Adapted from Ellenhorn MJ, Barceloux DG. Medical Toxicology: Diagnosis of Human Poisoning. 1st Edition, New York: Elsevier, 1988:1125.

rattlesnakes (*Crotalus*). The massasauga averages about 45–75 cm (18–30 in) in length with a slender tail and small rattles.

VENOM

The venom of the southeastern pygmy rattlesnake (*Sistrurus miliarius barbouri*) contains a unique component called barbourin, which inhibits platelet aggregation by binding to the platelet membrane glycoprotein IIb-IIIa receptor and preventing the binding of fibrinogen.[192] Eptifibatide is a cyclic heptapeptide inhibitor of platelet membrane glycoprotein IIb-IIIa receptor derived from barbourin that has undergone clinical trials as an antiplatelet drug for acute coronary syndromes.[193]

CLINICAL RESPONSE

The clinical presentation of envenomations by *Sistrurus* species is similar, but less severe, than envenomation by true rattlesnakes (*Crotalus* spp.). Often bites occur without envenomation and the clinical picture of *Sistrurus* envenomation frequently resembles envenomation by a copperhead rather than *Crotalus* species. Edema is usually mild, but hemorrhagic blebs frequently develop after massasauga envenomation. Some nausea may occur, but other systemic symptoms (vomiting, paresthesias, fasciculations) are unusual. Laboratory abnormalities are rare, but severe thrombocytopenia may develop.[194] Rarely, anuric renal failure may develop in envenomated patients with rhabdomyolysis, myoglobinuria, and coagulation abnormalities.[195]

TREATMENT

There are few clinical data on the use of antivenom for *Sistrurus* envenomations. In general, the management of *Sistrurus* envenomation follows protocols for *Crotalus* envenomations, with gradation of clinical symptoms and administration of CroFab™ or antivenom (Crotalidae) polyvalent as needed.[196] Most envenomations by *Sistrurus* species do not require the administration of antivenom.

Copperhead

Copperheads (*Agkistrodon contortrix*) account for about 25% of venomous snakebites in the United States. The head is solid copper to red brown. The rest of the body is marked with dark cross bands that resemble dumbbells. Highland moccasin is another common name. These snakes possess no rattles.

EXPOSURE

Five subspecies of *Agkistrodon contortrix* (copperhead) range from the eastern United States to southern Texas. The adult copperhead averages about 60–90 cm (24–30 in) in length. The head is copper-colored and the body is thick with reddish brown hourglass designs and no rattles. These snakes inhabit mountains and wooded hillsides as well as streams beds and lowlands in the

southern portion of the United States. Copperheads inflict a large portion (about 25–30%) of venomous snakebites, in part, because of their propensity to invade human living areas.[197] Along the Atlantic seaboard, copperhead bites are more common than rattlesnake bites. However, clinical effects from envenomation are usually less severe than other *Crotalus* bites because copperhead venom is the least venomous among North American pit vipers. The incidence of copperhead bite is highest in North Carolina, West Virginia, and Arkansas.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

In general, the venom of the copperhead contains relatively weak thrombin-like and anticoagulant activity compared with rattlesnakes.[198,199] Like rattlesnake venom, copperhead venom contains enzymes (fibrolase) that incompletely split fibrin and directly inactivate clot-stabilizing factors without activation of plasminogen.[200] Fibrolase is a zinc metalloproteinase that degrades the α-chain of fibrin and the Aα-chain of fibrinogen, but fibrolase does not activate plasminogen.[201] Alfimeprase is a recombinant product derived from a truncated form of fibrolase that possesses direct proteolytic activity against the fibrinogen Aα chain. Copperhead venom also contains a protein C activator. Disintegrins antagonize the effects of integrins, which are membrane-bound molecules that enhance cell movement by providing traction for migrating cells, by assembling extracellular matrices to serve as tracks for migration, and by transmitting guidance signals that direct cells or cell processes to their targets. Contortrostatin is a disintegrin found in the venom of the southern copperhead that has been tested in clinical trials as an agent to reduce the progression of breast cancer by inhibiting angiogenesis.[202] Contortrostatin does not destroy tumor cells.

CLINICAL RESPONSE

Envenomation by copperhead snakes typically produces mild to moderate effects secondary to local tissue reaction that are usually less severe than rattlesnake envenomations. Clinical features of a copperhead envenomation include edema, ecchymosis, and mild pain, and the pain may be out of proportion to local tissue injury. Pain and swelling may continue more than 4 hours after envenomation.[203] Lymphadenopathy occurs commonly, and occasionally with nausea and vomiting develops after envenomation. The clinical presentation of copperhead envenomations are similar between subspecies, although case reports of bites by the Southern copperhead (*A. contortrix contortrix*) suggest that this subspecies produces more severe systemic complaints (vomiting, diarrhea, hematuria) than other subspecies.[204] Systematic symptoms (e.g., fasciculations, paresthesias, coagulopathies, thrombocytopenia) are unusual, and severe envenomations are rare.[205] Most symptoms of copperhead envenomation resolve within one week, although occasionally pain, edema, limb dysfunction, and poor healing may last several months.[206] Death due to copperhead envenomation is rare.[207]

TREATMENT

There are limited data on the treatment of copperhead envenomation, in part, because most copperhead envenomations produce mild to moderate local effects without significant systemic toxicity. Antivenin (Crotalidae) polyvalent is effective against copperhead envenomations, but the administration of antivenom is usually necessary only for the presence of systemic complications in children or the elderly.[208,209] Although there are little clinical data on the use of CroFab™ for the local tissue effects following copperhead envenomation,[210] this antivenom is probably at least as efficacious and much less immunogenic than the Wyeth (Crotalidae) antivenom based on preliminary data.[211] Guidelines for the administration of CroFab™ following copperhead and rattlesnake evenomation are similar pending further data to clarify the benefits and risks associated with the use of CroFab™ for the alleviation of moderate local tissue effects. General wound care, first aid, and antivenom administration are similar to the treatment of *Crotalus* envenomations. The venom of *Agkistrodon* species contains fractions that may prolong neuromuscular blockage with anesthetic agents (e.g., vecuronium).[212]

Cottonmouth

Cottonmouths (water moccasins) account for about 1% of venomous snakebites in the United States. The common name, cottonmouth, reflects the white buccal mucosa characteristic of this species (*Agkistrodon piscivorus*).

EXPOSURE

Three species of cottonmouth are distributed across the semiaquatic environments of the southeastern United States. The usual habitat of the cottonmouth includes bayous, lakes, swamps, streams, drainage ditches, and

rice fields with the highest estimated bite rates occurring in Louisiana, Mississippi, Arkansas, Georgia and Florida.[213] Characteristics of this genus include a unique white buccal mucosa on a dark head, a broad heavy body, and the lack of a rattle on the tail. Mature members have a broad head and a dark olive color that provides camouflage in swampy marshes. The cottonmouth shares the features of pit viper characteristics with rattlesnakes. Cottonmouths are capable of envenomating victims while submerged.

CLINICAL RESPONSE

Cottonmouth bites produce an envenomation intermediate in severity between those of rattlesnakes and copperheads. The clinical manifestations should be graded similarly to rattlesnake envenomation.

TREATMENT

Although there are few data on the clinical efficacy of CroFab™ after envenomation by the cottonmouth, this antivenom contains antibodies to cottonmouth venom formed during the production process. The clinical grading and indications for CroFab™ use during cottonmouth envenomation is similar to the use of CroFab™ during rattlesnake envenomation. However, the frequency and dose required to treat cottonmouth envenomation is less than rattlesnake envenomations.

CENTRAL AND SOUTH AMERICA

EXPOSURE

The most important venomous snakes in Central and South America belong to the Crotalinae subfamily.[214,215] The pit vipers are distributed throughout Central and South America including species from the genera *Atropoides*, *Bothriechis*, *Bothrops*, *Cerrophidion*, *Ophryacus*, and *Porthidium*. Central American venomous crotaline snakes include rattlesnakes (*Crotalus* spp.), cantil (*Agkistrodon* spp.), palm pit vipers (*Bothriechis* spp.), forest pit vipers, and lanceheads (*Bothrops* spp.), bushmaster (*Lachesis muta*), and the hog-nosed and montane pit vipers (*Porthidium*, *Atropoides*, and *Cerrophidion* species).[216] *Bothrops atrox* inhabits most of the northern part of South America. The heads of these pit vipers are distinctly wider than the necks. *Bothriechis schlegelii* (palm pit viper) is an arboreal snake in the rain forests, whereas *Bothrops jararaca* (Jararacucu) is a long, wide-bodied, terrestrial snake of the savanna in South America from Brazil to southern Bolivia, Paraguay, and northeastern Argentina. The bushmaster (*Lachesis muta*) is the largest viper in the world with a length up to 3 m (~10 ft). The tail ends in a horny spine rather than the terminal rattles present in crotalids. This timid snake lives in the undergrowth of tropical rain forests from Nicaragua to South America. In South America, the representative of the Crotalinae subfamily is *Crotalus durissus terrificus*, and these crotalines prefer secluded dry, rocky areas. Bite marks of crotalines typically demonstrate isolated single or double puncture wounds, but the presence of these marks does not necessarily indicate envenomation.[217]

VENOM

The venom of pit vipers produces hemorrhage and tissue necrosis from the presence of highly active proteases (e.g., zinc metalloproteinases) and thrombin-like enzymes. High concentrations of hemorrhagic proteases occur in the venoms of pit vipers, particularly *Protobothrops flavoviridis*. These proteinases act on basal membranes causing disruption of the endothelial lining of the small blood vessels. The thrombin-like enzymes split fibrinopeptide A or B from fibrinogen, leading to a consumptive coagulopathy. Some crotaline venoms contain muscle toxins (e.g., crotamine) that produce skeletal muscle damage and rhabdomyolysis.[218,219] Aspercetin is a disulfide-linked heterodimer that is a platelet-aggregating protein isolated from the venom of *Bothrops asper*.[220] Aspercetin-mediated platelet aggregation results from the interaction of von Willebrand factor with platelet glycoprotein receptor Ib (GPIb), and this protein has functional similarities to botrocetin from *Bothrops jararaca* venom. The venom of *Crotalus durissus terrificus* (South American rattlesnake) contains a neurotoxin (crotoxin) that blocks presynaptic neuromuscular transmission via phospholipase A_2. This neurotoxin is similar to the neurotoxin in the Mojave rattlesnake (*Crotalus scutulatus scutulatus*).

CLINICAL RESPONSE

Pit viper envenomations produce the rapid onset of edema and pain that may progress to hemorrhagic vesicles and necrosis along with variable degrees of a coagulopathy. The clinical pattern of envenomation by Central and South American pit vipers is generally similar to North American rattlesnake evenomation, and the severity of envenomation depends on a variety

of factors including the potency and amount of venom injected, the health of the victim, the pit viper species, and the size of the snake. Similar to North American rattlesnakes, some bites by South American pit viper do not result in envenomation. In a study of 41 bites by the South American rattlesnake (*Crotalus durissus*), 12% of the victims did not develop signs or symptoms of envenomation.[221]

Particularly after envenomation by lance-headed viper (*Bothrops* spp.), a consumption coagulopathy may develop with hemorrhagic vesicles, local and intraoral bleeding, hematuria, hypotension, hypofibrinogenemia, fibrin-split products, and prolonged coagulation profiles. Necrosis, gangrene, rhabdomyolysis, myoglobinuria, and acute renal failure may complicate pit viper envenomations, particularly bites by the South American rattlesnake (*Crotalus durissus terrificus*),[222] bushmaster (*Lachesis* species),[223] and lance-headed vipers (*Bothrops* spp.).[224] The venom of the *Bothrops jararaca* contains relatively higher concentrations of muscle toxins, and therefore these envenomations commonly cause rhabdomyolysis and myoglobinuria in addition to necrosis and coagulopathy compared with other *Bothrops* species (e.g., *B. neuwiedii*).[225,226] Envenomation by *Lachesis* species (Bushmaster) produces vomiting, profuse diarrhea, diaphoresis, salivation, hypotension, bradycardia and respiratory distress. In contrast to North American crotalids, envenomations by some South American rattlesnakes (e.g., *Crotalus durissus*) also produce neurological symptoms similar to elapid envenomation including myalgias, weakness, ptosis, ophthalmoplegia, dysarthria, and dysphagia that progresses to respiratory failure.[227,228] The prevalence of cerebrovascular complications (intracerebral hemorrhage, subarachnoid bleed, cerebellar hemorrhage) following envenomation by *Bothrops* species is low, but the prognosis for patients with intracranial bleeding is poor in most, but not all patients.[229] Envenomations by *Bothriechis* species (arboreal snakes) and montane pit vipers (*Cerrophidion* spp.) are usually less severe than lanceheaded vipers and the South American rattlesnakes.

TREATMENT

The local treatment of South American pit viper envenomations is similar to the treatment of North American rattlesnakes (see section North America, subsection *True Rattlesnakes*). First aid treatment includes rest, reassurance, immobilization of the bitten extremity at or below the heart, and rapid transport to medical facilities. Moderate to severe envenomations require the intravenous administration of antivenom. Although there are some antigenic similarities between venoms of different species of pit vipers, there is clinically significant variability between venoms from various pit viper species and subspecies.[230,231] Consequently, antivenom developed from the specific area where the envenomation occurred is usually preferable, if available, to polyvalent antivenom. A comparative study of patients receiving Colombian, Ecuadorian, and Brazilian antivenom for pit viper (i.e., *Bothrops* species, *Lachesis muta*) envenomations detected little difference in the efficacy of these three types of antivenom, although the incidence of early anaphylactoid reactions were higher for the Colombian and Brazilian antivenom than for the Ecuadorian antivenom.[232] Crotalidae polyvalent antivenom with antibodies against venom from the tropical rattlesnake (*Crotalus durissus terrificus*) and fer-de-lance (*Bothrops atrox*) has been used successfully for the treatment of envenomation by the hog-nosed viper (*Porthidium nasutum*).[233] Victims with clinically significant envenomations should be evaluated for rhabdomyolysis (serum creatinine, urine myoglobin, serum creatine phosphokinase, serum electrolytes) and coagulation abnormalities (fibrin split products, fibrinogen, complete blood count, prothrombin time, activated partial thromboplastin time). Antibiotics are not usually require unless the wound is heavily contaminated or a secondary infection (e.g., *Aeromonas hydrophilia, Staphylococcus, Streptococcus, enterobacteria*) is suspected.[234,235]

ASIA

EXPOSURE

Table 176.10 lists common Asian pit vipers. The Old World Asian pit vipers are not closely related to the New World pit vipers (*Agkistrodon*), and therefore the Asian pit vipers are no longer classified in the genus *Agkistrodon*. The Asian counterparts of the South American lance-headed vipers (*Bothrops* spp.) are the Asian lance-headed vipers, tree vipers, and bamboo vipers (*Trimeresurus* spp., *Ovophis* spp., *Protobothrops* spp., *Tropidolaemus wagleri*). Well-known *Trimeresurus* species include *T. albolabris* (white-lipped tree viper), *T. flavoviridis* (habu), *T. gramineus* (green tree viper), and *T. stejnegeri* (Chinese green tree viper). Figure 176.10 displays a specimen of the Mangrove pit viper (*Trimeresurus purpureomaculatus* Gray) from India and Southeast Asia. Representatives of the New World *Agkistrodon* species in Asia include the Malayan pit viper (*Calloselasma rhodostoma*), Asian pit vipers (*Gloydius* spp.), and hundred-pace or sharp-nosed pit

TABLE 176.10. Important Venomous Asian Pit Vipers[a]

Species	Common Name	Description	Distribution	Habitat
Calloselasma rhodostoma Boie	Malayan pit viper	Wide-bodied snake up to 1.5 m (~5 ft) with distinctive pit between eyes and nostrils and variable dark triangular markings.	Malayan peninsula and Indonesia	Humid rain forests, rice fields, plantations
Deinagkistrodon acutus Günther	Sharp-nosed pit viper	Heavy-bodied snake with variable coloration, pits between nostrils and eyes, and triangular markings	China	Terrestrial
Gloydius spp.	Mamushi, Himalayan pit viper, Central Asian pit viper	Heavy-bodied snake with variable coloration, pits between nostrils and eyes, and triangular markings	Central Asia/Middle East to Japan	Widespread distribution—dry deserts to cool mountain areas up to 3,000 m (~10,000 ft)
Hypnale hypnale Merrem	Hump-nosed viper	Heavy-bodied snake with variable coloration, pits between nostrils and eyes, and triangular markings	South India, Sri Lanka	Terrestrial
Protobothrops elegans Gray	Japanese lace-headed viper, Sakishima-habu	Monochromatic large yellow eyes with highly variable coloration ranging from green yellow to brown with light markings.	Japan	Arboreal in trees and bushes
Tropidolaemus wagleri Wagler	Wagler's or temple pit viper	Large triangular shaped head with a wide variety of colors, a relatively thin body, and a prehensile tail to aid climbing	Malaysia	Arboreal in trees and bushes
Protobothrops flavoviridis Hallowell	Habu	Large, heavy-bodies snake up to 2 m (~5–6 ft) in length.	Southern Asia	Terrestrial in forests, mangrove areas

viper (*Deinagkistrodon acutus*). The most common envenomations by snakes in Taiwan involve *Trimeresurus mucrosquamatus* and *Trimeresurus stejnegeri*,[236] whereas the most common pit viper envenomations in South Vietnam involve the green pit viper (*Trimeresurus* spp.) and the Malayan pit viper (*Calloselasma rhodostoma*).[237] Bites by *Deinagkistrodon acutus* occur primarily in southern and eastern Taiwan. These pit vipers have retractable fangs. The hump-nosed viper is one of the smallest venomous snakes in India with a total length below 55 cm (~22 in.). Distinctive features include five large symmetrical plate scales on the triangular head and weakly keeled body scales.

VENOM

Clotting enzymes and hemorrhagic factors are the most important constituents of the venom from Asian pit vipers. The venom of the Malayan pit viper (*Calloselasma rhodostoma*) directly lyses fibrinopeptide A from fibrinogen to form fibrin similar to effect of thrombin. A purified fraction of venom from the Malayan pit viper *Calloselasma rhodostoma* is called ancrod, which contains a serine protease capable of cleaving fibrinopep-

tide A from fibrinogen that produces a hemorrhagic defibrination coagulopathy. This fraction of the venom acts as cofactor in tPA-induced plasminogen activation, leading to the production of large amounts of fibrinogen and fibrin degradation products (D-dimer).[238] The venom of *Gloydius halys* Pallas contains metalloproteinase-like prothrombin activators similar to the venom of South American fer-de-lance (*Bothrops atrox*).[239]

CLINICAL RESPONSE

Envenomations by Asian pit vipers produce local pain and swelling along with varying degrees of coagulopathy. Typically, envenomation by the humped-nose viper (*Hypnale hypnale)* produces signs of local envenomation manifested by pain, swelling, and induration at the site of the bite that occasionally progresses to hemorrhagic blister formation and regional lymphadenopathy.[240] Signs of systemic envenomation are rare, but severe envenomation (renal failure, coagulation disorder with low fibrinogen concentrations, and increased fibrin degradation products) may occur.[241,242] Platelet counts, prothrombin time, and the partial thromboplastin time are usually normal.[243] Characteristic features of envenomation by *Deinagkistrodon acutus* (hundred-pace viper), *Gloydius* species, *Trimeresurus* species, and *Protobothrops* species include extensive swelling and hemorrhage at the site of envenomation progressing to necrosis along with various degrees of a consumption coagulopathy. Envenomation by arboreal green pit vipers (*Trimeresurus albolabris, T. macrops* Kramer) often causes only painful local edema and mild coagulation abnormalities (thrombocytopenia, prolonged clotting times). Occasionally internal bleeding may result from a defibrination syndrome manifest by low fibrinogen concentrations and elevated fibrin degradation products.[244,245] Bites by the Malayan pit viper cause local tissue damage that often resolves over 1–2 weeks.[246] However, the venom of the Malayan pit viper induces plasmin formation, and the resulting clinical effect following *Calloselasma* envenomation is a defibrination syndrome. Bites by the mamushi pit viper (*Gloydius halys*) usually produce local symptoms without serious systemic complications.[247] However, in addition to local tissue damage, envenomations by *Gloydius halys* may produce blurred vision, ptosis, diplopia, difficulty in opening the mouth, dysphonia, dysphagia, generalized weakness, and in severe cases hemoglobinuria, disseminated intravascular coagulopathy, renal failure, and respiratory failure.[248–250]

TREATMENT

Treatment of Asian pit viper envenomation is similar to crotaline envenomation. Most envenomations require antivenom with the exception of some tree vipers (*Trimeresurus* species). These latter envenomations are usually mild similar to European vipers, and antivenom is not usually necessary unless the envenomation is associated with a significant coagulopathy. Envenomation by the hump-nosed viper (*Hypnale hypnale*) may not require polyvalent antivenom unless the envenomation is associated with systemic complications, and there is no specific polyvalent antivenom for envenomation by this viper.[251] The specificity and efficacy of antivenom varies with different localities and species. The antivenom should be administered intravenously as soon as possible within four to six hours after envenomation.[252] Coagulation profiles and complete blood count should be followed serially until the parameters substantially improve. The presence of dark urine indicates the need to evaluate the patient for myoglobinuria, hematuria, and renal dysfunction. Generous intravenous fluid replacement should be administered to maintain adequate urine flow if rhabdomyolysis occurs.

ELAPIDS

The family **Elapidae** is divided into the following three subfamilies: 1) **Elapinae** (North American coral snakes [*Micrurus*], Asian and African cobras [*Naja*], Asian kraits [*Bungarus*] and coral snakes [*Calliophis*, *Maticora*], African mambas [*Dendroaspis*], and all venomous snakes in Australia (See Table 176.11 and Table 176.12), 2) **Hydrophiinae** (sea snakes), and 3) **Laticaudinae** (sea kraits).[253,254] In contrast to vipers, elapids have more slender bodies, less triangular heads, and fewer body scale rows. Elapid fangs are usually smaller in proportion to body size compared with vipers. Although some Australian elapids possess potent myotoxins and procoagulants, most elapid venoms contain primarily postsynaptic neurotoxins.

NORTH AMERICAN CORAL SNAKES

EXPOSURE

Two genera of poisonous coral snakes (*Micrurus, Micruroides*) represent the cobra family in the United States. Coral snakes are slender snakes ranging between 2 ft and 4 ft (~60–120 cm)with brightly colored, circumferen-

TABLE 176.11. Scientific and Common Names of Venomous Coral Snakes and Cobras from the Family Elapidae[a]

Group Name	Scientific Name	Common Name
Coral Snakes		
	Calliophis spp.	Oriental coral snake
	Micruroides euryxanthus Kennicott	Sonoran or Western coral snake
	Micruroides euryxanthus euryxanthus Kennicott	Arizona coral snake
	Micrurus frontalis Duméril, Bibron & Duméril	Brazilian giant coral snake
	Micrurus fulvius L.	Northern coral snake
	Micrurus tener Baird & Girard	Texas coral snake
Cobras		
	Boulengerina species	Water cobras
	Hemachatus haemachatus Lacépède	Rinkhals cobra
	Naja anchietae Bocage	Anchita's cobra
	Naja atra Cantor	Taiwan or Chinese Cobra
	Naja haje L.	Egyptian or brown cobra
	Naja katiensis Angel	Western brown spitting or Mali cobra
	Naja kaouthia Lesson	Monocled or Thai cobra
	Naja melanoleuca Hallowell	Forest or black, white-lipped cobra
	Naja mossambica Peters	Spitting cobra
	Naja naja L.	Indian cobra or Cobra de Capello
	Naja nigricollis Reinhardt	Black-necked spitting cobra
	Naja nivea L.	Cape or yellow cobra
	Naja oxiana Eichwald	Central Asian cobra
	Naja pallida Boulenger	Red spitting cobra
	Naja philippinensis Taylor	Philippine cobra
	Naja sagittifera Wall	Indian cobra
	Naja siamensis Laurenti	Indochinese spitting cobra
	Naja sputatrix Boie	Malayan cobra
	Naja sumatrana Müller	Equatorial spitting cobra
	Ophiophagus Hannah Cantor	King cobra
	Paranaja multifasciata Werner	Burrowing cobra
	Pseudohaje goldii Boulenger	African tree cobra, Gold's tree cobra
	Pseudohaje nigra Günther	Hoodless cobra
	Walterinnesia aegyptia Lataste	Desert blacksnake or black desert cobra

[a]Source: Adapted from Ref 1.

tial rings on their body. In North America, the coral snake's red and yellow rings are contiguous, whereas nonvenomous North American snakes have a black ring separating the red and yellow rings. The following mnemonic describes the difference between coral snake and nonpoisonous snakes: "Red on yellow, kill a fellow; red on black, good for Jack."

In contrast to pit vipers, coral snakes have round pupils, fixed fangs, small heads, and no facial pits. Generally, coral snakes are docile, preferring to chew rather than bite with their fixed fangs. The classification of coral snake remains controversial. The three species of coral snakes in the United States are *Micruroides euryxanthus* Kennicott (Sonoran or Western coral snake), Texas coral snake (*Micrurus tener* Baird & Girard) and the Northern coral snake (*Micrurus fulvius* L.). Subspecies of the Sonoran coral snake include *Micruroides euryxanthus australis* Zweifel & Norris, *Micruroides euryxanthus euryxanthus* Kennicott (Arizona coral snake), and *Micruroides euryxanthus neglectus* Roze. Subspecies of the Texan coral snake include *Micrurus tener fitzingeri* Jan, *M. tener maculatus* Roze, *M. tener microgalbineus* Brown & Smith, and *M. tener tener* Baird & Girard.

Geographic Distribution

Coral snakes (*Micrurus* spp., *Micruroides* spp.) range from the southeastern United States to central Argentina, and these snakes have adapted to a variety of habitats from desert areas to tropical rain forests. The Northern coral snake (*Micrurus fulvius* L.) inhabits the southeastern United States from Arkansas to Florida, whereas the Texas coral snake (*Micrurus tener* Baird & Girard) lives in Texas, Louisiana, Arkansas, and Northern Mexico. The Western or Sonoran coral snake

TABLE 176.12. Australian, Asian, and Other Elapids[a]

Australian and Pacific Elapids		
	Acanthophis antarcticus Shaw	Common death adder
	Acanthophis praelongus Ramsey	Northern death adder
	Acanthophis pyrrhus Boulenger	Desert death adder
	Acanthophis rugosus Loveridge	Jayan death adder
	Acanthophis wellsi Hoser	Pilbara or black head death adder
	Austrelaps labialis Jan	Pygmy copperhead
	Austrelaps ramsayi Krefft	Highland copperhead
	Austrelaps superbus Günther	Lowland copperhead
	Demansia Psammophis Schlegel	Spotted-headed snake
	Hoplocephalus bitorquatus Jan	Pale headed snake
	Hoplocephalus bungaroides Schlegel	Broad-headed snake
	Hoplocephalus stephensii Krefft	Stephen's banded snake
	Notechis scutatus Peters	Tiger snake
	Oxyuranus microlepidotus McCoy	Inland Taipan
	Oxyuranus scutellatus Peters	Taipan
	Pseudechis australis Gray	King brown or Mulga snake
	Pseudechis butleri Smith	Butler's mulga snake
	Pseudechis colletti Boulenger	Collett's snake
	Pseudechis guttatus De Vis	Spotted or blue bellied black snake
	Pseudechis papuanus Peters & Doria	Papuan black snake
	Pseudechis porphyriacus Shaw	Red-bellied black snake
	Pseudonaja affinis Günther	Dugite
	Pseudonaja guttata Parker	Speckled brown snake
	Pseudonaja inframacula Waite	Peninsula brown snake
	Pseudonaja ingrami Boulenger	Ingram's brown snake
	Pseudonaja nuchalis Günther	Western brown snake
	Pseudonaja textilis Duméril, Bibron & Duméril	Eastern brown snake
	Rhinoplocephalus nigrescens Günther	Eastern small-eyed snake
	Tropidechis carinatus Krefft	Rough-scaled snake
Other Elapids		
	Bungarus caeruleus Schneider	Indian or Blue (common) krait
	Bungarus candidus L.	Malayan krait
	Bungarus fasciatus Schneider	Banded krait
	Bungarus multicinctus Blyth	Formosan or Chinese krait
	Dendroaspis angusticeps Smith	Eastern green mamba
	Dendroaspis jamesoni Traill	Jameson's or green mamba
	Dendroaspis polylepis Günther	Black mamba
	Dendroaspis viridis Hallowell	Western green mamba

[a]Source: Adapted from Ref 1.

(*Micruroides euryxanthus* Kennicott) is found in the southwestern United States (Arizona, New Mexico, Northern Mexico).

Habitats/Characteristics

In contrast to *Crotalus* species, coral snakes possess black snouts and round pupils. There are no facial pits or rattles. North American coral snakes have small round heads and eyes, fixed fangs, and tricolor, slender bodies consisting of black and red bands separated by yellow or white stripes. The black bands on coral snakes are wide and circumferential, whereas black bands on scarlet king snakes are usually narrow and do not encircle the body. Coral snakebites produce a row of teeth marks rather than individual fang marks because the coral snake needs prolonged contact (i.e., approximately 30 s) to infuse their venom into the skin. This shy, nocturnal snake avoids human contact, and most bites result from provocation of the snake. Bites from coral snakes are relatively rare, accounting for <1% of annual poisonous snakebites in the United States. Coral snakebites are often superficial, leading to a lower rate of envenomation compared with rattlesnake bites. The coloration of coral snakes varies more in Central and South America than in the United States; therefore, the dif-

ferentiation of coral snakes from nonvenomous snakes is difficult in Central and South America.

VENOM

Coral snake venom is primarily a neurotoxin and causes little local tissue reaction. Because of the more primitive venom apparatus, envenomation is less common following coral snakebites than following *Crotalus* snakebites. All elapids, including coral snakes, have a venom apparatus with proteroglyphous dentition characterized by large recurved, front-fangs and an *almost-closed* venom groove that terminates near the tip of the fang. Injection of venom requires pressure on the venom gland created by surrounding muscle. Effective envenomation by a coral snake requires several seconds to allow the venom to flow down the grooves on the anterior fangs. The teeth of the coral snake are small, averaging about 2 mm (~0.1 in.) in length. The bite marks are usually obvious with minor bleeding from the puncture wounds, but occasionally the teeth marks may be absent.[255] Neurologic toxicity (i.e., blockade of neuromuscular transmission) results from the competitive, nondepolarizing blockade of nicotinic acetylcholine receptors at the neuromuscular junction similar to cobra neurotoxin and α-bungarotoxin (Formosan krait).[256] Elapid venom typically affects peripheral nerves rather than the central nervous system because the neurotoxins do not penetrate the blood–brain barrier. The acetylcholinesterase activity of coral snake venom is limited compared with some other elapid venoms. Envenomations by Eastern and Texas coral snakes produce more severe neurotoxic effects compared with the Arizona coral snake.[257] Elapid venoms contain few proteases compared with viperid venoms.

CLINICAL RESPONSE

Approximately 25–40% of the bites from coral snakes do not cause envenomation, but even following envenomation local signs of envenomation may be absent.[258] Although minor pain may occur at the bite site, local edema, erythema, and pain are usually minimal.[259] Typically, the onset of neurological effects occurs several hours after envenomation with the development of ptosis, but envenomation by the Eastern coral snake may cause neurological symptoms up to 12 hours after envenomation.[258] The clinical features of coral snake envenomation include cranial nerve palsies (dysphagia, drooling, dysarthria, ptosis) followed by limb weakness, loss of deep tendon reflexes, dyspnea, and respiratory paralysis. Euphoria, lightheadedness, and drowsiness are early symptoms of envenomation. Fasciculations, tremor, muscle weakness, increased salivation, nausea, and vomiting also occur. Neurological symptoms may progress to bulbar palsy and respiratory depression within 10 hours after envenomation, manifested by diplopia, dysarthria, drooling, slurred speech, ptosis, dysphagia, and dyspnea. Seizures are uncommon, but convulsions may occur, particularly in small children.[260] Signs of bulbar palsy usually, but not always, precede the development of respiratory failure. Envenomation by the Arizona coral snake causes headache, blurred vision, abdominal pain, and gait disturbances, but these neurological symptoms are not usually as severe as envenomations by the Eastern coral snakes.[261] In a retrospective case series of bites by the Texas coral snake (*Micrurus tener*), systemic symptoms were reported in only 7% of the cases and none of the symptoms were life-threatening.[262] Over one-half of these patients received coral snake antivenom. Following severe envenomations, case reports suggest that muscle weakness and paresthesias may persist for several weeks, particularly in patients without antivenom therapy. Cardiac and hematological effects are usually minimal following envenomation by coral snakes, and laboratory abnormalities are typically none to minimal.

TREATMENT

First-Aid

The patient should be transported to an emergency medical facility as soon as possible. Capture of the snake is helpful to identify the species, provided the snake can be captured safely with minimal risk to the rescuer. *Ineffective* first aid measures include giving ethanol to the victim, the use of tourniquets, and the utilization of incision and drainage. The wound should be washed with soap and water as soon as possible to remove any remaining venom on the skin.

Antivenom

North American coral snake (*Micrurus fulvius* L.) antivenom (Wyeth Pharmaceuticals, Collegeville, PA) is an effective, lyophilized, equine-based antivenom produced by the immunization of healthy horses with Northern coral snake (*Micrurus fulvius* L.) venom. Indications for this antivenom include the following clinical situations: 1) confirmed Texas and Eastern coral snake envenomations (i.e., bite marks or prolonged contact with coral snake) with neurological symptoms, and 2) patients with suspected coral snakebite and early neurological symptoms of envenomation (lethargy, muscle weakness, ptosis, dyspnea). Results of cross-neutralizations tests indicate that this antivenom is not effective for envenomations by the Western or Sonoran coral snake (*Micru-*

roides euryxanthus Kennicott). Although the clinical effects of some coral snakebites produce only local reactions, there are few data on the clinical course of these envenomations without antivenom. The antivenom should be administered before the development of the bulbar palsy (i.e., within 4–8 hours of the bite) because the antivenom does not reverse preexisting neurotoxicity.[263,264] Precautions for the development of hypersensitivity responses include intravenous access, slow initial titration of the antivenom, and the immediate availability of epinephrine and H_1- and H_2-histamine receptor blockers, similar to the administration of other equine antivenom (e.g., antivenin [Crotalidae] polyvalent). The efficacy of skin testing is controversial because of the false-positive and false-negative tests and the delay in administering antivenom. Skin testing involves the intradermal injection of 0.02–0.3 mL of a 1:10 dilution of normal horse serum or antivenom along with an intradermal control test on the opposite extremity with a similar amount of sodium chloride. A positive test occurs when a wheal develops within 5–30 minutes with or without pseudopodia and surrounding erythema.

Approximately 5–10 vials of antivenom should be administered in 250–500 mL of normal saline over 1–2 hours with the actual dose depending on the potential severity of the envenomation. The initial infusion should be slow (3–5 mL/h over the first 5 minutes) with the infusion increased in the absence of adverse effects.[265] If neurological signs worsen, an infusion of an additional 3–5 vials of antivenom should be given. The administration of coral snake antivenom does not rapidly reverse the clinical features of coral snake envenomation; therefore, the patient should be monitored closely for signs of respiratory failure. Urticaria is the most common adverse effect during the administration of coral snake antivenom, and the urticaria usually resolves after slowing of the antivenom infusion and the use of diphenhydramine.[258] The administration of coral snake antivenom to envenomated patients with a positive skin test requires careful evaluation of the potential seriousness of the envenomation and the benefits of early treatment. Severely envenomated patients have survived without antivenom following the use of supportive care with early elective intubation.

Experimental studies suggest that Fab-based ovine antivenom preparations are less immunogenic than the Wyeth antivenom,[266] but the ovine preparation is not commercially available. Rodent studies suggest that the use of Mexican *Micrurus* antivenom (Instituto Bioclon, Mexico City, Mexico) and Tiger Snake (*Notechis scutatus*) antivenom (CSL Limited, Parkville, Victoria, Australia) reduces lethality in mice envenomated by the Northern coral snake (*Micrurus fulvius* L.).[267] However, there are few human data on the clinical effectiveness of these antivenoms for envenomations by US coral snakes. In general, immunochemical assays suggest that antivenoms demonstrate greater reactivity toward venoms from geographically related snakes.[268] There is no commercial antivenom available for the Arizona or Sonoran coral snake (*Micruroides euryxanthus*), but symptoms following envenomation from snakes in this genus are usually mild. In the US, an antivenin index is available from the American Zoo and Aquarium Association (301-562-0777) or the American Association of Poison Control Centers (800-222-1222). Otherwise, treatment is supportive.

Supplemental Care

Respiratory failure is the major life-threatening complication of coral snake envenomation. All victims of coral snake envenomations should be carefully observed for at least 24–48 hours for signs of bulbar palsy (ptosis, diplopia on upward gaze, dysphagia) and impending respiratory failure. Rhabdomyolysis may develop in patients with severe envenomation. Serum sickness may develop 7–14 days after the administration of antivenom similar to that following administration of antivenin (Crotalidae) polyvalent, although the incidence is lower (approximately 10%). Treatment of serum sickness is similar (i.e., corticosteroids) to the regimen outlined for serum sickness following crotalid envenomations.

CENTRAL AND SOUTH AMERICA

The main venomous representatives of the family Elapidae in Central and South America are the coral snakes (*Micrurus* spp., *Micruroides* spp., *Leptomicrurus* spp.). These small snakes are distributed throughout tropical and subtropical Central and South America, but bites are relatively rare because of their reclusive habits. Their wide-ranging locations include seclusion in rocky desert environments and submersion under leaves in forest habitats. Many snake species mimic the red-yellow-black coloration of most coral snakes. However, some coral snakes are bicolored, and differentiation of coral snakes from nonvenomous snakes may be difficult for Central and South American coral snakes. The venom apparatus of coral snakes and other elapids are similar with two fixed, grooved, front fangs up to a few millimeters in length. Bite marks are usually present, but the bite marks from these small fangs frequently are difficult to detect. The venom of coral snakes contains neurotoxins that block neuromuscular transmission at

the postsynaptic membrane. These venoms are low in tissue-toxic enzymes (e.g., proteinases, phosphodiesterases, and 5′-nucleotidase activity); consequently, local tissue damage is minimal.

The rapid onset of local pain may develop following coral snake envenomations.[269] Localized swelling usually is present, but necrosis does not usually occur. Neurological symptoms of envenomation are similar to other elapids, manifest by paresthesias, weakness, ptosis, ophthalmoplegia, dysphagia, and dysarthria that progresses to respiratory failure. These symptoms may be delayed up to 12 hours. Other symptoms include metallic taste, myalgias, fasciculations, lightheadedness, nausea, and vomiting. First aid involves rest, reassurance, sitting-up to minimize respiratory difficulty, and rapid transport to medical facilities for the intravenous administration of monovalent antivenom. Treatment is similar to the treatment of envenomation by North American coral snakes. All patients should be observed for at least 24 hours.

MIDDLE AND NEAR EAST/AFRICA

Geographically, the Middle East includes Asian Turkey, Lebanon, Syria, Jordan, Israel, Palestine, Saudi Arabia and the Arabian Peninsula, Iraq, Iran, and the former Southern Asiatic Soviet Republics. This region is predominantly arid, and vipers are the most common cause of serious snakebites in these areas. Elapids are present in restricted ranges, primarily in areas close to northern Africa. Venomous members of the family Elapidae in the Middle East include the Egyptian cobra (*Naja haje*) and the desert black snake or desert cobra (*Walterinnesia aegyptia*). Spitting cobras include *Naja nigricollis*, *N. mossambica*, *N. pallida*, *N. katiensis*, and *Hemachatus haemachatus*. Mambas (*Dendroaspis* spp.) and cobras (*Naja* spp.) are the most important venomous elapid species in Africa (see Table 176.13). Most of these snakes exhibit warning sounds (e.g., cobras lift their head and neck). Although some cobras (*Naja melanoleuca*, *Hemachatus haemachatus*) are nocturnal, most elapids are diurnal and active at dawn. Mambas are predominately arboreal and diurnal. Nonspitting cobras and mambas produce highly potent neurotoxic venoms that act on postsynaptic membranes of the motor nerve endplates similar to curare. The venom of the desert cobra (*Walterinnesia aegyptia*) contains at least three neurotoxins that block neuromuscular transmission postsynaptically.[270] Most elapid venoms contain acetylcholinesterases including the desert cobra.[271] Mamba venom also contains potent neurotoxins called dendrotoxins that inhibit voltage-gated KV1.1, KV1.2, and KV 1.6 potassium channels and block muscarinic receptors.[272] Fasciculin is a peptide that inhibits acetylcholinesterase and produces muscle fasciculations.

Clinical features of envenomation by nonspitting cobras and mambas involve primarily peripheral neuro-

TABLE 176.13. Important African, Middle Eastern, and Near Eastern Venomous Elapids[a]

Species	Common Name	Description	Distribution	Habitat
Naja species	Cobra	Large, heavy bodied up to 1–3 m (~3–10 ft) with characteristic defensive posture of forming round hood from spreading cervical ribs	*N. haje*: Africa to Middle East *N. melanoleuca*: West to South African forests *N. nigricollis*: South of Sahara *N. mossambica*: Southern Africa *N. pallida*: Southern Africa *N. nivea*: Western South Africa *N. katiensis*: West Africa *Hemachatus haemachatus*: South Africa *Walterinnesia aegyptia*: North Africa to Middle East/Iran	Terrestrial habitat of rain forests, swamps, river beds to dry savannah and mountain areas
Dendroaspis species	Mamba	Agile, slender, long snake up to 4 m (~13 ft) that retreats quickly when disturbed	*D. angusticeps*: Coastal Eastern to Southern Africa *D. jamesoni*: Central Africa *D. polylepis*: Eastern and South Africa *D. viridis*: West Africa	Black mambas are primarily terrestrial (wooded savannah, rocky hills, riverine forests), but they may climb trees. Green mambas are almost exclusively arboreal.

[a]Source: Adapted from Ref 2.

logical symptoms including slurred speech, dysphagia, ptosis, and ophthalmoplegia. Symptoms usually develop within 1 hour of envenomation and may progress to paralysis and to respiratory failure. Envenomation by mambas cause the rapid onset of perioral and generalized paresthesias, nausea, vomiting, hypersalivation, and hyperacusis followed by generalized weakness, ptosis, dysphagia, diaphoresis, goose flesh, and drowsiness. Local tissue necrosis is rare, except following envenomation by spitting cobras, such as *Naja nigricollis* (black-necked spitting cobra)[273] and *Naja mossambica* (spitting cobra).[274] Intraocular instillation of spitting cobra venom causes severe conjunctivitis, blepharospasm, local edema, and conjunctival congestion. Complications include corneal ulcers, anterior uveitis, and blindness.[275]

First-aid treatment includes reassurance, rest, and transport to a medical facility as soon as possible. There is no direct scientific data to support the use of compression dressings. Copious irrigation of the eyes is indicated as soon as possible after ocular contact with spitting cobra venom. The eye should be examined by slit lamp for evidence of corneal injury, and treated with topical antibiotics. There are no data to support the intraocular instillation of antivenom. Treatment primarily involves supportive care and the intravenous administration of antivenom as soon as possible after neurological symptoms develop. The erratic and incomplete administration of antivenom following intramuscular injection severely limits the effectiveness of the intramuscular route.[276] The South African polyvalent elapid antivenom covers all African species of elapids.

ASIA

EXPOSURE

Cobras and kraits are the main representatives of venomous snakes in Asia. There are about 10 species of Asian cobras that now represent separate species rather than subspecies of *Naja naja*.[277] These Asian cobras include *Naja atra* Cantor (South China, North Vietnam, Central Taiwan), *Naja kaouthia* Lesson (Thailand, Burma, West Malaysia, Indochina, Bengal), *Naja naja* L. (India, Pakistan, Sri Lanka, Nepal, Bangladesh, South Vietnam), *Naja oxiana* Eichwald (Middle East, North Pakistan, *Naja philippinensis* Taylor (Philippines), *Naja sagittifera* Wall (Andaman Islands), *Naja siamensis* Laurenti (Thailand, Indochina), *Naja sputatrix* Boie (Java, Sunda Islands), *Naja sumatrana* Müller (Malayan Peninsula, Sumatra, Borneo), and *Ophiophagus hannah* Cantor (King Cobra of India, South China, Southeast Asia). These large, wide-bodied snakes grow up to 4 m (~13 ft) in length (King Cobra), and they spread their cervical ribs, inflate their bodies, and hiss when disturbed. Coloration varies from light-brown to olive-black with most a monochromatic pattern. Several Asian cobras can discharge their venom several meters in the air toward their victims including the *Naja philippinensis*, *Naja siamensis*, *Naja sputatrix*, and *Naja sumatrana*. Figure 176.11 displays a specimen of the Siamese Spitting Cobra (*Naja siamensis* Laurenti). Occasionally, several other cobra species (*N. atra*, *N. samarensis*) display this behavior. Eastern cobras are primarily nocturnal, and evenomation may occur during the night when these snakes are searching for prey (e.g., rats, mice).

Kraits are slender snakes about 1 m (~3 ft) in length with white or yellow stripes on a black background. Some species are all black. There are approximately 13 species distributed throughout Asia with the exception of the Philippines including *Bungarus caeruleus* Schneider (Indian subcontinent), *B. candidus* L. (Cambodia, Indonesia, Malaysia, Thailand), *B. fasciatus* Schneider (Southeast Asia), and *B. multicinctus* Blyth (Taiwan, South China). Asian kraits are nocturnal, and bites often occur at night without the perception of the bite by the victim after the snake enters a house in search of prey (mice, rats, lizards).[278] They are terrestrial snakes found in open forests and bush as well as agricultural areas (e.g., rice fields).

VENOM

These snakes have anterior fangs that are relatively small and fixed. The venoms of Asian cobras (e.g., cobratoxin from *N. naja atra*) are similar to African cobra venoms consisting of curare-like neurotoxins that block neuromuscular transmission at the postsynaptic nicotine

FIGURE 176.11. Siamese Spitting Cobra (*Naja siamensis* Laurenti). © 1996 Rune Midtgaard. See color insert.

receptors in motor endplates.[279] Both cobra and krait venoms also contain cardiotoxic and cytotoxic components that lyze cell membranes.[280] Asian krait venom also contains curare-like neurotoxins (α-bungarotoxin), which bind postsynaptically to the α-subunit of the nicotinic acetylcholine receptor of the neuromuscular junction, and phospholipase A_2-containing β-bungarotoxin that acts presynaptically.[281] The latter bungarotoxin is the main constituent of krait venom. κ-Bungarotoxins are unique components of krait venom that are structurally similar to α-bungarotoxins and also bind to nicotinic acetylcholine receptors. However, these unique components are minor constituents of krait venom.[282] The exact mechanism of action of bungarotoxins is unclear.[283]

CLINICAL RESPONSE

Cobra envenomations typically produce signs of severe neurotoxicity that may rapidly progress to respiratory failure within 30 minutes of envenomation, particularly following envenomation by the King Cobra (*Ophiophagus hannah*).[284] A case report describes the onset of cranial neuropathy, respiratory failure, and coagulopathy 10 hours after envenomation by an Asiatic cobra (*N. kaouthia*).[285] Neurological effects following cobra envenomation include ptosis, blurred or double vision, dysphagia, drooling, dysarthria, loss of deep tendon reflexes, flaccid paralysis, respiratory failure, and coma. Although most cobra bites cause minimal tissue damage involving the local skin and subcutaneous tissues, bites from some Asian cobras (e.g., *Naja naja, Naja atra*), including spitting cobras, frequently can cause severe local pain, edema, vesiculation, and necrosis in addition to neurological symptoms.[286,287] In a study of 85 patients presenting to provincial hospitals in Thailand with envenomations by *Naja kaouthia* (Thai cobra), 27% of the patients required minor surgical debridement of the wounds and one patient required amputation of his thumb.[288]

Envenomation by Asian kraits (e.g., *Bungarus caeruleus, Bungarus multicinctus*) produces dyspnea, dysphagia, ptosis, blurred vision, generalized neuromuscular weakness, abdominal pain, vomiting, chest pain, myalgias, alteration of consciousness, prolonged respiratory failure, and occasionally a delayed neuropathy.[289] Neurological symptoms typically develop within 1–6 after envenomation, and local reactions (i.e., swelling, erythema) to the bites are generally minimal or mild.[290,291] Typically, the local tissue damage from krait venom is less than Asian cobra venom. Cardiotoxicity is unusual following krait envenomations, but rare case reports associate cardiogenic pulmonary edema with severe krait envenomation.[292] Coagulation profiles usually remain normal following cobra and krait envenomations.

TREATMENT

First-aid treatment involves immediate transport to a medical facility for intravenous administration of antivenom along with rest and reassurance. Although the use of a proximal tourniquet may delay the onset of symptoms, rapid deterioration to respiratory arrest may occur after removal of the tourniquet.[293] Consequently, once applied the tourniquet should be removed only when facilities are available to provide rapid intubation and respiratory support. Most cases of cobra and krait envenomation require the use of antivenom. Because of the high variability in the composition of cobra and krait venom, clinically significant variation occurs in the efficacy of antivenom produced from venom of different species. Although case reports describe the successful use of polyvalent snake venom (e.g., 10 vials, South African Institute of Medical Research [Johannesburg, South Africa] polyvalent snake antivenom) for Asian cobra envenomation, polyvalent cobra antivenom may not effectively treat envenomation of all Asian cobra species. A mono-specific Thai Red Cross Society King Cobra antivenom effectively reverses the neurotoxicity associated with King Cobra envenomation in doses of 15–20 vials.[294] Although current antivenom prevents further deterioration, the polyvalent antivenom does not usually reverse existing respiratory insufficiency or the delayed neuropathy.[295] Cobra antivenom is not efficacious for krait envenomations. High doses of polyvalent antisnake venom (Haffkine Bio-pharmaceutical, Acharya Donde Marg, Parel, Mumbai, India) may be necessary to treat the neurological symptoms associated with krait envenomations.[296] An experimental enzyme-linked immunosorbent assay (ELISA) has been developed to detect Taiwan cobra (*Naja atra*) venom in the serum of snakebite victims.[297] Serum concentrations of this venom remain elevated for at least 24–48 hours after envenomation unless the administration of antivenom neutralizes the venom.

AUSTRALIA

EXPOSURE

Geographical Distribution

All of the venomous snakes in Australia belong to the family Elapidae, and a majority of snakes in Australia are venomous. The distribution of snakes in New Guinea including Papua New Guinea and the Indonesian portion (Irian Jaya) is similar to Australia. The major

groups of elapids in Australia include the following species: 1) tiger snakes (*Austrelaps*, *Hoplocephalus*, *Notechis*, *Tropidechis*), 2) brown snakes (*Pseudonaja*), 3) Taipan (*Oxyuranus*), black/mulga snakes (*Pseudechis*), 4) small-eyed snakes (*Micropechis*), and 5) death adders (*Acanthophis*). Death adders are the most widely distributed venomous elapids ranging from continental Australia to the Indonesian islands of Seram and Tanimbar. The common brown snake (*Pseudonaja textilis*) and other brown snakes (*P. inframacula*, *P. nuchalis*, *P. affinis*) are the most common venomous snakes in South Australia. Envenomations by snakes from the genus *Pseudonaja* are the leading cause of mortality from snakebites in Australia.[298] Other Elapidae species associated with Australian fatalities include the tiger snake (*Notechis scutatus*), taipan (*Oxyuranus scutellatus*), and the common death adder (*Acanthophis antarcticus*). Figure 176.12 displays a specimen of the common tiger snake (*Notechis scutatus* Peters). Snakes from the genus *Pseudechis* (e.g., *P. porphyriacus*, red-bellied black snake) are also widely distributed venomous snakes in Australia.[299,300] *Pseudechis australis* causes the largest number of snake envenomation in Australia.[301] In general, these snakes produce little local tissue damage. Figure 176.13 displays a specimen of the King Brown Snake (*Pseudechis australis* Gray). The death adder (*Acanthophis* spp.) inhabits most of Australia and a number of eastern Indonesian islands, whereas the taipan (*Oxyuranus* spp.) lives in the Northern coast and some interior sections.

Habitats/Characteristics

Australian elapids occur in a wide variety of habitats including some areas near population centers. Table 176.14 lists the habitat and physical characteristics of important venomous elapids in Australia.

VENOM

The fangs of Australian elapids are fixed and relatively nonmobile with lengths up to 13 mm (~0.5 in.). The amount of venom ejected with each bite is highly variable, and therefore the degree of envenomation is also highly variable. The Australian small-scaled snake (*Oxyuranus microlepidotus* McCoy) is an Australian Elapidae species that, potentially, is the most poisonous snake in the world on the basis of an LD_{50} in mice of 0.01 mg/kg.[302] Experimental studies in rodents suggest that the venom from this Elapidae species contains a component that relaxes vascular smooth muscle and produces hypotension as well as a component that results in the synthesis of arachidonic acid metabolites.[303] Most venomous Australian elapids (e.g., tiger snakes, taipans, rough-scaled snakes) produce venom that contains neurotoxins that block postsynaptic membranes and the presynaptic release of acetylcholine at the neuromuscular junction.[304,305] The latter neurotoxins (e.g., notexin, taipoxin, textilotoxin) contain phospholipases A_2. Notexin produces rhabdomyolysis as well as paralysis. This neurotoxin causes prolonged paralysis by destroying the terminal bulbs and irreversibly inhibiting the release of acetylcholine.[306]

Venom from the viper-like common death adder (*Acanthophis antarcticus*) contains at least five postsynaptic neurotoxins and four phospholipase A_2 components. Some, but not all species of *Acanthophis* possess myotoxic venom. An *in vitro* study of *Acanthophis* species from Australia and neighboring islands demonstrated myotoxicity from venoms extracted from species

TABLE 176.14. Habitat and Characteristics of Important Australian Venomous Elapids[a]

Species	Common Name	Description	Distribution	Habitat
Notechis scutatus Peters	Common tiger snake	Wide-bodied snake up to 1.2 m (~4 ft) in length with brown to black background and highly variable yellow bands	Southeastern Australia near densely populated areas	River banks, moist forests
Notechis ater Krefft	Black tiger snake	Wide-bodied snake up to 1.2 m (~4 ft) in length with brown to black background and highly variable black bands	Southeastern Australia near densely populated areas	River banks, moist forests
Acanthophis spp.	Death adder	Broad, triangular head with wide body similar to vipers; background color ranges from light-brown to red and dark-gray with irregular strips	Mainland Australia, New Guinea, Molucca Islands	Sand or soil near shrubs and trees—primarily nocturnal
Pseudechis australis Gray	Mulga snake	Slender snake up to 2–3 m (~6–10 ft) in length with light brown background	Southern Australia; other species throughout Australia and New Guinea	Wide variety of habitats including deserts and tropical forests
Pseudonaja textilis Duméril, Bibron & Duméril	Brown snake	Slender snake up to 1.5–2 m (~5–6 ft) in length with brown background; other species vary between yellow, orange, brown, olive, and black backgrounds, occasionally with stripes or spots	Eastern Australia; other species range over all of Australia and Eastern New Guinea	Species inhabit all dry and wet areas
Oxyuranus scutellatus Peters	Taipan	Large, slender snake up to 2 m (~6 ft) with light-brown, yellow or dark-brown background	North and North East Australia and new Guinea	Wide habitat including tropical rain forests, open savanna, woodlands, and dry areas

[a]Source: Adapted from Ref 2.

of *A. praelongus* Ramsey (northern death adder), *A. rugosus* Loveridge, and *A. wellsi* Hoser (black head death adder), but not from venoms extracted from *A. hawkei* Wells & Wellington (Barkly Tableland death adder), *A. pyrrhus* Boulenger (desert death adder), and regional variants of *A. antarcticus* Shaw.[307] *Pseudechis* venoms contain phospholipase A_2, pre- and postsynaptic neurotoxins, platelet inhibitors, myotoxins, and variety of factors with pro- and anticoagulant, hemorrhagic, and necrotic activities.

Venoms from the brown snake and taipan contain enzymes that interfere with hemostasis and produce clinically similar envenomations. These venoms probably act at the site of the prothrombin complex rather than thrombin (e.g., crotalines) or fibrinogen.[308] The venom of brown snakes (*Pseudonaja* spp.) contains a procoagulant, textarin, which converts prothrombin to thrombin.[309] This procoagulant is a serine protease with a sialic acid component that contributes to the coagulant effects.[310] There is substantial interspecies variability with the venom of some species requiring factor V for the procoagulant activity, whereas other species do not. This venom can cause severe defibrination coagulopathy and secondary renal damage. Brown snake venom rarely causes paralysis and never causes myolysis. The black tiger snake (*Notechis ater*) and Stephen's banded snake (*Hoplocephalus stephensi* Krefft) also produce a procoagulant that causes a defibrination-type coagulopathy after envenomation. This coagulant resembles factor Xa and requires factor V for procoagulant activity.[311] Variation in the composition of the venom, including the procoagulant, during the year adds to the variability in the clinical response to an envenomation.[312] Most Australian elapid venoms do not contain hemorrhagic factors that cause local tissue edema and necrosis. However, the venom of the brown snake (*Pseudonaja textilis*) does contain at least two group 1B phospholipase A_2 enzymes.[313]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Postmortem findings following death from elapid snake envenomation are usually unremarkable other than evidence of coagulation disorders.

CLINICAL RESPONSE

Envenomations by Australian elapid snakes produce a wide variation of clinical effects ranging from local swelling (black-bellied swamp snake, *Hemiaspis signata* Jan)[314] to myoglobinuria, paralysis (Rough-scaled snake, *Tropidechis carinatus* Krefft),[315,316] and sudden death (brown snake, *Pseudonaja* spp.).[317] In general, Elapidae venoms produce only minor local damage and swelling at the bite site with the exception of the mulga snake (*Pseudechis australis*).[318] Initial symptoms include lightheadedness, diaphoresis, headache, nausea, vomiting, abdominal pain, and painful regional lymph nodes. Typical neurological symptoms include slurred speech, ophthalmoplegia, ptosis, dysphagia, and paralysis of respiratory muscles. Systemic symptoms following envenomation by the red-bellied black snake (*Pseudechis porphyriacus*) and the spotted black snake (*Pseudechis* guttatus) are typically mild (e.g., headache, blurred vision, nausea, vomiting, diarrhea, upper abdominal cramping, diaphoresis).[319] The brown snake (*Pseudonaja* spp.), black tiger snake (*Notechis ater*), and the Stephen's banded snake (*Hoplocephalus stephensii* Krefft) possess procoagulants in their venoms that cause a defibrination-type coagulopathy and hemorrhage. Serious complications of Australian elapid envenomations include hyperkalemia, intracranial hemorrhage, convulsions, rhabdomyolysis, myalgias, acute renal failure, hemorrhagic shock, cardiovascular failure, and respiratory arrest.[320,321] Envenomation by the death adder produces neurotoxicity (ptosis, ophthalmoplegia, fixed dilated pupils, dysarthria, respiratory failure) with little effect on coagulation or local tissue.[322] The onset of flaccid paralysis after envenomation by death adders can occur 12–18 hours following the bite. Taipan snakes cause a variety of clinical effects including paralysis, complete defibrination coagulopathy, hemorrhage, rhabdomyolysis, and secondary renal failure. Tiger snakes produce a neurotoxin and a myotoxin that causes paralysis, rhabdomyolysis, local edema, and secondary renal failure.[323] The rhabdomyolysis associated with tiger and malga snake envenomations may also be delayed 12–18 hours after the bite. Slight prolongation of the PT and PTT may occur, but these changes usually resolve within 12–18 hours and defibrination does not develop. Some, but not all species of death adders (*Acanthophis* spp.) can produce rhabdomyolysis.[324]

DIAGNOSTIC TESTING

Venom Detection Kit

The venom detection kit issued by Commonwealth Serum Laboratories in Melbourne, Australia is the only commercial diagnostic kit for detection of snake venoms by ELISA methods from urine or from the snakebite site.[325,326] Blood is an unreliable test sample for this kit because of the difficulty interpreting the results.[327] The bite site is the most reliable sample site for the snake venom kits; a urine sample is suitable only when systemic envenomation occurs. This kit detects the venom from the five major venomous snakes in Australia including the common brown snake (*Pseudonaja textilis*), tiger snake (*Notechis scutatus*), death adder (*Acanthophis antarcticus*), king brown snake (*Pseudechis australis*), and taipan (*Oxyuranus scutellatus*). The use of these kits allows the use of specific rather than polyvalent antivenom. The venom detection kits determine the most appropriate antivenom to administer, but this test does not determine the need for antivenom or the recent occurrence of envenomation. Both false-positives (e.g., brown snake) and false-negatives occur, even during severe envenomation.

Abnormalities

Marked defibrination occurs with variable thrombocytopenia following envenomation by brown snakes (*Pseudonaja* spp.), taipans (*Oxyuranus* spp.), or tiger snakes (*Tropidechis* spp., *Hoplocephalus* spp., *Notechis* spp.) that produce procoagulants. These coagulation defects involve the consumption of factor V, factor VIII, fibrinogen, and partial consumption of prothrombin with little effect on other coagulation factors.[328] Fibrin degradation products are markedly elevated with prolongation of the PT and PTT as well as low fibrinogen concentrations. The severity of these coagulation abnormalities is variable with some envenomations resulting in mild changes.[329] In contrast to envenomations by brown or tiger snakes, envenomations by black snakes (e.g., mulga snakes, some *Pseudechis* spp.) produce an anticoagulation syndrome characterized by prolongation of the PT and aPTT times, but normal fibrinogen concentrations and fibrin split products. Rhabdomyolysis may cause hyperkalemia, elevated serum creatinine, and myoglobinuria, as well as increased serum creatine phosphokinase.

TREATMENT

The principal methods of treating Elapidae envenomations is identification of the involved species, determi-

nation of the presence of neurological symptoms and signs, close observation of the victim for respiratory failure, administration of antivenom when necessary, and supportive care.

First-Aid

The snakebite victim should be rapidly transported to a medical facility with antivenom resources. In Australia, the Sutherland pressure immobilization first aid technique is the first aid measure of choice despite the lack of clinical trials.[330] This technique involves the pressure immobilization by crepe bandage and splint. A broad bandage is firmly applied over the bite site similar to wrapping a sprained ankle. The bandage covers the entire limb including toes or fingers. The extremity is then immobilized. In Australia, the wound is not cleansed in the field because of interference with the identification of the snake by ELISA testing of dermal traces of venom. Tight tourniquets should be avoided, and the use of constricting bands may increase damage from snake venoms that produce local damage. Once applied, the dressing should not be removed until the patient is hospitalized with intravenous access and antivenom ready to administer. Victims should rest, seated in an upright position with back support to maximize diaphragmatic function. They should be observed closely for respiratory failure. Walking should be minimized to reduce the flow of the venom through the lymphatic system.

Antivenom

Most Australian elapid envenomations with systemic symptoms (e.g., ptosis, ophthalmoplegia, prolonged prothrombin time, rhabdomyolysis, myoglobinuria) require the intravenous administration of antivenom. Identification of the species causing the envenomation is important to the administration of the proper antivenom. The lack of pain and bite marks suggests envenomation by brown snakes. The presence of obvious redness and bruising along with marked swelling within 3 hours suggests the mulga, red-bellied black, or yellow-faced whip snakes, whereas the lack of swelling in the presence of obvious bite marks suggests the tiger or the rough-scaled snakes. Figure 176.14 outlines the use of laboratory data and clinical presentation to determine venomous Australian species of Elapidae snakes, and Table 176.15 lists the appropriate antivenom for these species. The administration of antivenom should be guided by the clinical presentation and laboratory data (i.e., swab of bite site for venom detection kit).[331] Because of the false positive tests associated with the use of the venom detection kits, a positive result on the venom detection kit *alone* is not an indication to administer antivenom and a negative result does not necessarily exclude envenomation.[332] The venom detection kit is designed to help choose the appropriate antivenom rather than confirm snake envenomation. However, *in vitro* studies suggest that there is some cross-neutralization between commercial antivenoms (e.g.,

[b]Antivenom from Commonwealth Serum Laboratories, Ltd (Melbourne, Australia).

brown snake and tiger snake antivenoms).[333] For patients with clear signs of system envenomation, urine may be sampled; however, blood samples are usually unreliable.

The presence of systemic signs of envenomation is the main criteria for the administration of antivenom including evidence of paralysis (ptosis, weakness, ophthalmoplegia), altered consciousness, internal hemorrhage, hypotension, myoglobinuria, or nonclotting blood. The antivenom is diluted 1:10, if possible. Infusion begins slowly to check for an anaphylactic response, and then, in the absence of a response, the dose is infused over 15–20 min. Repeat dosing of antivenom may be necessary to reverse the consumptive coagulopathy and hypofibrinogenemia associated with brown snake envenomations, particularly if there is no improvement in coagulation factors three hours after initial administration of antivenom. In a case series of four brown snake envenomations, at least 9 vials of antivenom was required to reverse the envenomation-induced coagulopathy.[334] In another case series, 90% of severe brown snake envenomations as defined by nondetectable fibrinogen concentrations (<30 mg/dL) responded to between 1–10 ampules with a range up to 23 ampules.[335] The recommend dose of antivenom for severe brown snake envenomation was 10 ampules, but a recent case series on severe brown snake envenomation suggests that even severe envenomations respond to an initial dose of one to two ampules (1000 U/ampule).[336] Repeat dosing with antivenom may be required to completely neutralize all the antivenom including late release from the envenomation site. Regeneration of fibrinogen concentrations requires at least 3–6 hours after adequate neutralization of the venom. The improvement in the PT and aPTT times is a sensitive marker of the complete neutralization of venom by antivenom, and detectable fibrinogen concentrations add little additional information. In a study of Australian snake envenomations, the mean times from initial antivenom dose to recover of PT < 24 seconds and measurable aPTT were 9.2 hours and 5.2 hours, respectively, compared with 8.8 hours for detectable fibrinogen.[337] There are no clinical data to support the use of premedication or sensitivity testing prior to the administration of antivenom.[338] *In vitro* neurotoxicity studies of black snakes (*Pseudechis* spp.) suggest that tiger

snake venom neutralizes the neurotoxic effects of envenomations by *Pseudechis* species, particularly *P. porphyriacus*.

Supplemental Care

Envenomated patients must be observed closely for the development of respiratory failure. Generous fluid replacement is important for patients with myoglobinuria, but the role of urinary alkalinization is unclear. These patients should be evaluated for the development of acute renal failure. Supportive care includes monitoring of coagulation disorders (PT, aPTT, fibrinogen level, fibrin or fibrinogen degradation products, and platelet count), as well as kidney function. The use of cryoprecipitate, fresh-frozen plasma, and red blood cell (RBC) transfusions may be necessary for life-threatening internal bleeding. Although fresh-frozen plasma and cryoprecipitate should never be withheld during life-threatening bleeding, neutralizing doses of antivenom should usually be administered as soon as possible before large doses of fresh-frozen plasma and cryoprecipitate.

COLUBRIDS

Despite the large size of the family Colubridae, this family contains only a few venomous species (e.g., bird snake, African boomslang, keelback). These snakes have posterior fangs, and they rarely bite humans. Secretions from the venom gland of colubrid snakes are highly variable, and serious envenomations are unusual. In 1957, a professional herpetologist died after envenomation by a juvenile boomslang (*Dispholidus typus* Smith) that he thought was only mildly venomous.[339] Many of these severe reactions probably involve an allergic response.[340] Potentially dangerous snakes from the Colubridae family include the African boomslang (*Dispholidus typus* Smith), the African bird or twig snake (*Thelotornis kirtlandii* Hallowell, *Thelotornis capensis* Smith), the East Asian yamakagashi (*Rhabdophis tigrinus* Smith), and the South American colubrid (*Philodryas olfersii* Lichtenstein).[341]

EXPOSURE

Geographic Distribution

This enormous family comprises 1,400–1,700 species divided into a variety of subfamilies compared with approximate 500 species in the families Elapidae and Viperidae. Almost all of the snakes in these latter two families contain specialized venom glands. Table 176.16 lists the location and effects of colubrid species commonly associated with envenomations.

There are approximately 38 genera from the family Colubridae in the United States. Case reports suggest that local tissue reaction may result from envenomations by some colubrid snakes in the following colubrid genera from North and Central America: *Alsophis, Conophis*, *Coniophanes*, *Crisantophis*, *Dryophiops*, *Erythrolamprus*, *Leptodeira*, *Oxybelis*, and *Pliocercus*.[342–344]

Most snakebites in South America result from contact with pit vipers (*Bothrops, Crotalus, Lachesis* spp.) or coral snakes (*Micrurus* spp.) rather than colubrid species.[345] Rear-fanged colubrid species associated with colubrid envenomations in South America include snakes from the following genera: *Clelia, Elapomorphus, Helicops, Liophis, Philodryas, Tachymenis*, and *Thamnodynastes*. These envenomations usually produce only mild local symptoms (pain, edema, ecchymosis).[346,347] Snake envenomations in Chile result only from colubrid species because of the lack of front-fanged venomous snakes in this country. Most Colubrid bites in Europe, the Middle East, and Africa produce variable amounts of local edema and pain.[348] However, envenomations by the African tree snakes (*Dispholidus typus, Thelotornis capensis*) may cause serious coagulation disorders.[349,350]

Habitat/Characteristics

Colubrid species have elliptical pupils, and they lack the loreal pit associated with crotaline species. Envenomations by colubrid snakes are uncommon and almost always result from handling the snakes. They are active hunters that move frequently, rarely bite humans, and avoid human contact unless threatened. Bites on young children from the brown tree snake occurred primarily at night on the extremities.[351]

Venom Apparatus

Most snakes from this family have aglyphous dentition, and therefore these snakes lack the specialized venom-injecting apparatus present in venomous species from the families Viperidae and Elapidae. However, about one-third of the species from the Colubridae family have opisthoglyphous dentition characterized by rear fangs that can deliver toxic saliva during chewing (see Figure 176.15). The efficiency of the venom-delivery is relatively poor. In an experimental study of brown tree

TABLE 176.16. Colubrid Species Commonly Associated with Envenomations

Species	Common Name	Location	Effects
Amplorhinus multimaculatus Smith	Cape many-spotted snake	Marshes of southern Africa	Local pain/swelling
Boiga blandingii Hallowell	Tree snake	Central Africa	Local pain/swelling
Boiga irregularis Merrem	Brown tree snake	Coastal Australia, Papua New Guinea, NW Melanesia	Local, nonspecific effects
Coluber ravergieri[a]	Middle Eastern racer	Middle East	Local pain/swelling
Crotaphopeltis hotamboeia Laurenti	Herald snake	Sub-Saharan Africa	Local pain/swelling
Dipsadoboa aulica Günther	Marbled tree snake	Southern Africa	Local pain/swelling
Dispholidus typus Smith	Boomslang	Senegal and Eritrea south to Cape of South Africa	Minimal pain, rarely severe coagulopathy
Malpolon monspessulanus Hermann	Montpellier snake	Southern Europe, Mediterranean	Local pain/swelling
Pliocercus elapoides Cope	Variegated false coral snake	Mexico, Central America	Local pain/swelling
Philodryas olfersii Lichtenstein	Green snake	Brazil	Local pain/swelling with local anticoagulant effects
Psammophis phillipsi Hallowell	Olive grass racer	Southern Africa	Local pain/swelling
Psammophylax rhombeatus L.	Spotted skaapsteker	South Africa	Local pain/swelling
Rhabdophis subminiatus Schlegel	Red-necked keelback	Asia	Minimal pain, rarely severe coagulopathy
Rhabdophis tigrinus Boie	Yamakagashi	Asia	Minimal pain, rarely severe coagulopathy
Thelotornis capensis Smith	Savannah vine snake (African bird snake), Eastern twig snake	Savannas/ forests of Eastern/ Southern Africa	Minimal pain, rarely severe coagulopathy
Stenorrhina freminvillei Duméril, Bibron & Duméril	Blood snake	Central America, Mexico	Local pain/swelling

[a]Ambiguous synonym for *Hemorrhois nummifer* Reuss.

snakes feeding on mice, only about one-half of the contents of the Duvernoy's gland were released during the feeding, and only approximately one-half of the injected material reached the viscera of the prey.[352] The rest of the material remained on the skin.

About 12% of US colubrid species (e.g., hog-nosed snake) and over 100 genera in the Colubridae family have enlarged rear teeth (fangs) that contain lateral or anterior grooves.[353] Both rear-fanged (i.e., opisthoglyphous) and nonfanged (aglyphous) colubrid snakes possess a specialized salivary gland called Duvernoy's glands, which are located above some rear maxillary teeth and below the orbit.[354] The small size of the fangs and the difficulty injecting large amounts of venom limit the toxicity of colubrid species. In addition, the secretions from these glands are highly variable between species with some species secreting only serous material, whereas other species produce proteins and mucous in these glands.[355] Prolonged contact with the snake (>1 minute) enhances the ability of the snake to inject secretions from the Duvernoy's gland into the victim and to increase the risk of a clinically significant envenomation.

PRINCIPAL TOXINS

There are over 700 potentially venomous colubrid species, but the data on the composition of these venoms are limited. In a study of the secretions from 12 colubrid snakes, most of the venoms demonstrated variable amounts of proteolytic activity with little evidence of hyaluronidase, antithrombin activity or kallikrein-like effects.[356] However, venom from the red-necked keelback (*Rhabdophis subminiatus* Schlegel) and several other colubrid species causes serious coagulation abnormalities as a result of prothrombin activation (factor II) and fibrinolysis secondary to intravascular fibrin deposition.[357,358] This venom produces little consumption of antithrombin III despite the extensive formation of thrombin.[359] Variable amounts of phospholipase A_2 (*Trimorphodon biscutatus* Duméril, Bibron & Duméril), proteases, hemorrhagic metalloproteinase (*Dispholidus typus*), myotoxins (*Philodryas olfersii*), and phosphodiesterases are also present in the Duvernoy's gland secretions from some colubrid species.

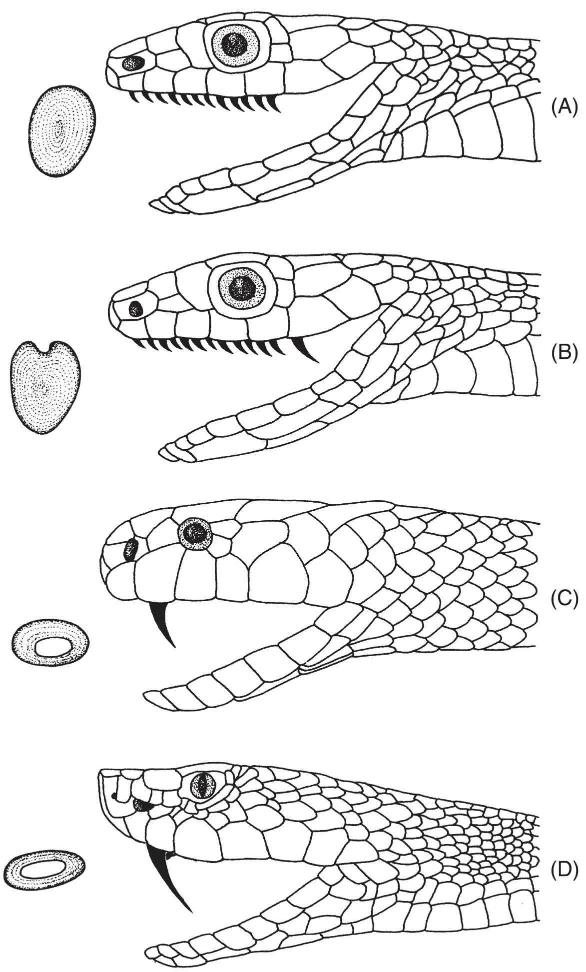

FIGURE 176.15. Dentition of various snake families. (A) Colubridae—aglyphous (ungrooved teeth). (B) Colubridae—opisthoglyphous (posterior grooved teeth). (C) Elapidae—proteroglyphous (front fangs with almost closed groove). (D) Viperidae—solenoglyphous (front, hallow teeth). Adapted from Mebs D. Venomous and Poisonous Animals. A Handbook for Biologists, Toxicologists, Toxinologists, Physicians and Pharmacists. Stuttgart: Medpharm Scientific Publishers, 2002:242.

CLINICAL RESPONSE

Local Effects

Most colubrid bites result only in minor abrasions and anxiety without systemic effects. However, bites by a few colubrid species produce local effects including mild pain, ecchymosis, and localized swelling, particularly when the bite is prolonged (e.g., >30 seconds). The clinical effects of envenomation involve edema, local pain, hemorrhagic vesicles, and enlargement of regional lymph nodes.[360–362] Symptoms usually resolve within 24–72 hours without necrosis.[363,364] Occasionally, the swelling progresses to involve the whole extremity, but systemic symptoms (weakness, nausea, diaphoresis, gastrointestinal distress, vomiting) are rare. Case reports indicate that prolonged contact (1–5 minutes) with large wandering garter snakes (*Thamnophis elegans* subsp. *vagrans* Baird & Girard) produce pain, edema, and localized hemorrhage that involve the region around the bite, but systemic symptoms do not usually develop.[365,366] Bites from a number of Central American Colubridae species produce local pain and swelling including snakes belonging to the following genera: *Conophis, Leptodeira, Leptophis, Oxybelis, Philodryas, Stenorrhina, Tachymenis*, and *Trimorphodon*. In a Brazilian study of 43 patients admitted with the diagnosis of *Philodryas olfersii* envenomation, the most common clinical features were local pain (37.2%), swelling (35%), erythema (19%), and ecchymosis (9%).[367] There was no evidence of abnormal coagulability in this case series. However, *in vitro* studies indicate that Duvernoy's gland secretions from *Philodryas patagoniensis* Girard contain metalloproteinases and serine protease capable of hydrolyzing activity fibrinogen and fibrin.[368] In a series of envenomation by the brown tree snake (*Boiga irregularis*) seen in an Emergency Department in Guam, all bites were associated with localized pain, discoloration, and edema.

Systemic Toxicity

Most envenomations by colubrid snakes do not produce severe toxicity or coagulation disorders. However, several colubrid species can produce severe consumption coagulopathies and hemorrhagic diatheses including bites by the African tree snakes (*Dispholidus typus*, *Thelotornis capensis*), Japanese yamakagashi (*Rhabdophis trigrinus*), and the South Asian red-neck keelback (*Rhabdophis subminiatus*). Although many bites by these colubrid snakes cause minor symptoms, some envenomations produce severe coagulation abnormalities, particularly following prolonged bites. The clinical presentation of the hematological disorder associated with severe envenomations by these colubrid snakes is similar. Laboratory testing in severe envenomations demonstrates hemolysis and a coagulopathy with depletion of fibrinogen, factors V and VIII, markedly prolonged prothrombin and thromboplastin times, elevated fibrin split products, absent fibrinogen, fragmented erythrocytes, and thrombocytopenia that begins within 2–3 hours after envenomation.[369] Within 24 hours of a severe envenomation, extensive ecchymotic lesions develop, particularly near areas of trauma. Serious internal bleeding does not usually develop until 1–4 days after envenomation, and complications include upper intracranial hemorrhage, gastrointestinal bleeding, massive hematuria, hemoglobinuria, and acute renal failure.[370,371] Hematological abnormalities may remain

abnormal for 1–4 weeks after envenomation.[372] The bite wound is not usually painful, but frontal headache, weakness, paresthesias, nausea, persistent vomiting, and severe abdominal cramps may develop within 4 hours. In a series of envenomation by the brown tree snake (*Boiga irregularis*) seen in an Emergency Department in Guam, systemic complaints included lethargy, ptosis, and disorientation. Two infants required respiratory support.

TREATMENT

There are very few data on the management of colubrid envenomation. Management primarily involves local wound care. First-aid involves limiting the duration of bite to minimize the possibility of envenomation by placing the body of the snake on the nearest surface and striking its head. Identification of the envenomating snake is important to eliminate the risk of using inappropriate therapy (i.e., antivenom). The use of tourniquets, incisions, suction, or cryotherapy for colubrid bites is inappropriate. The wound should be cleansed with a disinfectant, and the tetanus immune status updated as necessary. There are no data to support the prophylactic use of antibiotics. The bite wound should be reevaluated in 24–48 hours for the presence of secondary infections. Although rare, hemorrhage may develop following envenomation by the red-necked keelback, African tree snakes (*Dispholidus typus*, *Thelotornis capensis*), and Japanese yamakagashi. Supportive care includes monitoring of coagulation disorders and the use of cryoprecipitate, fresh-frozen plasma, and RBC transfusions when life-threatening internal bleeding occurs. Envenomations by these snakes should be observed for 24–48 hours for the development of coagulation disorders. Heparin is not recommended for the treatment of a DIC-like consumptive coagulopathy. There is no commercial antivenom available to treat colubrid envenomations, and the use of colubrid antivenom is experimental because of the lack of adequate clinical data on efficacy. There are no data to support the use of Crotalidae or Elapidae antivenom following envenomation by colubrid species.

Chapter 177

SEA SNAKES

IDENTIFYING CHARACTERISTICS

Sea snakes are marine animals that rarely leave the sea. These marine snakes formerly were classified as a separate family (Hydrophiidae), but now these snakes belong to two Elapidae subfamilies, Hydrophiinae (sea snakes) and Laticaudinae (sea kraits).[1] Although sea snakes are all venomous, bites by these sea creatures are rare because of their reclusive disposition. Sea snake envenomations may cause fatalities as a result of neurotoxicity.[2] The common feature of sea snakes is the broad, flat tail that functions as a rudder and propeller. Sea snakes swim in an undulating fashion, powered by a flat, paddle-shaped tail.

Sea snakes are well adapted to the sea, and these snakes probably are the most abundant snakes in the world. There are over 50 species of sea snakes. Table 177.1 lists the common species of sea snakes. Sea kraits (*Laticauda* spp.) evolved independently from the genera of true sea snakes (*Enhydrina, Hydrophis, Lapemis, Pelamis*), probably originating from the Southeast Asian *Calliophis* genus of elapids. True sea snakes (Hydrophiinae) have nostril valves.

EXPOSURE

Geographic Distribution

Sea snakes inhabit tropical and temperate waters in the Indian and Pacific Oceans. Envenomation by sea snakes is most common in Malaysia, Southeast Asia, and the Persian Gulf.[3] There are no reports of sea snakes in the Atlantic Ocean or in the Caribbean Sea. *Pelamis platurus* Smith is the most common species, extending from the west coast of the Americas to the east coast of Africa. The waters off the tip of Africa and Cape Horn are too cool to allow the spread of sea snakes, which require temperate conditions above 20°C (65°F). Several species of sea snakes inhabit freshwater in Philippine lakes.[4]

Behavior

Sea snakes are docile, diurnal creatures, and most human encounters with these snakes do not result in bites or envenomation. These snakes feed primarily on small fish around rocky bottoms and coral reefs as well as fish that inhabit various depths in the water column.[5] Occasionally, sea snakes consume fish eggs or marine invertebrates. Most bites occur in fishermen when they inadvertently handle or step on the snakes after these snakes become entangled in fishing nets. Sea snake bites also occur when sunbathers and swimmers walk in shallow water, particularly near river estuaries. The sea kraits are less aquatic than true sea snakes, seeking rock crevices or land debris during inactive periods. Most sea snake species, except for *Pelamis* species, are bottom feeders that spend little time at the surface of the sea. Sea kraits (i.e., *Laticauda* species) lay their eggs on land, whereas other sea snakes are ovoviviparous and remain in the sea. Sea snakes do possess gills, and they must surface to breath. However, they can remain under the surface of the water for 2 hours.

TABLE 177.1. Common sea snakes

Species	Common Name
Aipysurus laevis Lacépède	Olive-brown sea snake
Astrotia stokesii Gray	Stokes's sea snake
Enhydrina schistosa Daudin	Beaked or common sea snake
Hydrophis cyanocinctus Daudin	Annulated sea snake
Hydrophis fasciatus Schneider (*Hydrophis gracilis*)	Small-headed sea snake
Hydrophis ornatus Gray	Reef sea snake
Hydrophis spiralis Shaw	Yellow sea snake
Lapemis hardwickii Gray	Hardwicke's sea snake
Laticauda colubrina Schneider	Yellow-lipped sea krait
Pelamis platurus Smith	Pelagic or yellow-bellied sea snake

PRINCIPAL TOXINS

Venom Composition

The venom of sea snakes is similar to the curare-like venom of terrestrial elapids, which inhibit postsynaptic neuromuscular transmission by binding to the α subunits of the nicotinic receptors at the neuromuscular junction.[6] The venom from the yellow-bellied sea snake (*Pelamis platurus*) contains two structurally similar neurotoxins (pelamis toxin a and b) that bind to postsynaptic acetylcholine receptors similar to α-bungarotoxin.[7] The sea snake venoms (e.g., *Enhydrina schistosa* Daudin, *Hydrophis cyanocinctus* Daudin) contain phospholipase A_2 (PLA_2) enzymes. These phospholipases demonstrate close sequence homologies to other elapid PLA_2 enzymes.[8] PLA_2 enzymes catalyze the hydrolysis of the 2-acyl ester bond of the 1,2-diacyl-*sn*-3-phosphoglycerol lipids in the presence of calcium to produce nonesterified fatty acids and lysophospholipids. These types of enzymes demonstrate a wide variety of pharmacological effects including hemolysis, myonecrosis, edema, cardiotoxicity, and neurotoxicity. PLA_2 enzymes within the same venom produce different effects despite similar structure.[9] Potentially, envenomations by sea snakes can cause skeletal muscle damage, myoglobinuria, and hyperkalemia.[10,11] There is substantial geographical variation in the composition of venom from sea snakes, probably as a result of differences in the prey of these snakes.[12]

Venom Apparatus

Sea snakes have proteroglyphous dentition similar to all elapids. The front fangs are small (2–7 mm/~0.1–0.3 in.) and hollow with the open tip communicating with venom glands. Fang marks are characterized by one to four tiny, punctate wounds that appear inconspicuous.[13] Most sea snake bites do not result in envenomation.[14] Multiple bite marks and serrated lacerations suggest serious envenomation when accompanied by symptoms.[14,15]

DOSE RESPONSE

Although the sea snake neurotoxin is more potent than terrestrial elapid venom, the small fangs inject substantially less venom from their crude venom apparatus compared with terrestrial elapids. Consequently, envenomation is less common with sea snakes than terrestrial elapids.

CLINICAL RESPONSE

Most sea snake bites do not result in envenomation,[16] and symptoms of envenomation may not develop even if abrasions or bite marks with surrounding erythema are present.[17] Characteristically, sea snake envenomations produce minimal local pain and swelling in contrast to the stings of other marine animals.[18] Occasionally, regional lymph node enlargement may occur near the site of the bite.[19] Neurologic symptoms typically begin within 30–60 minutes. Symptoms of envenomation include generalized myalgias, malaise, anxiety, euphoria, diaphoresis, and vomiting. Serious signs of envenomation include bulbar palsy (dysphagia, ptosis, external ocular muscle weakness, pupillary dilation, dysarthria), progressive muscle weakness, and respiratory depression. Muscle fasciculations do not usually occur. Clinical evidence of serious envenomations usually occurs within 2 hours unless delayed by the use of tourniquets on the affected extremity. The absence of symptoms within 6–8 hours indicates that envenomation did not occur.

DIAGNOSTIC TESTING

Envenomation by sea snakes does not typically produce significant laboratory abnormalities, such as coagulation disorders, electrolyte imbalance, rhabdomyolysis, disseminated intravascular coagulation, or hepatorenal dysfunction. Laboratory evidence of rhabdomyolysis (dark urine, severe myalgias, myoglobinuria, hyperkalemia, hyperphosphatemia, hypocalcemia) develops occasionally, particularly following envenomation by the common sea snake (*Enhydrina schistosa* Daudin).[20] Myoglobinuria commonly begins about 3–6 hours after envenomation along with evidence of rhabdomyolysis. In addition, skeletal muscle enzyme concentrations are often elevated and a leukocytosis frequently occurs. In

serious cases, hyperkalemia and acute renal tubular necrosis may occur within several days of envenomation.

TREATMENT

First Aid

Reassurance, immobilization of the affected limb in a dependent position, and immediate medical attention at a facility that possesses antivenin are the most important first-aid measures. Absorption of sea snake venom is rapid. Animal studies suggest that a lymph-restrictive bandage may be useful at the site of the envenomation if applied immediately (i.e., within the first 5–10 minutes of envenomation).[21] A thick gauze pad placed directly over the bite wound with a wide circumferential bandage provides lymphatic-occlusive pressure. Previously applied tourniquets should not be removed until supportive care (intravenous access, respiratory equipment) is available because of the potential deterioration of the patient following tourniquet removal.[15] The use of tourniquets is not part of the hospital management of snakebites. Incision and drainage even within the first 10 minutes is probably not efficacious.

Stabilization

Respiratory depression and aspiration are the immediate threatening complications. Symptomatic patient should be monitored for hyperkalemia as well as impending respiratory failure (i.e., cyanosis, increasing lethargy, disorientation, hypoxemia, hypercarbia).

Antivenom

Polyvalent equine sea snake antivenin (Commonwealth Laboratories, Melbourne, Australia) is indicated for all symptomatic patients (e.g., moderate myalgias, neurologic signs). Skin testing for horse serum sensitivity is usually recommended prior to the administration of antivenom. This antivenin is produced from the venoms of the common sea snake (*Enhydrina schistosa* Daudin) and the Australian tiger snake (*Notechis scutatus* Peters). *In vitro* studies indicate that this antivenom is effective against the potent postsynaptic neurotoxicity of all Indo-Pacific sea snakes.[22] Although occasionally used when sea snake venom is unavailable, tiger snake (*Notechis scutatus* Peters) antivenom is not as effective *in vitro* against sea snake venom as the specific sea snake antivenom. The sea snake antivenin should be administered as soon as possible (i.e., within 8 hours of envenomation) to all patients demonstrating signs of envenomation.[11] The initial dose is 1–3 vials intravenously, with further vials titrated to the clinical condition of the patient.

Supplemental Care

Patients with bites that do not produce symptoms (e.g., myalgias, muscle stiffness, ptosis, trismus, muscle weakness) within 6–8 hours of the bite can be safely discharged. Patients with serious envenomations should be followed closely for signs of respiratory failure and myoglobinuria. Elevation of serum creatine phosphokinase concentrations above 1000 U/L suggests the need to maintain good diuresis (2–3 mL/kg/h), particularly if myoglobinuria occurs. Envenomated patients should be well hydrated to reduce the risk of myoglobin-induced renal damage. There is limited evidence that alkalinization of the urine ($pH > 6.5$) increases myoglobin clearance. The patient should be monitored at least daily for hyperkalemia and renal failure. Hypocalcemia during rhabdomyolysis does not usually require treatment.

III Marine Invertebrates

Chapter 178

CONE SHELLS and BLUE-RINGED OCTOPUS
(Phylum: Mollusca)

CONE SHELLS

IDENTIFYING CHARACTERISTICS

Conus species comprise a large genus of predatory marine snail, and there are over 500 species of venomous *Conus* species found in all tropical marine habitats. Cone shells are frequently divided into the following groups based on the prey envenomated: worm-hunting (vermivorous), snail-hunting (molluscivorous), and fish-hunting (piscivorous).[1] The fish-hunting cone shells are potentially the most dangerous marine snails to humans.[2]

Common Name: Geographic Cone Shell
Scientific Name: *Conus geographicus* Röding
Family: Conidae
Physical Description: This dangerous, cone-shaped univalve has an attractive shell with a slit-like aperture running the full length of the shell. This species is one of the largest *Conus* species with a shell length up to 15 cm (~6 in.).

EXPOSURE

Clinical drugs from *Conus* species include ziconotide, which is a potent analgesic for opioid-refractory pain as a result of the blockade of *N*-type calcium channels involved in pain pathways. The US Food and Drug Administration (FDA) approved the intrathecal infusion of ziconotide as a treatment for severe chronic or refractory pain.[3]

Geographic Distribution

Cone shells inhabit shallow and deep topical waters of the Indian and Pacific Oceans east to Hawaii, north to Okinawa and south to New Zealand including the whole coast of Australia. A few *Conus* species live in cooler water. The only known species (*Conus ventricosus* Gmelin or *Conus mediterraneus*) in the Mediterranean Sea has not been associated with human envenomation.[4] These organisms are most abundant in shallow waters, particularly among coral reefs where many species inhabit the same reef.

Behavior

Predatory snails from the family Conidae are a diverse group of marine mollusks that use venom to capture prey (fish, mollusks, polychaete worms). These predators feed on worms by paralyzing prey with a detachable radula tooth. During the day, the cone shell seeks shelter under sand or stones. These nocturnal creatures are often at least partially buried in the sand during daylight hours. Most human envenomations occur during the handling of the cones that may wash ashore after storms or dredging operations. Inadvertent contact while digging in sand or coral debris may also occur. Typically, the venom from cone shells that prey on worms and snails are less toxic than other cone shells.

PRINCIPAL TOXINS

Venom Composition

Conus species produce water soluble toxins that disrupt neuromuscular transmission to paralyze their prey. The venom from each species is distinct, and individual venoms contain over 100 biologically active peptides and proteins.[5] The major biologically active compounds in *Conus* venoms are small (12–50 residues), extensively disulfide-cross-linked, neurotoxic peptides (conotoxins) that target ligand-gated or voltage-gated ion channels, G-protein-coupled receptors, or neurotransmitter transporters.[6] The internal disulfide bonds add stability to the peptide, while altering the conformation to optimize interaction with specific receptors. The venoms of each group of cone shells vary according to the target prey (e.g., piscivorous vs. vermivorous) as well as between individual specimens depending on the specific physiological end-point or "cabal."[7] The "lightning-strike cabal" of fish-hunting *Conus* species rapidly immobilizes prey by injecting peptides that inhibit voltage-gated Na^+ and K^+ channels resulting in massive depolarization of axons in the prey. The venom from these fish-hunting cone shells also contains peptides that inhibit the presynaptic Ca^{++} channels, postsynaptic nicotinic receptors, and the Na^+ channels. This "motor cabal" causes paralysis of the prey by inhibition of neuromuscular transmission.

There are over 5,000 unique peptide sequence present in approximately 500 *Conus* species, and these peptides are arranged into superfamilies (e.g., A, M, O) based on the characteristic arrangement of cysteine residues in the mature peptides.[8] Most families of toxins target a specific, voltage-gated ion channel (Na^+, K^+, Ca^{++}), ligand-gated ion channel (nicotinic acetylcholine, *N*-methyl-D-aspartate, 5-HT-3, α-adrenergic), G-protein-coupled receptors (neurotensin, vasopressin) or neurotransmitter transporters.[9] Different conotoxin families may bind to different sites on the same ion channel (e.g., μ-conotoxins bind to site 1 of the sodium channel whereas δ-conotoxins bind to site 6). Table 178.1 lists some conotoxin families and their respective molecular targets. Peptides of the same superfamily usually share a characteristic sequence of cysteine residues in the mature region of the toxin.[10] Members of the A-superfamily (cysteine framework: CC-C-C-C-C) contain competitive nicotinic acetylcholine receptor antagonists (α-conotoxins, αA-conotoxins) and inhibitors of voltage-gated potassium channels (excitatory κA-conotoxins),[11] whereas the M-superfamily includes voltage-gated sodium channel blockers (μ-conotoxins) and noncompetitive antagonists of the nicotinic acetylcholine receptor (ψ-conotoxins). The M-superfamily conotoxins contain similar cysteine arrangement (CC-C-C-CC) with at least four subfamilies that target different types of ion channels.[12] The O-superfamily (C-C-CC-C-C) is a highly diverse superfamily that contains a variety of active agents including voltage-sensitive calcium channel blockers (ω-conotoxins), delayed inactivators of the voltage-sensitive sodium channel (δ-conotoxins), voltage-gated sodium channel blockers (μO-conotoxins), and voltage-gated potassium channel blockers (κ-conotoxins).[13] The T-superfamily conotoxins are small peptides (9–17 amino acids) that occur in all three major feeding types of cone shells. This superfamily consists of τ-conotoxins (cysteine framework: CC-CC) and χ-conotoxins (cysteine framework: CC-C-C).[14] The other major group of *Conus* peptides contains no or one disulfide linkage. The wide diversity of structures in these superfamilies results in the continual discovery of new superfamilies, such as the V-superfamily (C-C-CC-C-C-C-C).[15] The pharmacological properties of this group of peptides include *N*-methyl-D-aspartate (NMDA)-glutamate receptor antagonists (conantokin), neurotensin-like peptides (contulakin), and vasopressin agonists (conopressin), as well as toxins with poorly defined targets (conorfamide, contryphans).[8]

TABLE 178.1. Superfamilies of Disulfide-Rich Conopeptides

Superfamily	Primary Target	Conotoxin Family
O	Sodium channel	δ, μO
	Potassium channel	κ
	Calcium channel	ω
M	Sodium channel	μ
	Potassium channel	κM
	Nicotinic ACh	ψ
A	Potassium channel	K
	Nicotinic ACh	α, αA
	α-Adrenergic receptor	ρ
S	Serotonin receptor	σ
T	Norepinephrine transporter	χ
	Nicotinic receptors	αS
P	Unknown	Unknown
I_1/I_2	Potassium channel	None defined
J	Potassium channel (?)	None defined

The I-conotoxin superfamily has four disulfide bonds with the cysteine sequence C-C-CC-CC-C-C; this family was divided into two different gene superfamilies (I_1, I_2) based on different types of signal peptides and distinct functions. Conotoxins from the I_1 superfamily have unique posttranslational modifications at the C-terminus, whereas conotoxins from the I_2 superfamily lack the propeptide region.[16]

Venom Apparatus

All *Conus* species have a venom apparatus that includes a long, highly convoluted venom duct (synthesis, storage of venom), a venom bulb for pumping out the venom, a radula sheath (formation of radula teeth), and harpoon-like teeth along with a long distensible proboscis for delivery of the venom to the prey. Thin-shelled species with wide openings have a more developed venom apparatus; therefore, these species are potentially more harmful.[17] The cone shells have sharp radicular, barbed teeth and a muscular proboscis that propels the hollow tooth (radula tooth) into the prey. Upon touching the prey, the extensible proboscis projects one small (6–8 mm/~0.2–0.3 in.), hollow tooth outward surrounded by the circular muscles at the anterior tip of the proboscis. The venom is then injected into the prey through the hollow tooth.[18] Figure 178.1 displays the venom apparatus of *Conus* species.

Dose Response

In general, the venom of cone shell species is specific to that species; therefore, the potency of venom varies between species.[7] The crude venom from piscivorous cone shells is usually more potent than vermivorous or molluscivorous species. The intraperitoneal LD_{50} of the more potent conotoxins from piscivorous cone shells in rodents is approximately 3–6 μg/kg, similar to ricin. In a study of crude venom from the vermivorous species, *Conus loroisii* Kiener, collected from the Bay of Bengal, the LD_{50} of the crude venom in mice was about 5 mg/kg following intraperitoneal injection.[19] Ziconotide is the synthetic analog of the ω-conotoxin from *Conus magus*.[20] This *N*-type calcium channel blocker inhibits the transmission of nociceptive stimuli, and this drug is approved as nonopioid treatment for chronic pain.

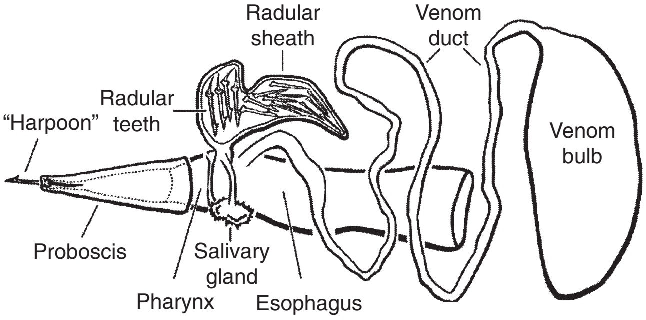

FIGURE 178.1. Venom apparatus of *Conus* species. From Norton RS, Olivera BM. Conotoxins down under. Toxicon 2006;48:782. Reprinted with permission from Elsevier.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Every conotoxin has a highly specific ligand that binds to a biologically active receptor, primarily on voltage-gated or ligand-gated ion channels and, in a few cases, on G-protein-linked receptors.[21] These peptides affect the functioning of different voltage-gated ion channels and neurotransmitter-gated receptors. α-Conotoxins are potent nicotinic antagonists similar to cobratoxin and α-bungarotoxin, whereas μ-conotoxins are sodium channel blockers similar to tetrodotoxin and saxitoxin. Voltage-sensitive neuronal calcium channels are the target of ω-conotoxins. The α-conotoxins are competitive antagonists of the nicotinic acetylcholine receptor that can distinguish between muscle- and neuronal-type nicotinic acetylcholine receptors.[22] These nicotinic antagonists target specific receptor subtypes that allow the venom to cause paralysis (muscle-type receptor) and inhibition of the flight and fight response (neural receptors).

CLINICAL RESPONSE

The severity of an envenomation varies substantially depending in part on the cone shell species. Typically, envenomation by a cone shell causes variable pain followed by swelling and numbness at the puncture site. Local effects include immediate pain varying from mild to severe, followed by local edema and erythema that frequently resolve within 1 hour. Hypoesthesia, hyperesthesias, local cyanosis, and ischemia may occur in more serious envenomations, and the swelling and sensitivity may last several weeks. More serious cases involve generalized muscle weakness and neurological signs characterized by ataxia, hoarseness, dysphagia, diplopia, perioral paresthesias, slurred speech, weakness, paralysis, and dyspnea. Intubation may be required as a result of respiratory failure. Gastrointestinal symptoms with the exception of nausea are not usually part of the clinical presentation. Symptoms typically resolve within 6–8 hours.[23] A 29-year-old Filipino male developed altered consciousness, swelling at the site of envenomation, and right-sided facial weakness 1 hour after placing a cone shell snail (*C. geographicus*) next to his extremity while diving.[24] He suddenly developed a respiratory arrest during transfer that did not respond to oxygen, noradrenaline, and artificial ventilation.

DIAGNOSTIC TESTING

The peptides in *Conus* venom are identified by cDNA cloning and polymerase chain reaction (PCR) amplification to determine the amino acid sequence by using

primers designed according to the signal sequence of the subfamily or superfamily genes.[25]

TREATMENT

Treatment is supportive with immobilization of the victim, immersion of the affected area in hot water, and careful cleaning of the wound. Hot water immersion (110–115 °F/43–46 °C) for 30 minutes may provide some relief, but there are few clinical data to guide management. After immersion, analgesics may be necessary, although symptoms usually abate by 1 hour. Patients with systemic symptoms should be observed closely for signs of respiratory depression for at least 6 hours. Rarely, ventilatory support is necessary. No antivenin is available.

BLUE-RINGED OCTOPUS

IDENTIFYING CHARACTERISTICS

Three species of blue-ringed octopi (*Hapalochlaena maculosa* Hoyle, *H. lunulata* Quoy and Gaimard, *H. fasciata* Hoyle) are the only species of the 650 species in the class Cephalopoda (e.g., octopus, squid, cuttlefish) that cause serious evenomation in humans.

Common Name: Southern or Lesser Blue-Ringed Octopus

Scientific Name: *Hapalochlaena maculosa* Hoyle

Physical Description: This octopus is about 15–20 cm/~6–8 in. with tentacles extended and weighs <100 g. The lesser blue-ringed octopus has dark brown-yellow bands that cover the body and arms along with iridescent blue rings. These colors darken and the rings fluoresce following stimulation of the octopus.

EXPOSURE

Geographic Distribution

The distribution of the blue-ringed octopus ranges from the Indo–West Pacific north to Okinawa, east to the Philippines, west to India, and south to New Zealand. The southern or lesser blue-ringed octopus (*H. maculosa* Hoyle) inhabits the warm shallow coastal waters of Australia, whereas the range of *Hapalochlaena lunulata* Quoy and Gaimard (greater blue-ringed octopus) includes tropical waters along the northern coastline of Australia near crevices, rock pools, and small caves as well as tropical waters of the western Pacific Ocean. The blue-lined octopus (*Hapalochlaena fasciata* Hoyle) lives in shallow, intertidal rocky shores and coastal waters from southern Queensland to southern New South Wales. All reported cases of envenomation by the blue-ringed octopus have occurred in Australia.

Behavior

The blue-ringed octopus captures prey (crabs, other crustaceans) either by discharging saliva into the vicinity of the prey and waiting for the paralysis of the prey or by covering the prey with the web between its arms to maintain high concentrations of the venom. Aggressive or hungry blue-ringed octopi may dart onto the back of the prey and inject the venom with its beak. Normally, this octopus is nocturnal and shy. Human envenomation by the blue-ringed octopus frequently occurs during inspection of the small, colorful octopus by an unsuspecting victim.

PRINCIPAL TOXINS

Venom Composition

The posterior salivary glands of the blue-ringed octopus contain the neurotoxin, maculotoxin, which is chemically identical to tetrodotoxin.[26,27] The eggs of the Australian blue-ringed octopus also contain tetrodotoxin along with most other soft body parts.[28] In a study of six juvenile blue-ringed octopuses (*Hapalochlaena maculosa*), tetrodotoxin was present in all three body parts (arms > abdomen > cephalothorax) tested.[29] Analysis of the posterior salivary gland and other soft parts from six specimens of *H. maculosus* demonstrated the presence of tetrodotoxin-producing strains of bacteria including strains from the genera *Alteromonas*, *Bacillus*, *Pseudomonas*, and *Vibrio*.[30] Other substances present in the venom or saliva of the octopus include proteolytic enzymes and various amines (e.g., hyaluronidase, hydroxyphenylethanolamine, noradrenaline, serotonin, dopamine, acetyl choline, tryptamine, taurine, tyramine, histamine).[31] The blue-ringed octopus is resistant to the effects of high concentrations of tetrodotoxin and venom extract from their posterior salivary glands, but the mechanism of this resistance is not known.[32] In animal models, tetrodotoxin is several times more toxic than structurally related compounds (e.g., anhydrotetrodotoxin, methoxytetrodotoxin).[33]

Venom Apparatus

Posterior salivary glands are connected to a sharp beak that is located near the central portion at the base of the arms.[34] These glands form compound tubuloacinar exocrine structures that contain muscle fibers in the interstitial regions of the secretory tubules.[35] Contractions of these fibers force secretory material along the salivary ducts into the intestinal blood space. These fibers probably are under voluntary control. The bite usually produces two small, painless puncture wounds that may bleed slightly.

Dose Response

The minimal lethal dose of tetrodotoxin varies substantially between animal species.[33] The oral LD_{50} of tetrodotoxin in mice is approximately 332 μg/kg.[36] Although the hypotensive effects of saxitoxin are weaker than tetrodotoxin, the lethal dose of tetrodotoxin and saxitoxin in animal models is similar.[37]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The neurotoxin, maculotoxin, is structurally identical to tetrodotoxin, and presumably the mechanism of toxicity of the venom and tetrodotoxin is similar. Tetrodotoxin binds to a site near the external orifice of the sodium channel and blocks the sodium channel selectively without affecting other types of voltage-activated and transmitter-activated ion channels.[38] The binding and penetration of calcium ions to the sodium channel is probably responsible for the voltage-dependent block. In animal models, the parenteral administration of the extract from posterior salivary glands of *H. maculosa* produces paralysis of the respiratory musculature resulting in anoxia.[39] Rapid administration of this substance also causes severe hypotension secondary to decreased peripheral vascular resistance that typically responds to noradrenaline infusion.

CLINICAL RESPONSE

The bite of the blue-ringed octopus usually is painless, but bleeding may occur at the puncture site. The severity of envenomation ranges from mild to severe.[40] Severe envenomations by the blue-ringed octopus produce the rapid onset of muscle weakness and respiratory depression.[41] Typically, lightheadedness, generalized weakness, nausea, and vomiting begin within 10 minutes of serious envenomations followed by neurological signs (slurred speech, dysphagia, paresthesias, muscle weakness, blurred vision, diplopia). Other neuromuscular signs include myoclonic jerks and muscle spasms. Symptoms usually resolve within 24 hours. Case reports suggest that anaphylactoid, and perhaps anaphylactic, responses may occur after envenomation characterized by pruritus, generalized urticaria, and synovitis.[42]

DIAGNOSTIC TESTING

Methods for the detection of tetrodotoxin include immunoaffinity chromatography and mass spectrometry after conversion of tetrodotoxin to a C9-based derivative. A simple method for the detection of tetrodotoxin in serum and urine samples involves clean up by solid-phase extraction followed by high performance liquid chromatography with post-column derivatization and fluorescence detection.[43] The limits of quantitation for tetrodotoxin in serum and urine samples using this method are 5 ng/mL and 20 ng/mL, respectively. Depending on the dose, detection times for tetrodotoxin in serum and urine samples are less than 1 day and 4–5 days, respectively.

TREATMENT

There are no specific first aid measures. In some locations, the use of compression bandages is recommended, but there are few clinical data to guide management. Because of the potential for respiratory failure following severe envenomations, the victim should be evaluated carefully for respiratory depression with pulse oximeter and evaluation of the adequacy of respirations. Respiratory failure may occur rapidly following severe envenomation, and intubation of the trachea may be necessary to support oxygenation. Otherwise, management is supportive. There are no clinical data to support the use of wound excision and hot water immersion. Patients displaying neurotoxic effects should be observed for 4–8 hours and admitted to an intensive care facility if symptoms progress.

Chapter 179

JELLYFISH, HYDROIDS, SEA ANEMONES, and CORALS
(Phylum: Cnidaria)

Cnidarians (coelenterates) are marine animals with long tentacles that contain multiple venomous stinging cells (nematocysts). This phylum is subdivided into Cubozoa (families: Chirodropidae, Carybdeidae), Hydrozoa (hydroids), Scyphozoa (jellyfish), and Anthozoa (sea anemones, true corals). Cnidarians in this phylum are simple metazoans with radial, biradial, or radio-bilateral symmetry.[1] These delicate creatures are covered with two epithelial layers that surround one internal cavity called the coelenteron. This gastrovascular cavity functions as both a gastrointestinal tract and a circulatory system. The dominant characteristic of this group is the presence of long tentacles surrounding the mouth to this cavity. These tentacles contain stinging organelles called nematocysts that vary in size between 0.005–1 mm (~0.0002–0.04 in.).

Two morphological forms of coelenterates (polyp, medusa) appear alternately during their life cycle. The polyp is the sedentary form that attaches to objects via the caudal end, and polyp feeds through the oral end. The medusa is the mobile form that contains a dome-shaped cavity and a mouth surrounded by tentacles on the concave undersurface. The highest concentrations of nematocysts appear near the mouth and outer surfaces of the tentacles. The cnidarians (coelenterates) cause more marine envenomations than species within any other phylum.

The generic term, jellyfish refers to a multitude of free-floating medusa (jellyfish) belonging to the phylum *Cnidaria*. The fourth class of *Cnidaria*, the anthozoans (e.g., corals, sea anemones), lack the medusa stage and remain attached to the sea bed in the form of a polyp. Figure 179.1 outlines the currently recognized members of the phylum that cause clinically significant envenomations in humans. The specific jellyfish involved in serious envenomations is frequently not identified,[2] and therefore other seriously venomous jellyfish probably exist.

TRUE JELLYFISH and BOX-JELLYFISH

This class of cnidarians is composed of the true medusae or larger jellyfish. Species of true jellyfish (Class: Scyphozoa) are the most conspicuous jellyfish based on the large size and coloration of the medusa stage, such as *Nemopilema nomurai* Kishinouye (Nomura's jellyfish or *Stomolophus nomurai*).[3] These creatures have eight notches along the margin of their dome. The most important venomous species of jellyfish occur in the class Cubozoa, which includes chirodropids (box-jellyfish—*Chironex fleckeri* Southcott, *Chiropsalmus quadrigatus* Haeckel) and carybdeids (Irukandji jellyfish).[4] The carybdeids usually have only one tentacle arising from each corner of the bell, whereas chirodropids usually have many tentacles connected to each

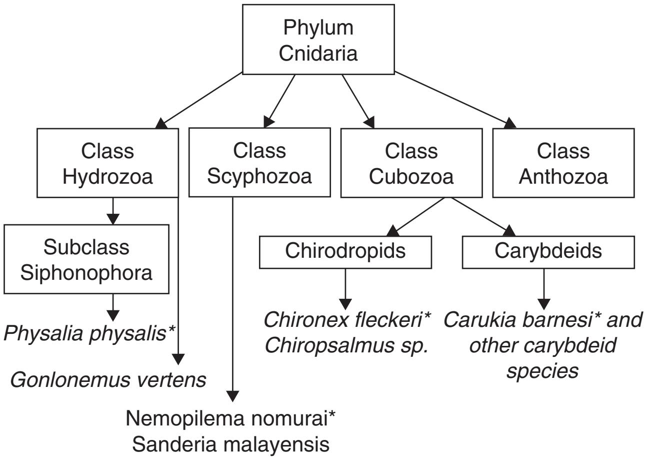

FIGURE 179.1 Overview of medically significant jellyfish with (*) indicating lethal or potentially lethal species. Adapted from Winkel KD, et al. Jellyfish antivenoms: past, present, and future. J Toxicol Toxin Rev 2003;22:117.

corner. Although some species of hydroids (*Physalia physalis* L., *Gonionemus vertens* Agassiz) resemble true jellyfish, these multitentacled hydroids are colonies of hydroids rather than true jellyfish. Fatalities occur as a result of envenomation by species in the three main Cnidarian classes, but the majority of deaths result from contact with chirodropids (i.e., *Chironex fleckeri* Southcott, *Chiropsalmus quadrigatus* Haeckel), primarily in children.[5]

HISTORY

The first reported fatality from envenomation by the North Australian box-jellyfish (*Chironex fleckeri* Southcott) occurred in 1883. In 1944, Southcott observed two different syndromes following jellyfish stings in troops stationed in north Queensland during World War II.[6] In the first syndrome, severe cutaneous pain and markings developed without systemic complaints, whereas the second type caused minor skin marks followed by the delayed onset of severe systemic symptoms. The jellyfish associated with former syndrome (severe cutaneous pain) was discovered in 1955, when Flecker caught several large, box-shaped jellyfish after the death of a young child. Later, Southcott confirmed that this new species causes this syndrome. He named the new species (*Chironex fleckeri* Southcott) after Flecker.[7] In 1952, Flecker named the delayed syndrome, the Irukandji syndrome, after the Aboriginal tribe that inhabited the region where most of the stings occurred.[8] Barnes discovered one of the sources of Irukandji syndrome in 1964 when he and his son developed the syndrome after being stung by a small jellyfish (*Carukia barnesi* Southcott) caught in the local area.[9]

IDENTIFYING CHARACTERISTICS

True jellyfish are the umbrella-shaped, gelatinous medusa stage of a hydroid polyp. The two main classes of true jellyfish are Scyphozoa (true jellyfish) and Cubozoa (box-jellyfish). Scyphozoans are common marine animals throughout the world. Their tentacles appear radially at regular intervals around the bell, and some species possess tentacles arising from inside the bell. True jellyfish associated with human envenomation include the mauve stinger (*Pelagia noctiluca* Forskål), lion's mane jellyfish (*Cyanea capillata* L.), and bluefire jellyfish (*Cyanea lamarckii* Péron & Lesueur). Box-jellyfish (cubozoans) are similar in form to the "true" jellyfish (scyphozoans). However, cubozoans (i.e., box-jellyfish) have a square shape on transverse section along with well-developed eyes and four evenly-spaced groups of one or more tentacles arising from the corners of the bell. The base of each tentacle is distinctively flattened, and the edge of the umbrella turns inward to form a rim (i.e., volarium). Two species of box-jellyfish (*Chironex fleckeri* Southcott, *Chiropsalmus quadrigatus* Haeckel) are indigenous to the southern Pacific Ocean, and these coelenterates are among the most venomous of all sea creatures. Other species of *Chiropsalmus* (e.g., Atlantic species *C. quadrumanus* F. Müller,) produce primarily severe local pain with less significant systemic symptoms,[10] although a fatality occurred in a 4-year old boy soon after envenomation by *C. quadrumanus* F. Müller.[11] The bells are difficult to see, and the tentacles are nearly invisible. Carybdeids are small box-jellyfish species (*Tamoya* spp. [morbakka], *Carybdea rastoni* Haacke [jimble], *Carukia barnesi* Southcott [Irukandji]) that also produce painful stings and an Irukandji-like syndrome. These large, widely distributed carybdeids have single large (i.e., up to 1 m/~3 ft in length) tentacles attached to each corner of a large bell ranging between 4–18 cm (~1.5–7 in.) in diameter.

Common Name: Lion's Mane, Hair Jelly
Scientific Name: *Cyanea capillata* L.
Class: Scyphozoa
Physical Description: *C. capillata* is a large, yellow or reddish-purple jellyfish whereas *C. lamarckii* Péron & Lesueur is blue. These saucer-shaped jellyfish range up to 2 m (~7 ft) in diameter with long, thin tentacles and scalloped edges on the bell.

Common Name: Mauve Stinger, Phosphorescent Floater
Scientific Name: *Pelagia noctiluca* Forskål
Class: Scyphozoa

Physical Description: These yellow to pink jellyfish have four thick oral arms on the bell along with thin tentacles ranging up to 3 m (~10 ft) in length.

Common Name: Sea Nettle

Scientific Name: *Chrysaora quinquecirrha* Desor

Class: Scyphozoa

Physical Description: This clear to light pink jellyfish has a bell containing four central thick oral arms and several thread-like tentacles up to ~3 m (~10 ft) in length.

Common Name: Sea Wasp, Box-Jellyfish, Marine Stinger

Scientific Name: *Chironex fleckeri* Southcott

Class: Cubozoa

Physical Description: These chirodropids have a square shape and more than one tentacle in each corner of the bell. The transparent bell can reach up to 25–30 cm (~10–12) in diameter with 60 tentacles, each 3 m (~10 ft) long. The total maximum potential tentacle length is about 180 m (~600 ft).

Common Name: Box-Jellyfish, Sea Wasp, Fire Medusa, Indringa, Killing Jellyfish

Scientific Name: *Chiropsalmus quadrigatus* Haeckel

Class: Cubozoa

Physical Description: This small jellyfish has a bell up to 7 cm (~3 in.) in diameter, and the appearance is similar to *Chironex fleckeri* except *Chiropsalmus quadrigatus* has fewer and shorter tentacles. These pale blue, transparent, cube-shaped box-jellyfish are often difficult to see. On each of the four corners of the bell, a group of up to 15 tentacles 3 m (~10 ft) long projects into pedaliums (feeding appendages). The outer layer (epidermis) contains the stinging cells (nematocysts). The inner endoderm (gastrodermis) covers the gut. The mesoglea is a jelly-like substance occupying the space between the epidermis and gastrodermis that contains collagen fibers and some cells. A ring of nematocyst-containing tentacles surrounds the mouth.

Common Name: Irukandji

Scientific Name: *Carukia barnesi* Southcott

Class: Cubozoa

Physical Description: This jellyfish has a tiny (<2 cm/~0.8 in.) transparent bell with four small tentacles. These tentacles are attached at the corners of the bell characteristic of box-jellyfish. In contrast to *Chironex* and *Chiropsalmus* box-jellyfish, there is only one tentacle at each corner.

EXPOSURE

Geographic Distribution

The hair jelly (*Cyanea* spp.) inhabits colder areas of the North and Baltic Seas as well as the Atlantic and Pacific Oceans including parts of the Australian coast. The mauve stinger (*Pelagia noctiluca* Forskål) drifts in currents in the Mediterranean Sea, tropical and subtropical Atlantic Ocean, and the English coast. At night, the presence of this jellyfish in the ocean waves produces a rose-red luminescence. The sea nettle (*Chrysaora quinquecirrha* Desor) is a free-floating jellyfish often present in large swarms in the tropical and subtropical Atlantic and Pacific Oceans. The chirodropid-type box-jellyfish appear during the summer months along coastal waters of tropical parts of the northern and southern hemispheres between the Tropic of Capricorn and the Tropic of Cancer. Although stings occur throughout the year, most stings occur in the summer months in shallow coastal waters, particularly during hot, calm days. These chirodropids live in tropical waters along the eastern and western Atlantic Ocean, the east coast and midportion of the Indian Ocean, and the Indo-West Pacific Ocean. Box-jellyfish from the species *Chironex fleckeri* Southcott inhabit coastal areas of northern Australia, adjacent waters of the tropical Indo-West Pacific, and southeastern Asia. These marine animals live in aquatic areas along the shoreline and adjacent estuaries. *Chiropsalmus quadrigatus* Haeckel inhabits the Indian Ocean near the northern Australian coast as well as the Philippine coast. The distribution of Irukandji in Australian tropical waters ranges from north Queensland northwards and westwards to Exmouth, Western Australia. The season for carybdeids is summer, similar to other box-jellyfish. An Irukandji-like syndrome occurred in unprotected divers following stings by jellyfish, when they were swimming over a shallow grassy bottom near the Florida Keys during combat training.[12] However, the etiology of this Irukandji-like syndrome remains unknown because these carybdeids are not known to inhabit this area.

Behavior

Chironex fleckeri Southcott are solitary marine animals that feed on large active prey (e.g., sergestid prawns, plankton, shrimp, small fish) in shallow water near the shoreline. These feeding habits result in incidental contact with humans. The medusa has feeding appendages (pedaliums) that lift food to its mouth. They are strong swimmers that can accelerate in bursts up to 5 ft (~2 m) per second. Their lifespan is measured in months. They reproduce both sexually and asexually. In late

summer, they gather in river mouths and estuaries to spawn before dying. Although most (>90%) envenomations occur in Australia from October 1st until June 1st, occasionally *C. fleckeri* envenomations occur in the cooler mid-year, particularly in the Northern Territory of Australia.[13] These stings typically occur in shallow water (≤1 m/<3 ft) on afternoons with low wind speed.

The food source for *Chiropsalmus quadrigatus* Haeckel includes small crustaceans and fish. These creatures tend to congregate near the mouths of creeks and rivers in search of prey, particularly after a rain. In general, these fast swimming jellyfish are not aggressive, and they often trap prey in their tentacles while swimming. Like the other sea wasp (*C. fleckeri* Southcott), reproduction occurs both sexually and asexually. During the sexual phase, the male jelly fertilizes eggs released by the female, and the fertilized eggs develop into larva and then into polyps. The polyps reproduce asexually by budding that releases young polyps to swim freely and to develop into adults. Chirodropids occur in tropical waters in the summer months with the season longest near the equator (e.g., Darwin, Australia) and shorter in areas distant from the equator.

Unlike chirodropids, which live near coastal shorelines, Irukandji stings can occur offshore on the Great Barrier Reef. Most *Chironex* stings occur on the legs, whereas Irukandji stings are more common on the arms.[14] Although Irukandji stings can occur anytime of year, most envenomations in Australian waters occur January through May.[15] Factors that favor Irukandji stings include high, incoming tide, warm ambient temperatures (>28 °C/82 °F), and windy days.

PRINCIPAL TOXINS

Venom Composition

The venoms from *Chiropsalmus quadrigatus* and *Chironex fleckeri* are among the most potent in the world. Animal experiments indicate that these venoms contain dermonecrotic, hemolytic, and lethal factors, but the chemical composition of these factors is not well defined.[16,17] The venoms from coelenterate species contain various enzymes and inflammatory mediators. Constituents include serotonin, ATPase, hyaluronidases, fibrinolysin, peripheral calcium antagonist, and a neurotoxic agent (tetramine), as well as the low-weight-molecular fractions that cause hemolysis, local necrosis, and myocardial depression.[18] Although the composition of the venoms from *Chiropsalmus quadrigatus* and *Chironex fleckeri* is similar, the clinical features of envenomation by the latter are more intense as a result of greater venom injection. Characterization of these thermolabile venoms is complicated by the propensity of the venoms to aggregate and to adhere to equipment surfaces.[19] Additionally, these venoms are relatively unstable when exposed to extreme pH changes and certain chemicals. An *in vivo* study on the stability of venom from *Chironex fleckeri* indicated that the response to this venom in rats was not significantly altered by preparing the venom between pH 5 and pH 9 or between temperatures 4 °C/39 °F to 30 °C/86 °F for $1\frac{1}{2}$ hours.[20] Boiling, but not freeze drying, abolished the cardiovascular effects of this venom. Tentacles may detach from the cnidarians (coelenterates) in rough waters, and the free-floating nematocysts may cause local irritation called sea lice. Even though the nematocysts are detached and the coelenterate is dead, the nematocysts may continue to discharge for a substantial period.

Venom Apparatus

Cnidarians rely primarily on chemical and mechanical perturbations rather than vision to detect and catch prey with their nematocyst-containing tentacles. Each double-walled capsular nematocyst is enclosed by specialized epidermal cells called a cnidoblast (cnidocyst). Some species have a triggering devise (cnidocil), whereas other species possess specialized chemoreceptors that activate the cnidoblast in the presence of prey. The two classes of chemoreceptors include chemoreceptors specific for free and conjugated *N*-acetylated sugars, whereas the other class exhibits broad specificity for low-molecular-weight amino acids. The presence of submicromolar concentrations of known chemical triggers (*N*-acetylated sugars, mucin) sensitize the mechanoreceptors to the frequencies (5–40 Hz) that correspond to the movements of swimming prey.[21] Although there are at least 27 types of nematocysts, most types of nematocysts share the common form of a tightly coiled, open-ended, threadlike tube surrounded by a venom capsule or cnidoblast (see Figure 179.2).[1] On top of this capsule is a lid-like covering or apical cap (i.e., operculum). The shape of the undischarged nematocyst is usually spherical or rod-like. The fluid within the nematocyst is the venom. The harpoon-like, hollow tube contains many spicules, some of which anchor the tube to the skin following discharge. The tube discharges through the operculum when the cnidoblast senses chemical changes or mechanical stimulation. The discharge of the nematocyst requires only a few milliseconds, although the everted thread tube penetrates small dermal capillaries and injects the surrounding venom intravascularly.[22] Absorption of the venom into the lymphatic system occurs from the surrounding dermal tissue following extrusion of venom through the hollow lumen of the thread tube. The severity of the envenomation depends on the ability of the thread tube to penetrate the human

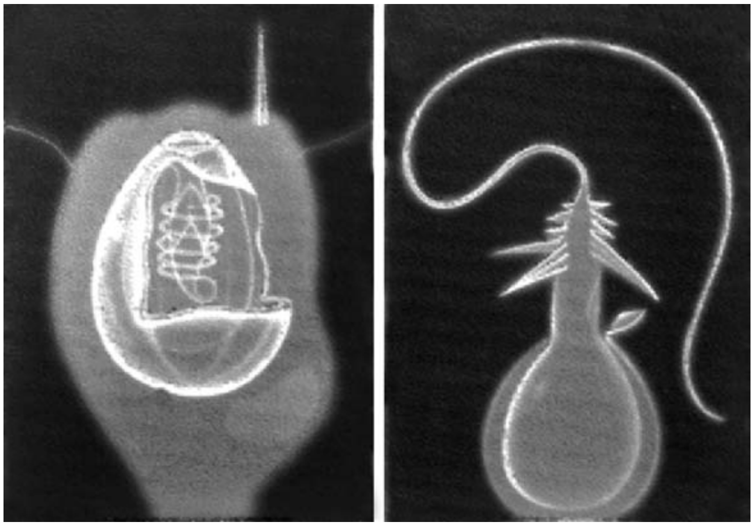

FIGURE 179.2 Uncharged and discharged nematocyst. Adapted from Halstead BW. Coelenterate (Cnidarian) stings and wounds. Clin Dermatol 1987;5:12. Reproduced with permission from Elsevier.

epidermis and to transfer venom to the dermis and capillaries.

Chironex fleckeri tentacles contain at least four types of nematocysts (microbasic mastigophores, atrichous isorhizas, holotrichous isorhizas, microbasic euryteles).[22] The eurytele nematocysts possess a tube with a butt composed of three bulbs and a middle bulb bearing long spines, whereas each holotrichous isorhiza contains a coiled tube with small spines along its length. The atrichous isorhiza nematocysts have spineless tubes that fold loosely in the undischarged condition. The microbasic mastigophore contains a capsule composed of a granular capsular matrix and an inverted, smooth-walled tube that narrows to form a tightly coiled, helical thread. These cigar-shaped structures are the most important type of nematocyst involved with envenomation.

Dose Response

Large coelenterates may discharge hundreds of thousands of nematocysts. The severity of the envenomation depends on the size and quantity of nematocysts, duration of contact, the size (width, length, thickness) of contact with the envenomated skin, presence of protective garments or hair, individual penetrating power of the nematocysts, individual sensitivity of the victim, and the cnidarian (coelenterate) species. Severe envenomations by *Chironex fleckeri* in children typically involve 10–15 tentacles. Envenomation of a 5-year-old boy by *Chironex fleckeri* that involved about 4m (~13ft) of tentacle contact was associated with a fatal outcome despite supportive care.[23] The boy arrived at the emergency department in cardiopulmonary arrest within 15 minutes of the envenomation.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Death from box-jellyfish venom probably results from respiratory failure or direct cardiotoxicity.[24] These venoms contain cardiotoxic, myotoxic, neurotoxic, cutaneous vasodilating, dermatonecrotic, and hemolytic properties, but these effects are not well-characterized.[25,26] Jellyfish venoms cause nonspecific production of large cation-selective channels or pores that modulate excitable neuromuscular membranes.[27] The venom also produces perturbations in the ionic calcium and/or sodium transport across excitable membranes, but the exact role of pore formation in the development of toxic cardiac and neurological effects remains unclear.[28] The principal clinical reaction of jellyfish envenomation is a toxic rather than immune response because repeat envenomations display similar symptoms and immunity to jellyfish envenomation does not usually develop.[29] However, allergic reactions may play a significant role in a few human envenomations. Specific anti-jellyfish venom IgE levels persisted several years in several envenomated patients with exaggerated responses to sea nettle (*Chrysaora quinquecirrha*), and these antibodies cross-reacted with Portuguese man-of-war (*Physalia*) venom.[30] A patient with a prolonged pruritic, erythematous rash following a jellyfish envenomation developed a positive response to a radioallergosorbent test for jellyfish antigens.[31] The venom from the *Carukia barnesi* (Irukandji) contains a neuronal sodium channel agonist that stimulates the release of massive quantities of catecholamines.[3]

Postmortem Examination

Postmortem examination of a 4-year-old boy, who died soon after a *Chiropsalmus quadrumanus* envenomation, demonstrated frothy white foam in the airways, widespread interstitial and perivascular lymphoid infiltration of the myocardium without necrosis, and focal subendocardial hemorrhage in the septum of the left ventricle.[11] There was marked passive congestion of the internal organs including the lungs. These findings were consistent with a massive catecholamine discharge and acute cardiac dysrhythmia with congestive heart failure. In the postmortem examination of a five-year old boy who died within 40 minutes of an envenomation by *Chironex fleckeri*, dermal changes were minimal.[32] Dermal abnormalities included congestion of superficial and mid-dermal capillaries, occasional melanin-containing melanophages, and mild perivascular edema. There was no evidence of an acute inflammatory infiltrate in the area of the envenomation. Electromicroscopy revealed that the nematocyst tubes penetrated the keratinocytes rather than following intercellular spaces, and the tubes from the nematocysts were present in the deep layers of the epidermis and dermis.

CLINICAL RESPONSE

Jellyfish envenomation (e.g., sea nettle) causes painful, linear, erythematous, vesicular lesions on the skin similar to lesions produced by a whip or a branding iron. Most stings occur on the lower legs or body with tentacles frequently adherent to the victim like a sticky thread. These stings usually produce only localized pain, and frequently the envenomating jellyfish is not identified. The pain typically resolves within 24 hours, although dermal lesions (hemorrhagic vesicles, urticaria) may persist for a month.[33] Systemic symptoms include headache, lightheadedness, malaise, muscle cramps, diaphoresis, and syncope. Recurrent eruptions at the site of envenomation, persistent granulomatous lesions, and activation of herpes labialis after the envenomation are rare sequelae. Atrophy of subcutaneous fat, granuloma annulare, and keloid formation may also occur at the site of injury.[34] Other complications of exposure to jellyfish include the development paralytic ileus after envenomation,[35] and ciguatera poisoning after ingestion of a jellyfish body without the tentacles.[36] Sea bather's eruption is a pruritic, maculopapular or vesicular skin eruption that primarily affects the cutaneous areas underneath swim wear.[37] These lesions develop up to 24 hours after exposure to the thimble jellyfish (*Linuche unguiculata* Schwartz) present in Florida coastal waters, the Gulf of Mexico, and the Mexican Caribbean. Pain and systemic symptoms are usually absent.

Chirodropids (Multitentacled Box-Jellyfish)

Symptoms range from mild discomfort caused by a contact dermatitis to serious systemic complaints. Envenomations by the most venomous, multitentacled box-jellyfish (*Chiropsalmus quadrigatus, Chironex fleckeri*) produce immediate, severely painful, cross-hatched areas of erythema, edema, and vesiculation that may result in necrosis. The majority of *Chironex fleckeri* envenomations are small, and these stings cause severe local cutaneous pain.[14] Most of these stings are not life-threatening.[13]

Severe symptoms include pulmonary edema, respiratory arrest, and cardiovascular collapse. There have been over 60 fatalities from *Chironex fleckeri* envenomations, primarily in children.[5] Cardiorespiratory arrest usually develops within a few minutes of a fatal envenomation; therefore, intervention with antivenom is typically too late to prevent death.[38] Delayed hypersensitivity reactions over the area of the envenomation frequently occur about 7–14 days after envenomation. These reactions involve a pruritic, erythematous maculopapular rash in a pattern over the initial tentacle contact consistent with papular urticaria.[39] Rarely, acute myocardial infarction develops in patients with chest pain after envenomation by jellyfish. A 45-year-old diver without risk factors for coronary artery disease had an acute inferior myocardial infarction manifest by chest pain and diaphoresis after envenomation by an unidentified jellyfish on the left forearm while diving near Qatar.[40] Coronary angiogram 4 days after the envenomation and after receiving streptokinase demonstrated normal coronary arteries.

Irukandji Syndrome (*Carukia barnesi*)

In contrast to the sting of chirodropids, the sting of the Irukandji is usually mild without significant tissue damage. The clinical features of this syndrome range from mild pain to serious cardiac dysfunction. Systemic symptoms typically begin about 30 minutes (range: ~5–40 minutes) after envenomation. Several types of clinical patterns may develop following envenomation by these jellyfish including 1) acute muscular pain in the chest and back, 2) sympathomimetic effects—sweating, headache, tachycardia, nausea, vomiting, hypertension, and 3) cardiorespiratory failure.[3] The initial symptom typically involves dull aching pain in the sacrum followed by the rapid development of diffuse muscle spasms and severe, colicky chest and abdominal pain.

These symptoms usually diminish within 24 hours, but complete resolution of symptoms may require up to one week.[12]

Many of the clinical features of the Irukandji syndrome are similar to the excessive release of adrenaline (e.g., pheochromocytoma) characterized by profuse sweating, piloerection, anxiety, restlessness, severe headache, tremor, pallor, hypertension, and tachycardia. Other serious complications include non-cardiogenic pulmonary edema and/or left ventricular dysfunction.[2,41] Complications of Irukandji envenomation include severe hypertension and fatal intracerebral hemorrhage.[42] Although most envenomations associated with the Irukandji syndrome result from *Carukia barnesi*, other jellyfish (*Tamoya* spp, *Carybdea* spp.) also cause this syndrome based on analysis of residual nematocysts by skin scrapings.[43,44] However, the clinical features of these envenomations are usually less severe than *Chironex* and *Chiropsalmus* box-jellyfish envenomations.[45]

DIAGNOSTIC TESTING

Analytical Methods

Identification of the envenomating jellyfish involves the harvesting of the nematocysts from the skin using either 1) the scraping of the sting site (after appropriate first-aid measures) with a scalpel and preservation of the specimen in 1–4% formalin, or 2) the application of 4–8 cm (~2–3 in.) of sticky-tape to the sting site and placement of tape on a glass slide. Both methods have similar yields of nematocysts following box-jellyfish envenomation, [46] although the sensitivity of these tests for Irukandji syndrome is unknown because of the low nematocyst identification rates.

Abnormalities

Case reports suggest that elevated serum troponin concentrations occur after jellyfish envenomation, even in the absence of significant reduction in cardiac contractility or elevated serum creatine kinase concentrations.[43] Following Irukandji stings, direct cardiac damage may occur, manifest by elevated cardiac troponin I, elevated creatine kinase, reduced cardiac index, nonspecific electrocardiographic abnormalities (i.e., T-wave inversion, ST-segment depression), and global ventricular dysfunction with poor ejection fraction. In a case series of 128 confirmed cases of Irukandji syndrome, 20% of the serum troponin I concentrations were abnormal with a range between 1.0–34 μg/L.[44] A case report associated elevation of serum creatine kinase and serum troponin I with myocarditis.[2]

TREATMENT

First Aid

Chirodropids (Multitentacled Box-Jellyfish)

Most victims of *Chironex* and *Chiropsalmus* box-jellyfish envenomation develop only local pain that responds to symptomatic treatment (cold packs, oral analgesics). However, these envenomations potentially may produce cardiorespiratory arrest; therefore, each victim should be evaluated immediately for the necessity of respiratory and cardiac support. Because of the potential seriousness of these envenomations, bystanders should immediately call for medical help. The presence of impaired circulation, breathing, or consciousness indicates a serious envenomation. The patient should be kept calm with limited motion of the affected extremity.

Although the covering of the contact site with vinegar for 30 seconds deactivates the nematocysts and prevents further envenomation, vinegar does not provide pain relief.[47] Cold packs may help relieve some of the pain, but there are few clinical data to determine the efficacy of cold or heat treatment. There are limited data suggesting that cold packs improve pain relief following envenomation by some jellyfish [*Physalia* spp., *Cyanea* sp. (hair jellyfish), *Tamoya* sp. (Moreton Bay stinger), *Carybdea rastoni*].[48] Other studies suggest that hot packs (45 °C/113 °F) may relieve the pain associated with envenomations by other chirodropids species [*Carybdea alata* (Hawaiian box-jellyfish)].[49,50] There are inadequate clinical data to support the use of pressure immobilization bandaging as a first-aid measure.[51] Although there are few data to confirm the efficacy of compression bandages during jellyfish envenomation, the use of compression bandages is recommended in some parts of Australia for application over the sting site of seriously envenomated victims.[4] If vinegar is not available, the tentacles must be removed by the rescuer prior to the use of compression bandages. These compression bandages are not recommended for minor to moderate jellyfish envenomations. In Australia, CSL *Chironex* antivenom is available for the treatment of serious *Chironex* box-jellyfish envenomations by trained health professionals on the beach. The dose is 1 ampule diluted 1:10 in saline administered intravenously over 10 minutes or 3 ampules intramuscularly. Up to 6 ampules may be administered intravenously during cardiopulmonary resuscitation (CPR).

Irukandji Syndrome

Most patients with Irukandji syndrome develop only minor symptoms that respond to local care. Occasion-

ally, noncardiogenic pulmonary edema occurs that requires intubation; therefore, victims of the Irukandji syndrome with any respiratory symptoms should be observed for respiratory distress with pulse oximetry, particularly if ongoing pain develops in an area of the body remote to the envenomation. The presence of continuous pain indicates the need for cardiac monitoring and evaluation of cardiac function (electrocardiogram, chest x-ray, cardiac troponin, creatine phosphokinase).

Non-Chirodropids

First-aid measures for jellyfish stings other than chirodropids are not well defined. The tentacles should be removed carefully from the skin. The rescuer may sustain some minor prickling sensations, but significant envenomation does not usually occur in the rescuer. If available, the use of double gloves reduces the risk of envenomation. Ice packs are a traditional part of the first aid that typically involves the application of ice for 5–15 minutes to the area of the sting after the removal of the jellyfish. Reapplication of the ice may be necessary if the pain recurs. However, the superiority of cold packs over the use of hot water for the treatment of pain associated with true jellyfish envenomations has not been well documented. Patients with systemic complaints should be referred for medical care.

Stabilization

The initial treatment of *Chironex* and *Chiropsalmus* box-jellyfish envenomations requires supplemental oxygen, intravenous access, and careful monitoring of cardiorespiratory status with pulse oximeter and cardiac monitor. Victims should be evaluated carefully for the need for endotracheal intubation. Patients with Irukandji syndrome may develop severe hypertension and chest pain that may require the use of intravenous sodium nitroprusside and intravenous nitrates. Intravenous phentolamine (5–10 mg IV) is an alternative to sodium nitroprusside for severe hypertension, but there are few clinical data to guide management. These patients should be observed closely for the development of pulmonary edema and myocardial dysfunction. Standard treatment for pulmonary edema includes diuretics (furosemide), morphine, and intravenous sodium nitrates. Testing includes electrocardiogram, cardiac enzymes (creatine phosphokinase with MB fraction, troponin), electrolytes, and measures of hepatorenal function.

Decontamination

The area envenomated by box-jellyfish should be irrigated copiously with 1–2 L vinegar for at least 30 seconds to inactivate any remaining nematocysts. After deactivation, the clinging tentacles should be washed off with either fresh or salt water.

Antivenom

The box-jellyfish antivenom is a purified ovine immunoglobulin that is available for the treatment of severe envenomations by *Chironex fleckeri* and the closely related cubozoan, *Chiropsalmus quadrigatus*. Indications include cardiorespiratory arrest, serious cardiac dysrhythmias, clinically significant dyspnea or dysphagia, severe pain unresponsive to narcotics, or extensive skin lesions, particularly in cosmetically important areas.[52] *In vitro* studies suggest that the antivenom is less effective against the neurotoxic and myotoxic effects of the venom.[53] Evidence supporting the efficacy of the antivenom in humans is primarily anecdotal.[52] Early use of the antivenom is important because there is no clear data to indicate that the antivenom can neutralize venom already bound to tissues, and the antivenom is unlikely to relieve pain following administration of the antivenom over 4–6 hours after envenomation.[54] The usual dose is 1 vial (20,000 U) for moderately severe stings to 3 vials for life-threatening stings. Adverse reactions to the antivenom are rare.[52] The efficacy of the current box-jellyfish antivenom (CSL Limited, Parkville, Australia) for the treatment of Irukandji syndrome remains unclear. This antivenom is not effective following envenomation by scyphozoan or hydrozoan jellyfish.[3]

Supplemental Care

Most patients with jellyfish stings develop only minor local symptoms, and these patients should be treated symptomatically (local ice packs, oral analgesics) and observed for 2 hours. If systemic symptoms do not occur, these patients may be discharged home with advice to return to the emergency department if systemic symptoms develop. Major envenomations frequently require intravenous narcotic analgesics (e.g., morphine, fentanyl, hydromorphone, meperidine) for pain relief. Following *Chironex* and *Chiropsalmus* box-jellyfish stings, patients with pain unresponsive to cold packs and analgesics are candidates for the administration of 1 ampule of dilute antivenom. Symptomatic patients should be monitored for the development of pulmonary edema and myocardial dysfunction, particularly during the first 24 hours. Delayed hypersensitivity responses to envenomation may develop in 7–14 days, and the pruritic rash usually responds to topical steroids creams and oral antihistamines. Patients with Irukandji syndrome may also develop severe pain that requires narcotic

analgesics. The use of intravenous magnesium sulfate is an experimental treatment for the pain and hypertension associated with the Irukandji syndrome based on case reports.[55] Patients with Irukandji syndrome and continuing pain despite adequate narcotic analgesics are at risk of developing cardiac complications.[43] These patients should be observed at least until the patient is pain-free 6 hours after the last dose of analgesics.[56] Observation should include a cardiac evaluation (creatine phosphokinase-MB, troponin I, chest x-ray, electrocardiogram, and echocardiography if evidence of cardiac dysfunction). Measurement of pulmonary artery pressures may be necessary to optimize the administration of vasopressors (dopamine, dobutamine, norepinephrine) for persistent hypotension. Secondary wound infections (*Vibrio vulnificus, Pseudomonas aeruginosa, Aeromonas salmonicida, Staphylococcus aureus, Streptococcus pyogenes*) are rare,[57] and when present usually respond to ciprofloxacin 500–750 mg twice daily.

HYDROIDS

Hydroids (Class: Hydrozoa) commonly occur as plume-like tufts growing on rocks, under corals, in seaweed, and along side underwater structures (pilings, piers). Small medusae project from branching tufts of the polyps. Hydroids are not true jellyfish, and *Physalia* species (Portuguese man-of-war) are colonial hydroids (siphonophores) rather than true jellyfish. The most toxicologically significant species of hydroids are the fire corals (*Millepora* spp.) and the Portuguese man-of-war (*Physalia* spp.) Other less common species of hydroids involved with adverse health effects include the tiny *Gonionemus vertens* Agassiz (orange-striped jellyfish) that has produced systemic symptoms similar to the Irukandji syndrome in Japan. Stings from hydroids produce symptoms ranging from mild, prickling sensations to extremely painful lesions (*Physalia* species) and severe systemic symptoms (*Gonionemus vertens* A. Agassiz).

Orange-Striped Jellyfish

This tiny hydrozoan (*Gonionemus vertens* A. Agassiz) is distributed worldwide, but serious envenomations have been reported only in the Sea of Japan, primarily during the hot summer months.[58] The bell is small (5–25 mm/~0.2–1 in.) with many tentacles attached to the entire edge of the bell. A distinctive symmetrical, right-angled cross is present on the transparent bell. *Gonionemus vertens* (*Gonionemus oshoro* Uchida) inhabits the Sea of Japan near Yamagata and the South Kuril Islands. Symptoms range from severe myalgias, muscle fasciculations, and arthralgias to rhinitis, lacrimation, hoarseness, cough, dyspnea, and mild hypertension. The symptoms last several hours to several days. Neuropsychiatric symptoms (malaise, depression, hallucinations) were associated with exposure to this hydrozoan, but there were no biomarkers to document envenomation by *Gonionemus* species.

Fire Corals

IDENTIFYING CHARACTERISTICS

Fire or stinging corals belong to the order Anthoathecata and Milleporidae family. These marine animals are not true corals. Although superficially similar to "true corals," these marine organisms share physical characteristics (e.g., nematocysts) with jellyfish and anemones. Fire coral (*Millepora* spp.) are a colony of nematocyst-bearing coelenterates with a calcareous skeleton rather than a true coral. These colony-forming polypoid hydrozoans secrete massive calcium carbonate skeletons that are covered with a thin epidermal layer. The skeleton has a smooth surface covered in pores of two different sizes for defensive polyps and feeding polyps. Defensive polyps (dactylozooids) arise from separate openings that encircle the gastrozooids (feeding polyps). *Millepora* species are upright, branching, calcareous growths. Fire coral may grow in a variety of shapes, including column-like, encrusting (flattened), branching, rounded, plate-like or box-shaped. Live colonies are usually yellow-brown with pale edges or branch tips, but some species may be white, yellow, pink, or green.

EXPOSURE

Geographic Distribution

Millepora species inhabit tropical and subtropical coastal areas in tropical and subtropical seas including the Mediterranean Sea, the Red Sea, and the Caribbean Sea. These organisms live in a wide range of coastal reef habitats including the Caribbean coast near Mexico (*M. complanata* Lamarck), Marshall Islands (*M. tenera* Boschma), the Red Sea (*M. platyphylla* Hemprich &

Ehrenberg, *M. dichotoma* Forskal), and the Florida Keys (*M. alcicornis* L.).

Behavior

The polyps live only 20 minutes out of water, and they are easily destroyed by host defenses. Tiny, hair-like dactylozooids may be visible during the day or night.

PRINCIPAL TOXINS

The venom from fire coral contains hemolytic, dermonecrotic, and lethal factors.[59–61] Extracts from the venom stimulate smooth muscle contraction, probably as a result of an increase in Ca^{++} permeability via *L*-type voltage-dependent Ca^{++} channels.[62] Hydroids from the genus *Millepora* possess nematocysts, like other members of the phylum Cnidaria. After chemical or mechanical stimulation, these nematocysts discharge toxins into skin in contact with the hydroid. Envenomation occurs when the nematocyst-containing polyps protrude through pores in the exoskeleton.

CLINICAL RESPONSE

Contact of unprotected extremities with most hydroids produces primarily mechanical injury along with varying degrees of erythema, edema, and pruritus. Rarely, these lesions progress to an indolent ulcer with irregular, necrotic borders. Stings by fire coral usually produce only minor discomfort characterized by small maculopapular lesions that develop about 1–10 hours after contact. Depending on the severity of the envenomation, pain may develop immediately along with an intense pruritus and urticarial wheals 5–30 minutes after envenomation followed by erythematous, edema, and vesiculation within 6 hours. Brief contact of unprotected skin with fire coral can produce more serious stings that classically involve the following four stages: 1) acute urticaria, 2) acute vesiculobullous dermatitis, 3) subacute granulomatous dermatitis, and 4) chronic lichenoid dermatitis.[63] Pruritus may persist during the development of chronic lichenified changes 3 weeks after envenomation. Resolution may require up to 4 months with some residual hyperpigmentation and hypertrophic scarring. Rarely, necrosis of the skin may occur.[64] Systemic symptoms (abdominal pain, diarrhea, fever, chills, muscle spasm, malaise) are unusual, and there are no well-documented fatalities from envenomation by fire corals. Other hydrozoans including sea-fern hydroids and other feather hydroids belonging to the order Leptothecata (*Aglaophenia cupressina* Lamouroux, *Macrorhynchia philippina* Kirchenpauer, *Halecium beanii* Johnston, *Nemalecium lighti* Hargitt) also produce dermal injuries characterized by pruritic, erythematous papular-vesicular lesions and rarely erythema multiforme.[65]

TREATMENT

There are few data to guide the management of fire coral stings. Theoretically, the irrigation of the lesion with vinegar would inactivate any remaining nematocysts. The wound should be inspected and, if necessary, probed carefully to detect any remaining skeletal fragments. Lacerations require thorough exploration and irrigation with copious amounts of saline after local anesthesia. Anecdotally, the antiseptic (nondetergent formulation) povidone-iodine (Betadine®, Purdue Pharma, Stamford, CT) solution may be added in very dilute concentration to the irrigating solution for grossly contaminated wounds. However, there are few clinical data to guide management of these wounds. After thorough cleansing, facial wounds can be closed. Old wounds (i.e., extremity wounds presenting 6–8 hours after injury) may benefit from delayed primary closure after cleaning. If no infection develops by the fourth day after cleansing, the wound can be closed safely. There are no data to support the use of prophylactic antibiotics unless the wound is grossly contaminated. Intradermal steroid injections may be beneficial for chronic, pruritic lichenified lesions that do not respond to oral antihistamines and topical steroids.[66]

Portuguese Man-of-War

IDENTIFYING CHARACTERISTICS

Although there are some structural similarities between *Physalia* species and true jellyfish, the Portuguese man-of-war is a colonial hydroid rather than a true jellyfish. This free-floating hydrozoan colony consists of four separate organisms living in a symbiotic relationship. These blue cnidarians (coelenterates) contain gas-forming glands (carbon monoxide, nitrogen) and form a float with a crest (pneumatophore) that functions as a sail. Gastrozooids enable the organism to digest food. The similarity of the body and long tentacles to a Portuguese admiral's hat accounts for the name Portuguese man-of-war. These tentacles sometimes reach 30 m (100 ft) in length and may contain over one million nematocysts.

Common Name: Atlantic Portuguese Man-of-War

Scientific Name: *Physalia physalis* L.

Physical Description: The clearly visible blue float ranges up to 25 cm (~10 in.) in diameter. The gastric cavity is 5–10 cm (~2–4 in.) in diameter, similar to the Pacific variety, but the highly retractable blue tentacles are longer and more numerous than the bluebottle (*P. utriculus*).

Common Name: Pacific (Portuguese) Man-of-War, Bluebottle

Scientific Name: *Physalia utriculus* La Martiniere

Physical Description: The blue body rarely exceeds 8–10 cm (~3–4 in.) in diameter, and the tentacles seldom reach 30 m (~100 ft).

EXPOSURE

Geographic Distribution

The distribution of *Physalia* species is worldwide in the temperate and tropical zones with more serious stings prevalent in warmer waters. The Atlantic Portuguese man-of-war (*P. utriculus* La Martiniere) inhabits the Atlantic Ocean and Caribbean Sea. The smaller version of the Atlantic variety (*Physalia utriculus* La Martiniere) is distributed across the Pacific and Indian Oceans. Small Portuguese man-of-war specimens appear in the fall, whereas larger specimens usually occur in the spring.

Behavior

This hydrozoan siphonophore forms a drifting polyp colony on the surface of the water with the long tentacles trailing underneath the surface. The bluish float is obscure on the surface of the water; therefore, the risk of contact with swimmers is high. The tentacles stick to fishing nets; consequently, fishermen can sustain injuries while retrieving their nets. These organisms are predators that use several markedly elongated tentacles called fishing tentacles to trap small fish. Exposure to active tentacles may result from the detachment of tentacles during mechanical trauma (e.g., storms) and the presence of these tentacles on the shore. Some sea slugs (*Glaucus* spp.) feed on Portuguese man-of-war tentacles. The undischarged nematocysts pass through the intestinal tract and lodge on the dorsal papillae of the sea slug, where contact with bathers produces a contact dermatitis. The Portuguese man-of-war lacks a free-swimming, bell-shaped medusa stage common to jellyfish. The fishing tentacles contain high concentrations of nematocyst, and contact with the fishing tentacles produces a characteristic pattern of injury that resembles a pearl necklace (i.e., a series of bumps).

PRINCIPAL TOXINS

Venom Composition

The major component of *Physalia physalis* venom is physalitoxin (CAS RN:77108-01-1), which is a potent hemolysin. *In vitro* studies indicate that Portuguese man-of war venom alters plasma membranes and causes calcium influx in several cell types including cardiac cells.[67] The venom-induced calcium influx accompanies a dose-dependent release of intracellular lactate dehydrogenase in an animal model that indicates a loss of plasma membrane integrity and cytolysis. *Physalia* venom contains a neurotoxin that produces intense pain and causes prostaglandin-induced vasodilation *in vivo* and *in vitro*.[34] This venom also releases of histamine and nonspecific endonucleases that cleaves DNA over a wide range of pH.

Venom Apparatus

The two sizes of nematocysts in *Physalia* tentacles average about 10 μm and 23 μm in diameter; *in vitro* studies indicate that the smaller nematocysts contain venom, whereas proteins separated from the larger nematocysts by flow cytometry do not cause toxicity.[68] The sensory trigger receptor for the *Physalia* nematocysts is the cnidocil apparatus.

Dose Response

A *P. physalis* evenomation involving a total length of approximately 9–12 ft (~3–4 m) on the upper extremities was associated with the rapid onset of coma, respiratory arrest, hypotension, and severe bradycardia.[69] The 67-year-old woman died 5 days later of aspiration pneumonia and respiratory failure without regaining consciousness.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Postmortem examination of a 67-year-old woman, who died 5 days after developing cardiorespiratory failure immediately after a *P. physalis* evenomation, demonstrated patchy areas of dermal necrosis with neutrophilic and lymphocytic infiltration and extravasation of erythrocytes.[69] There were focal areas of arteriosclerotic cardiovascular disease, but there was no evidence of myocardial necrosis. The victim initially developed a respiratory arrest followed by severe bradycardia and asystole.

CLINICAL RESPONSE

This marine organism is the most dangerous hydroid because of its propensity to cause systemic symptoms. However, most envenomations result only in local symptoms, and fatalities are rare. Stings by the Portuguese man-of-war cause immediate pain along with the early appearance of small, multiple, discontinuous, linear, erythematous papules. This distinctive pattern of the envenomation resembles a beaded, urticarial skin eruption with ladder-like spacing.[70] Localized pain may spread to larger muscle masses or to the whole body. Over several days, the papules can progress to vesicles and pustules that produce hemorrhage, ulcerations, and ultimately hyperpigmentation.[6] Delayed and recurrent skin lesions may develop along the linear area of the prior envenomation weeks to months after the initial envenomation including eczematous, urticarial, or vesiculobullous lesions. Rarely, case reports associate jellyfish envenomation and elevated serum titers against *P. physalis* with acute, localized narrowing of major vessels at the site of the sting and limb-threatening distal ischemia.[71] However, the envenomating jellyfish was not positively identified. Chronic, hypersensitivity-like skin responses following envenomation include erythema nodosum, erythema multiforme, granuloma annulare, postinflammatory hyperpigmentation, and hypertrophic scars.[72] Several case reports suggest that repeat stings may produce a hypersensitivity response that causes arterial spasm, local necrosis, and rarely anaphylaxis.[71,73]

Systemic reactions are more common with the Atlantic variety (*P. physalis*) than the Pacific variety, and the clinical features of envenomation include weakness, fever, malaise, headache, nausea, vomiting, severe muscle spasm and pain in the abdomen and back, paresthesias, and anxiety. These symptoms are similar to the Irukandji syndrome.[74] Rarely, respiratory or myocardial depression, seizures, hemolysis, acute renal failure, and anaphylactic reactions occur. Fatalities may occur as a result of respiratory arrest or cardiac dysthymias.[69,75] Symptoms may persist for 48 hours.

DIAGNOSTIC TESTING

Identification of the envenomating jellyfish involves the harvesting of the nematocysts from the skin using either scalpel-blade scraping of the sting site (after appropriate first-aid measures) or sticky-tape sampling. Both methods have similar yields of nematocysts following box-jellyfish envenomation. There are no specific laboratory abnormalities associated with envenomation by *Physalia* spp.

TREATMENT

The patient should be kept calm to limit the spread of the venom. Systemic symptoms may require cardiorespiratory support, particularly for children swallowing tentacles. First aid is similar to that for most cnidarians (coelenterate) venom. Exposure to vinegar produces varying effects on the discharge of nematocysts from different jellyfish species. Although vinegar inhibits the release of nematocysts from the box-jellyfish species (*Chironex fleckeri*, *Chiropsalmus quadrigatus*),[76] the use of vinegar may increase the discharge of nematocysts from *Physalia* species in Australian waters.[77] However, other studies suggest that this first-aid measure did not increase the discharges from nematocysts from the Atlantic Portuguese man-of-war.[78] Consequently, the safest decontamination measure is to wash off adherent tentacles with fresh sea water. An open-label, randomized comparison trial suggested that immersion of the sting site from *Physalis* species in 45 °C/113 °F water for 20 minutes reduces the pain associated with these stings, when compared with ice pack treatment.[79] Rarely, envenomated patients develop cardiorespiratory dysfunction; therefore, victims of envenomation require evaluation of the adequacy of ventilation and circulation. Elderly patients with cardiopulmonary disease may develop respiratory depression, particularly after the administration of narcotics. There is no antivenom for *Physalia* evenomation.

ANTHOZOANS

The Class Anthozoa contains sea anemones, hard corals, soft coral, zoanthids, sea pens, and sea fans (gorgonians). Anthozoans exist primarily as the polyp form, and there is no distinct medusa stage in the life cycle. Many anthozoans are colonies of polyps, such as anemone-like zoanthids. In some species, the polyps separate almost completely from each other after budding, whereas other species exist as interconnected polyps that form a continuous mat of tough, rubbery/leathery living tissue.

Sea Anemones

Sea anemones are primarily sedentary marine polyps with a columnar body and highly variable size and color. Sea anemones are present in all oceans ranging from

Arctic to Antarctic waters. These marine organisms develop stationary polyps with tentacles surrounding the mouth on an oral pole. The caudal pole stabilizes the body by forming attachments to an object (i.e., reef inhabitants such as coral). They rely on water currents and the movement of prey to bring the prey in contact with their tentacles. The tentacles contain nematocysts that discharge in response to appropriate chemical and mechanical stimuli. Mechanical stimulus alone is sufficient to cause the nematocyst to discharge. The number of nematocysts discharged depends on the frequency of the mechanical stimulation as well as the stimulation of chemoreceptors. There are at least two types of chemoreceptors that bind *N*-acetylated sugars in the mucins and amino compounds in the hemolymph of prey.[80] These chemical stimuli modulate the frequency and amplitude of the nematocyst discharge to increase the ability of the sea anemone to immobilize prey. Sea anemone venom contains toxins that block currents through voltage-gated potassium channels similar to scorpion toxins.[81] Additionally, some sea anemone venom contains small polypeptides (site-3 toxins) that bind to the extracellular surface of voltage-gated sodium channels.[82] After binding to a site near the S4 segment in domain IV, these toxins disrupt the normal fast inactivation transition resulting in a marked prolongation of the action potentials of excitable tissues of nerves and muscles.

Evenomation by sea anemones varies substantially in intensity depending on the species, but local symptoms are usually mild. The characteristic lesions are erythematous, slightly raised with a flower-like pattern of small, irregularly scattered vesicles. Clinical features of envenomation include pruritus, localized burning, edema, erythema, petechial hemorrhages, ecchymosis that rarely progress to necrosis and ulceration. Systemic symptoms are uncommon. Several case reports temporally associated progressive swelling of an extremity after a sea anemone envenomation with the development of acute renal dysfunction[83] and fulminant hepatic failure,[84] but the species was not specifically identified. Mild systemic symptoms (e.g., headache, weakness, lightheadedness) may accompany envenomations by sea anemones.[85]

Certain sea anemone genera (*Sagartia*, *Anemonia*) contain species that proliferate at the base of sponges and produce sponge fisherman's disease.[86] Secondary infections and abscesses may complicate stings by these creatures. The venom from the Okinawan sea anemone (*Phyllodiscus semoni* Kwietniewski) contains hemolytic polypeptides that cause a relatively more severe dermatitis with edema and ulcerations compared with other sea anemone species.[87] Although the effects of most sea anemone envenomation result in mild, local lesions, stings by the blue-gray to light brown sea anemone (*Actinodendron plumosum* Haddon) may cause extremely painful skin lesions that may persist for weeks. Treatment of sea anemone is similar to other coelenterate envenomations.

Hard Coral

Soft and hard corals (Order: Scleractinia) share a very simple body plan and a polyp structure. This group constitutes the major portion of massive coral reefs, where the calcified exoskeletons of hard corals surround small anemone-like polyps. Besides lacking a hard external skeleton and reef-building capacity, soft corals differ from the hard corals by the presence of eight tentacles rather than the multiples of six tentacles on hard coral polyps. Mechanical trauma is the major complication of exposure to hard coral (order: Scleractinia) because of the sharp edges, introduction of foreign bodies, secondary infection, and poor venom apparatuses. Coral injuries typically begin as mild, superficial wounds that progress to clinically significant cellulitis. Treatment of hard coral injuries requires careful debridement and irrigation because wounds may become indolent, like fire coral envenomations.

Soft Coral, Zoanthids, and Palytoxin

Some members of the order Alcyonacea [soft coral (*Palythoa* spp.), sea fans, sea pansies, sea pens] contain the potent marine toxin, palytoxin, but these organisms are not toxicologically significant unless the toxin accumulates in the food chain. However, toxicity usually results from the ingestion of predators that feed on these coral rather than the soft coral because the soft coral lack a venom apparatus to inject the palytoxin. Zoanthids are tropical and subtropical, anemone-like anthozoans (order: Zoantharia) that encrust rocky surfaces in the crevices of wave-swept tide pools or form mats in sandy back reef flats. These common inhabitants are one of the most abundant organisms in shallow coral reefs and tidal pools, and these organisms are soft corals that have no skeleton. Colonies of zoanthids, (e.g., *Palythoa tuberculoa* Klunzinger) are composed of large, flattened, fused polyps with diameters up to 2 cm (~1 in.).

Palytoxin is a highly potent marine compound first extracted from zoanthids of the genus *Palythoa* that live

in tidal rock pools in Maui.[88] Species from this genus are widespread throughout coastal areas of the Western Pacific and Caribbean. Other major sources of the palytoxin include zoanthids in the genus *Zoanthus* and dinoflagellates (*Ostreopsis* spp.).[89] In animal studies, palytoxin is a potent toxin. The LD_{50} of palytoxin in rodents following parental administration (10–100 ng/kg) is about 50 times lower than tetrodotoxin and saxitoxin.[90] The concentration of palytoxin in soft corals varies depending on a variety of factors including species, strain, and season. This toxin is a large (approximately 2,680 kDa), water-soluble compound that probably does not accumulate in fatty tissue. Palytoxin also occurs in marine organisms living in close association with zoanthid colonies, such as sea fans, sponges (phylum: *Porifera*), mussels and crustaceans.[91] Accumulation of palytoxin also occurs in marine animals (e.g., xanthid crabs) that graze on tropical coral reefs and in marine animals (e.g., filefish, triggerfish, mackerels, crown-of-thorn starfish, polychaete worms) that feed on these reef-grazing marine animals.[92] Palytoxin acts through the P-type enzyme, Na^+/K^+-ATPase, to convert the Na^+/K^+ ion pump into nonselective cation channels, possibly by disrupting the normal strict coupling between opening of one access pathway in the P-type Na^+/K^+ ATPase and the closing of the other.[93,94] These actions produce cation movement along ion gradients and the depolarization of excitable cells with release of neurotransmitters. The exact mechanism of the release of neuronal transmitters remains unclear. Palytoxin is a potent hemolysin and histaminic agent. Some species of soft coral (*Lophogorgia* spp.) contain lophotoxin (CAS RN:78697-56-0), which binds irreversibly to the muscle nicotinic acetylcholine receptor by forming a covalent bond with a tyrosine residue in the α-subunit of the receptor.[95] There are few data on the clinical significance of these nicotinic antagonists following exposure to this soft coral.

The ingestion of fish contaminated with palytoxin produces ciguatera-like seafood poisoning that includes rhabdomyolysis, severe muscle spasms and acute respiratory distress.[96,97] A monoclonal antibody-based, enzyme-linked immunoassay (ELISA) has been developed to rapidly detect palytoxin.[98] Patients with palytoxin poisoning should be evaluated for the presence of rhabdomyolysis and renal function. There are few data to guide management, and the treatment of palytoxin poisoning is supportive (analgesics, fluids).

Chapter 180

SPONGES
(Phylum: Porifera)

IDENTIFYING CHARACTERISTICS

The phylum Porifera (sponges) contains three classes: the largest class, Demospongiae, Calcarea (sponges with limy spicules), and Hexactinellida, (glass sponges).[1] There are at least 5,000 species of sponges, and over 600 species are associated with human toxicity.[2,3] These simple animals are extremely diverse, occurring in many colors, shapes, compressibility, and sizes.

Species associated with human toxicity include the Caribbean and Hawaiian fire sponge (*Tedania ignis*),[4,5] the Western Tropical Atlantic poison bun sponge (*Neofibularia nolitangere* Duchassaing & Michelotti), the Northeastern American red sponge (*Microciona prolifera*), and the Southern Australian stinging sponges (*Neofibularia mordens*, *Lissodendoryx* spp.).[6] Sponges are small multicellular animals with hollow centers, branched tubes, and mineralized skeletons that contain calcium carbonate or silica spicules. Dense masses of spicules are attached with spongin to form the sponge skeleton. Spongin is a fibrillar, intracellular collagen that cements the spicules at points of contact to form the skeleton.

Common Name: Australian Stinging Sponge
Scientific Name: *Neofibularia mordens* Hartman
Physical Description: This sponge is gray to royal blue on the outer surface with an ochre or yellow interior.

Common Name: Red-Bearded Sponge, Northeastern American Red Sponge, Oyster Sponge, Red Moss Sponge
Scientific Name: *Microciona prolifera*
Physical Description: This orange-red sponge forms dense clusters of curved and twisted, finger-like lobes. This sponge reaches 20 cm (~8 in.) in height

Common Name: Hawaiian Fire Sponge, Caribbean Fire Sponge, Scarlet Sponge, Fire Sponge
Scientific Name: *Tedania ignis* Duchassaing & Michelotti
Physical Description: The fire sponge is an orange to bright red sponge with distinctive, volcano-like ostia. The colony reaches 4–12 in. (~10–30 cm) in diameter.

EXPOSURE

Sponges occur worldwide, primarily in shallow waters. Most, but not all, of these sessile, long-lived organisms inhabit marine environments near coastlines. *Neofibularia mordens* Hartman inhabits coastal waters near Australia and New Zealand. The red-bearded sponge (*Microciona prolifera*) grows in small clumps on oyster shells and pilings in shallow, subtidal areas along the Atlantic and Pacific coasts. The range of the red-beard sponge extends from Nova Scotia to Florida and Texas, as well as from Washington to California on the Pacific Coast. The Caribbean fire sponge (*Tedania ignis*) lives in shallow coastal waters and tidal zones of the tropical western Atlantic and Pacific Oceans, particularly on the roots of mangrove trees or on other sponges. Other sponges associated with dermal lesions include *Haliclona* spp. (eastern Australia), *Biemna saucia* Hooper,

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

Capon & Hodder (northern Australia), *Ephydatia* spp. (central Australia), *Neofibularia nolitangere* (North America), *Tedania nigrescens* Schmidt, and *Tedania anhelans* Lieberkuhn (New South Wales, Australia).[7]

Sponges have porous exteriors composed of fibrous material (calcium carbonate, silicon dioxide, protein, or spongin). The surface structure of the sponge contains pores or ostia. Through these ostia, water and food enter a system of canals that direct these substances to chambers lined with hairlike flagellum and cells containing sticky, collar-shaped structures. Marine sponges are filter feeders that provide refuge for many small invertebrates and symbiotic microorganisms.[8]

PRINCIPAL TOXINS

Sponges are comprised of a skeleton of silica or calcium carbonate spicules and spongin fibers covered with a surface liquid or slime. Sponges do not possess specialized venom glands, but many species produce crinotoxins (surface liquids or slimes). This slime probably causes a contact dermatitis when the fine, sharp spicules of the sponge break during human contact; however, there are few data on the chemical composition of the slime or any active ingredients.[9] Calcareous spicules may contaminate the wound and contribute to mechanical trauma. These spicules range in size up to about 10 mm with one to four rays (actins).[10] A thin organic sheath covers the spicules. These biominerals have various shapes and consist mainly of magnesium-calcite. Drying reduces the toxicity of stinging sponges, and moisture can reactivate the dermal toxicity of the sponges.[6] *Neofibularia mordens* remains toxic despite 4 years of frozen storage.

The cause of these dermal lesions remains unclear with a variety of potential sources including chemical toxicity, trauma, fungi, viruses, cyanobacteria, and bacteria (*Bacillus* spp., *Pseudomonas* spp.).[11] Hypersensitivity probably does not contribute to the acute phases of the sponge-induced contact dermatitis.[12] The contact dermatitis associated with stinging sponges is distinct from sponge fisherman's disease. This latter entity develops after contact with nematocysts of sea anemones (*Sagartia* spp., *Actinia* spp.), which proliferate at the base of the sponge. Consequently, sponge fisherman's disease occurs when sponge collectors are stung by the nematocyst of the sea anemones that grow near the sponge. Dogger Bank Itch is a severe allergic contact dermatitis that develops in Danish and British trawlermen in the North Sea as a result of repeated exposure to the marine bryozoan, *Alcyonidium gelatinosum* L. This organism contains the allergen, (2-hydroxyethyl) dimethylsulfoxonium ion, which is also present in some sponges (e.g., *Theonella mirabilis* de Laubenfels).[13] However, the clinical significance of this allergen in marine sponges remains unclear.

CLINICAL RESPONSE

Direct contact with these sponges produces a contact dermatitis similar to poison oak or poison ivy (*Rhus*), and systemic reactions do not usually occur following contact with stinging sponges. Dermal injuries to the extremities usually occur when the sponges are handled with unprotected hands after removal from the marine environment. Typically, the victim develops a burning pruritus and erythema within 1 hour of contact. By the following day, mild edema, pain, and local stiffness occur that may spread beyond the area of contact. The intensity of the symptoms associated with these lesions depends, in part, on the species of sponge. The erythematous lesions may progress to vesiculation several days after contact. Pain and local stiffness may persist a few weeks to over several months. Late manifestations include exfoliation or desquamation of the involved skin 1–3 weeks following contact with the stinging sponge. A case report associated the handling of a specimen of Bermuda fire sponge (*Tedania ignis*) with an initial burning, pruritic erythema that resolved over 8 hours. Ten days later, pruritic target lesions appeared on the volar surface of the arms. These lesions became generalized to the face, palms, and soles consistent with erythema multiforme.[14] An anaphylactoid reaction occurred in this patient following patch testing to the Bermuda fire sponge. Secondary infections may develop following contamination of the skin lesion with marine organisms (*Mycobacterium marinum*, *Erysipelothrix rhusiopathiae*, *Erysipelothrix insidiosa*, *Vibrio parahaemolyticus*).

TREATMENT

Contact with sponges causes primarily local reactions. Treatment is supportive. The wound should be cleaned with saline after thorough inspection and removal of all spicules by careful scraping or the use of adhesive tape. Case reports suggest that dilute vinegar soaks (30 mL vinegar per liter of water) or 5% acetic acid soaks several times per day for 5–30 minutes may reduce symptoms of pain and pruritus.[6] Desquamation occurs despite vinegar soaks. Anecdotal experience does not support the use of topical steroids, antihistamines, or prophylactic antibiotics for the treatment of symptoms associated with stinging sponges. The role of topical steroids and antihistamines in delayed reactions remains undefined. Lymphadenopathy may result from the envenomation, and the presence of lymphadenopathy alone does not indicate an infection. Patients should be followed for signs of secondary infection.

Chapter 181

STARFISH, SEA URCHINS, SEA CUCUMBERS, and FIREWORMS (Phylum: Echinodermata)

STARFISH

IDENTIFYING CHARACTERISTICS

Crown-of-thorns starfish belong to the phylum Echinodermata (Class: Asteroidea), and this organism is the main venomous starfish.

Common Name: Crown-of-Thorns Starfish, Crown-of-Thorns Sea Star

Scientific Name: *Acanthaster planci* L.

Family: Acanthasteridae

Physical Description: Crown-of-thorns is an attractive starfish that possesses dorsal spines covered with a venom-secreting sheath. This organism grows up to 50cm (~20in.) in diameter. The radially arranged body has five arms surrounding a central disk. A green to green-red-purple epidermis covers this starfish that contains mucoid-secreting glands. Figure 181.1 displays a specimen of the crown-of-thorns sea star.

EXPOSURE

Starfish are widely distributed throughout tropical coastal waters. Crown-of-thorns (*Acanthaster planci*) is plentiful in the Great Barrier Reef off Australia. This starfish inhabits coral reefs in the Indo–Pacific Ocean and the Red Sea. The proliferation of this starfish causes considerate destruction of the coral reefs.[1]

PRINCIPAL TOXINS

The needle-sharp dorsal spines of *A. planci* extend 1–5cm (~0.4–2in.) in length with an elongated conical shape. These spines contain a dense calcitic cortex and a less dense medullary pulp that breaks easily. The venom from crown-of-thorns starfish contains myonecrotic, hemorrhagic, capillary permeability, and histamine-releasing factors. The constituents of the venom include phospholipases A_2,[2] thornasteroside A, acanthaglycosides A–F, versicoside A, plancinin (anticoagulant factor), and a lethal factor.[3,4] Although phospholipases are abundant in the venom of snakes and insects, relatively few marine species (i.e., the snail *Conus magus* L., the Mediterranean jellyfish *Rhopilema nomadica* Galil, Spannier & Ferguson) possess this enzyme. As purified by conventional column chromatography, the lethal factor is a basic glycoprotein with a molecular weight of about 20–25kDa.[5] This lethal factor is a mixture of toxins (plancitoxin I and II), which are hepatotoxic and structurally similar to mammalian deoxyribonucleases II (DNase II).[6] Several species of Japanese starfish (*Astropecten scoparius* Valenciennes, *A. latespinosus* Meissner, *A. polyacanthus* Müller & Troschel) contain tetrodotoxin and one Japanese starfish (*Astropecten amurensis* Fisher) contains paralytic shellfish poison.[7,8]

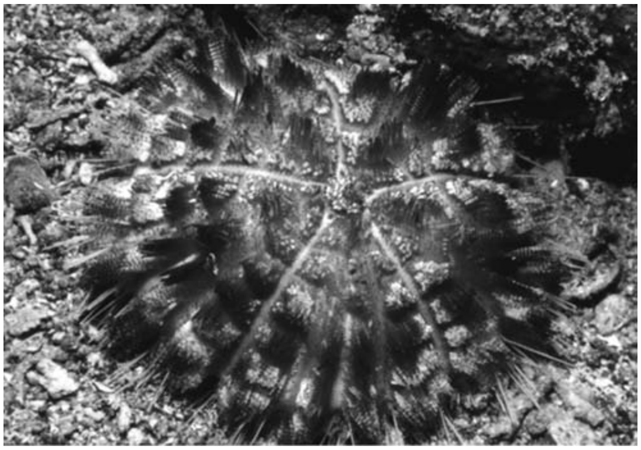

FIGURE 181.1. Crown-of-Thorns sea star (*Acanthaster planci* L.). Photograph courtesy of Paul Auerbach, MD. See color insert.

CLINICAL RESPONSE

Dermal contact with the spines of the crown-of-thorns starfish produces the immediate onset of acute burning pain followed within minutes by bluish discoloration at the puncture site.[9] During the next 4–6 hours, increasing erythema and edema occur around the wound site. The pain usually resolves within a few hours and the edema subsides within 12–24 hours. The wound appears normal by about 48 hours after envenomation. Following severe envenomations, limitation of motion may develop in affected digits. Systemic complaints are extremely rare, although anecdotal reports suggest that muscle weakness, nausea, vomiting, and paresthesias may develop. A chronic synovitis with limitation of motion may result from retained foreign bodies and granuloma formation.[10]

DIAGNOSTIC TESTING

Spines from crown-of-thorns starfish contain calcium carbonate, which is visible on radiography. There are no significant laboratory abnormalities following envenomation.

TREATMENT

Management of dermal contact with sea urchins is supportive. Hot water immersion may reduce pain, but there are few clinical data to guide management. All wounds should be thoroughly explored with magnification, if necessary, for the presence of foreign bodies. Radiography may help determine the presence of foreign bodies because the spines are radiopaque. However, small spines may not be detectable by plain radiographs. Antibiotics (ciprofloxacin 500–750 mg twice daily, doxycycline 100 mg twice daily) are indicated for severely contaminated wounds, but there are no data to support the use of prophylactic antibiotics. Steroid creams are appropriate only for the treatment of persistent lesions.

SEA URCHINS

IDENTIFYING CHARACTERISTICS

Sea urchins are free-living, bottom-dwelling, nocturnal, slow-moving, shy creatures that possess globular bodies covered with calcareous spines of varying shapes and sizes.[11] Although most species of sea urchins do not have venom glands, about 80 of 600 species of sea urchin are venomous.[12] There are 12 orders of the class Echinoidea in the phylum Echinodermata based on morphologic variation in color, size, and shape of the spines.

Common Name: Sea Urchins

Scientific Name: Class: Echinoidea

Physical Description: These ubiquitous creatures resemble globular pincushions surrounded by numerous sharp, detachable, spines. Figure 181.2 displays a specimen of the fire sea urchin (*Asthenosoma varium* Grube). Some species, such as the long-spined sea urchin (*Diadema antillarum* Philippi), contain long spines that easily fracture on contact with human skin.

EXPOSURE

Sea urchins live below rocks or between coral in shallow waters. The hard lime shells of these marine animals are usually globular or egg-shaped with calcareous spines projecting from the shell in many shapes and sizes. Painful injuries result from contact with sharp spines or venomous pedicellariae. These latter organelles are movable, jaw-tipped stalks that protrude between the spines. The pedicellariae contain venom glands and valves that extrude the venom on contact. The pedicellariae of some species (e.g., *Toxopneustes* spp.) are strong enough to penetrate human skin, but many sea urchin species do not envenomate humans. Sea urchin species in the Echinothuriidae and Diadematidae families possess long, slender spines containing venomous pedicellariae. Sea urchins are distributed worldwide with tropical venomous species including sea urchins from the genera *Asthenosoma, Diadema*, and *Echino-*

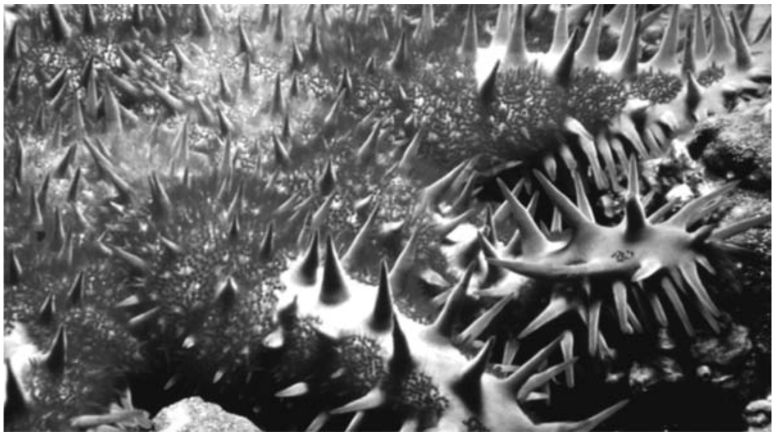

FIGURE 181.2. Fire sea urchin (*Asthenosoma varium* Grube). Photograph courtesy of Paul Auerbach, MD. See color insert.

thrix. Most injuries result from either stepping on the spines or carelessly handling the sea urchin. Sea urchin roe is a Japanese and Korean delicacy served with sushi, that is a potential food allergen and may cause anaphylaxis in sensitized individuals.[13,14]

PRINCIPAL TOXINS

Venom Composition

Venoms from species in the phylum Echinodermata contain a variety of chemical substances including serotonin, steroid glycosides, quaternary ammonium bases, and acetylcholine-like substances.[15] The venoms from some sea urchin species also include neurotoxins, hemolysins, serotonin, and proteases. The venom of species from the genus *Tripneustes* contains histamine- and bradykinin-like factors that can produce severe pain and cranial nerve palsies following injection by the pedicellariae.[16] However, the pretreatment of rodents with antihistamines does not reduce the toxicity of the venom.[17]

Venom Apparatus

Venomous and nonvenomous sea urchins inflict a painful puncture wound following contact of the spines with unprotected skin. These spines are brittle and may lodge in the wound. An indentation occurs at the base of the spine that fits over a tubercle with muscle fibers extending from the tubercle to a circular ledge (milled ring). The long, sharp spines of some species are hollow and these specialized spines contain venom. Figure 181.3 displays the morphology of sea urchin spines. The nerve ring in the epithelium at the base of the spine stimulates surrounding spines to bend toward the stimulated spine. The complexity of the venom apparatus varies between sea urchin genera. Certain species (e.g., *Asthenosoma*) possess well-developed venom spines, whereas other species (e.g., *Tripneustes, Toxopneustes*) have specialized venom organs called pedicellariae. These small, pincer-like organs are modified spines with flexible heads that contain an organelle capable of injecting venom. The pincers open on contact and discharge venom into the wound created by the spine. Tiny barbs with reverse orientation appear on the outer surface of the slender spines. A proteinaceous covering surrounds the spines. All species of sea urchins can inflict mechanical trauma that may produce local tissue reaction from retained debris.

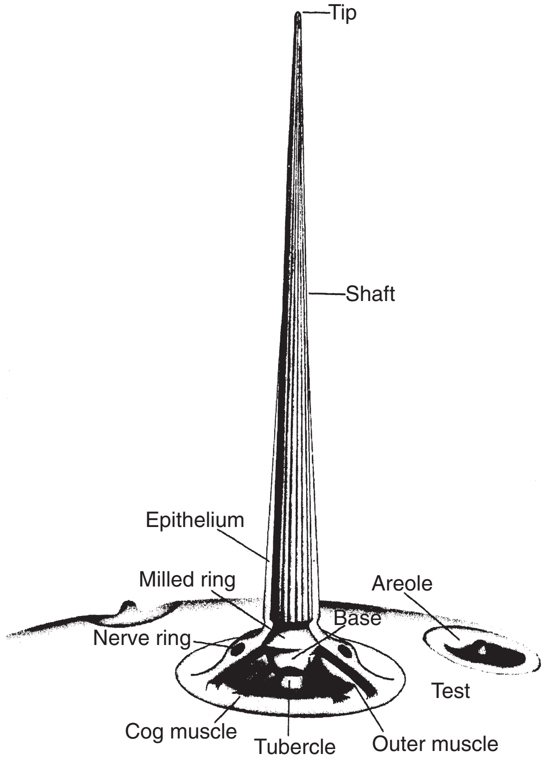

FIGURE 181.3. Morphology of sea urchin spine. From Baden HP. Injuries from sea urchins. Clin Dermatol 1987;5:113. Reprinted with permission from Elsevier.

Dose Response

The toxins in sea urchin venom are not well defined, and there are inadequate data to determine a dose response in humans.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Sea-urchin granulomas are chronic granulomatous skin lesions that demonstrate a wide morphologic spectrum; these lesions are not always related to retained foreign bodies. In a histological study of 50 biopsy specimens from 35 patients with sea urchin granulomas, foreign body and sarcoid were the most common patterns associated with the predominant granulomatous inflammatory reaction.[18] Other types of granulomatous reactions were tuberculoid, necrobiotic and suppurative granulomas. The remaining biopsies demonstrated a predominant inflammatory reaction with features of nonspecific chronic inflammation or suppurative dermatitis. Focal necrosis and microabscesses were common, but the identification of foreign materials in the granulomas was uncommon. The delayed reaction associated with sea urchin spines is classified as allergic foreign-body type with the identity of the antigen unknown. Chronic bacterial infection (e.g., *Mycobacterium marinum*) may contribute to the granulomatous reaction.[19]

CLINICAL RESPONSE

Following contact with sea urchins, clinical effects range from mild, local irritation for a few days to granuloma formation, infection, and rarely systemic symptoms. The initial contact with the spines produces little discomfort. However, contact with some sea urchin spines produces intense pain within several minutes of envenomation along with some localized erythema, local black discoloration, and edema. The pain is out of proportion to the extent of the trauma caused by the spines. Most symptoms resolve within 1–2 days, if there are no retained foreign bodies. Colored sea urchins leave multiple punctate areas of discoloration within human skin when the spines fracture. Periungual and subungual nodular lesions may develop from retained spine fragments.[20] In uncomplicated cases, these lesions resolve completely within one month as a result of the resorption of the spines and the extrusion of the spines from the skin.[11] Secondary bacterial infection, abscess formation and chronic foreign body granulomas may complicate the puncture wounds associated with contact with sea urchins.[21] Residual spine fragments can produce pink to bluish, nontender sarcoid-like granulomas up to 1–5 mm (~0.04–0.2 in.) in diameter.[22,23] Spines embedded near nerves and joint spaces may cause an acute synovitis characterized by hyperesthesias, sensory deficits, and painful joints, particularly in the hand.[24] Systemic symptoms associated with sea urchin envenomations include myalgias, nausea, syncope, lightheadedness, paresthesias, muscle spasm, dyspnea, and, rarely, respiratory depression and hypotension.[25]

DIAGNOSTIC TESTING

The calcium carbonate spines of sea urchins are radiopaque, and the use of soft tissue x-rays may help localize the presence of retained spines.[26] Magnetic resonance imaging (MRI) helps define the soft tissue and bony changes associated with synovial arthritis following contact with sea urchins.[12]

TREATMENT

Treatment of sea urchin envenomation includes the careful removal of the protruding spines and immediate immersion of the affected area in hot water (110–115 °F/43–46 °C). Technically, the removal of sea urchin spines is difficult because of the brittle properties of the spines; therefore, aggressive débridement of the area around the puncture wounds is not indicated. The wound should be thoroughly cleaned similar to the treatment of fire coral envenomation. Analgesics may be necessary after hot water immersion. Detached pedicellariae may secrete venom for several hours, and these structures should be removed following envenomation by the pedicellariae-containing species (e.g., *Toxopneustes pileolus* Lamarck). Surgical excision of embedded spines is not indicated routinely because fragmentation of the spines causes additional injury or infection. The presence of skin discoloration at the puncture site does not necessarily indicate the presence of retained spines because residual dye from the spines causes temporary tattooing that usually resolves within 48 hours.[27] Any attempt to remove embedded spines should be performed with good lighting sources and a bloodless field, preferably with radiological direction. Chronic granulomas usually require complete excision when intradermal steroids do not eliminate the chronic granuloma. Anecdotal evidence does not support the use of ammonia, systemic steroids, or prophylactic antibiotics. There are no antidotes. Secondary wound infections (*Vibrio vulnificus, Pseudomonas aeruginosa, Aeromonas salmonicida, Staphylococcus aureus, Streptococcus pyogenes*) are rare,[28] and when present usually respond to ciprofloxacin 500–750 mg twice daily.

SEA CUCUMBERS

IDENTIFYING CHARACTERISTICS

Common Name: Sea Cucumber

Scientific Name: *Bohadschia argus* Jaeger

Family: Holothuriidae (Class: Holothuroidea)

Physical Description: Sea cucumbers are bottom-dwelling scavengers with elongated, sausage-shaped bodies. Tiny tube feet and tentacles surround the mouth.

EXPOSURE

The habitat of sea cucumbers includes both shallow and deep water. Many sea cucumbers feed on jellyfish, and extrude undigested, intact nematocysts through their skin or mouth as a defensive maneuver. During threatening periods, a group of tubules located at the anal end absorb water and form long, sticky threads for protection. Additionally, sea cucumbers may eviscerate their intestinal tract through their mouth as a means to expose threatening predators to toxic nematocyst ingested from other marine animals.[29] Dried sea cucumbers are a delicacy in many eastern Asian countries (e.g., China, Malaysia). Known as trepang or Bêche-de-mer, aphrodisiac effects are attributed to the consumption of this delicacy.

PRINCIPAL TOXINS

Venom Composition

Specialized glands along the ventral and lateral sides of the sea cucumbers produce a toxic, steroidal saponin called holothurin A. This marine toxin is an anionic surfactant and detergent that is an irritant and a hemolysin.[30,31] This compound also impairs transmission across cholinergic neuromuscular junctions. Holothurin activates calmodulin-dependent bovine brain 3′-5′ phosphodiesterase, which is antagonized by classical calmodulin antagonists (e.g., chlordecone).[32]

Venom Apparatus

Certain sea cucumber species eject adherent, white or pink, Cuvierian tubules when mechanically stimulated. These tubules protrude from the cloaca (posterior body). The adhesiveness and high tensile strength allows Cuvierian tubules to entangle and immobilize potential predators.[33] Other species secrete a limy mucous that causes a local inflammatory reaction similar to contact with the Cuvierian tubules.

Dose Response

There are inadequate data on holothurin and other potential toxins in sea cucumbers to determine dose response of these toxins in human.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The toxins in sea cucumber are not well described.

CLINICAL RESPONSE

Contact with the venom from sea cucumbers results in a macular-papular eruption. Eye irritation may be severe. Additionally, the sea cucumber secretes undigested nematocysts in self-defense that may cause coelenterate envenomation following direct contact.

DIAGNOSTIC TESTING

There are no commercial biomarkers of envenomation by sea cucumbers.

TREATMENT

Treatment of sea cucumber lesions and other coelenterate envenomation is similar.

FIREWORMS

Fireworms (Class: Polychaeta) are a heterogeneous group of animals that produce a variety of toxin for the acquisition of prey and for defensive purposes. For example, *Paranemertes* species contain pyridine alkaloids, similar to anabasine present in wild tobacco plants.[34] Nereistoxin (4-*N*, *N*-dimethylamino-1,2-dithiolane, CAS RN: 1631-58-9) is a neurotoxin from the salivary glands of the marine annelid worm, *Lumbriconereis heteropoda* Marenzeller, that blocks nicotinic acetylcholine receptors, particularly in insects.[35] Glycerotoxin (CAS RN: 92229-20-4) from the venom of *Glycera convoluta* is a novel 320 kDa protein capable of reversibly stimulating acetylcholine release in the frog, but not at the murine neuromuscular junction because of differences in the subtype of voltage-dependent Ca^{2+} channels. Experimental studies indicate that glycerotoxin acts via Ca(v)2.2 (N-type) channels, but this toxin does

not activate Ca(v)2.1 (P/Q-type) channels.[36] Despite the presence of these toxins in worm species, systemic symptoms do not usually occur following contact with these worms. Injuries usually result from the handling of these worms (*Glycera* spp., *Eunice* spp.) and the subsequent contact with barbed bristles. Clinical effects typically include local burning pain, swelling, and erythema. Treatment is supportive with good wound care and special attention directed toward identifying the presence of foreign bodies to prevent the development of granulomas.

IV Eels and Lampreys

Chapter 182

MORAY EEL
(Superclass: Agnatha)

IDENTIFYING CHARACTERISTICS

Moray eels belong to the family Muraenidae and the superclass of jawless fish, Agnatha. Eels are long bony fish with no premaxillary bones. These fish apprehend their prey by biting and then transport prey by extreme protraction and retraction of their pharyngeal jaw apparatus.[1] The elongated, muscular body and the lack of paired fins (pectoral and pelvic) allow the eel to move more easily within the narrow crevices of the reef. The dorsal, anal, and caudal fins are fleshy ridges covered with thickened skin to protect the eel from abrasions. Because the eel lacks paired fins, they swim forward or backward in an S-shaped motion by moving their entire body side to side. These bottom dwelling creatures do not usually have scales. The moray eel is heavier and more compressed than most eel species. The absence of pectoral fins and presence of small round gill openings distinguish the moray eel from other marine eels. These nocturnal creatures reach up to 6ft (~2m) in length.

Common Name: California Moray Eel

Scientific Name: *Gymnothorax mordax* Ayres

Physical Description: This brown to green-brown, scaleless eel reaches up to 5ft (~1.5m) in length. Like other moray eels, this eel has a large mouth, strong teeth, small, round gill openings, and an elongated face with a broad head.

EXPOSURE

Moray eels are bottom dwelling creatures that inhabit tropical and temperate waters along shallow, rocky reefs. Human exposure occurs in these marine environments or in aquariums. The distribution of moray eels is worldwide in tropical waters with a few species present in temperate waters. The California moray lives in coastal waters from Point Conception to Baja California, whereas the spotted moray (*Gymnothorax moringa* Cuvier) lives in Atlantic coastal waters from North Carolina to Rio de Janeiro, Brazil. The blackedge moray (*Gymnothorax nigromarginatus* Girard) inhabits coastal waters from Florida to Yucatan, Mexico. The green moray eel lives in coastal waters from New Jersey to Bermuda as well as the Gulf of Mexico and the Atlantic coast to Brazil. These shy, bottom dwelling creatures rarely attack humans. Most bites result from provocation by humans, such as the blind exploration of marine caves and crevasses with hands. Moray eels emerge from holes and crevices at night to search for inactive, diurnal soft-bodied prey. They have a keen sense of smell due to the presence of lamellae richly covered with stereocilia. Morphology studies indicate that moray eels (e.g., *Echidna* spp.) with large numbers of stereocilia forage for prey primarily by olfaction, whereas other species with less stereocilia search for food visually.[2] *Gymnothorax* species use both methods to hunt prey. Banded sea kraits (*Laticauda colubrina* Schneider)

prey on eels of the genus *Gymnothorax*, and moray eels from the Pacific have developed resistance to massive doses of sea krait venom as a result of the coevolution of these two species.[3]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Moray eels have multiple rows of sharp, jagged teeth that cause ragged, deep wounds following bites. Muscular jaws, tenacious bites, and the sharp teeth of the moray eel produce deep lacerations and crushing injuries that are predisposed to bacterial infections. These animals do not possess a venom apparatus.[4] Therefore, injuries from moray eel bites are traumatic rather than toxic—similar to shark and barracuda bites. The viscera of moray eels from ciguatera endemic areas contain several ciguatoxins (CTX-1, CTX-2, CTX-3).[5] Ciguatoxins are potent sodium channel-activating toxins that share binding sites with brevetoxins. CTX-2 and CTX-3 are less polar and less potent than CTX-1.

CLINICAL RESPONSE

Moray eels can inflict deep, ragged lacerations that cause neurovascular or tendon injuries.[6] Rare case reports associate bites by moray eels with rectal perforation.[7] These wounds are predisposed to bacterial infections. Most marine bacteria are motile, halophilic, Gram-negative rods that are facultative anaerobes.[8] Evaluation of marine environments suggests that *Vibrio* species may contaminate moray eel bites, particularly *Vibrio vulnificus*. These bacteria are ubiquitous marine organisms comprised of two biotypes.[9] Biotype 1 is an opportunistic human pathogen associated with the consumption of raw oysters or with exposure of open wounds to seawater while swimming or handling contaminated fish, particularly in geographical areas with relatively high water temperatures.[10] Biotype 2 is an obligate eel pathogen that rarely infects humans.[11] Potentially, rapidly progressive cellulitis and septicemia may complicate moray eel-induced wounds, particularly in immunocompromised hosts. Soft tissue infections secondary to *V. vulnificus* usually demonstrate bronze discoloration, frequently with the formation of bullous lesions.[12] Case reports associate an indolent, ulcerative infection and regional lymphangitis secondary to *Mycobacterium marinum* following the handling of freshwater eels.[13]

Moray meat is a delicacy, and the consumption of smoked moray eel meat has been associated with an outbreak of *Salmonella blockley*.[14] Portions of the moray eel may contain ciguatoxin, particular the viscera, and the consumption of moray eel may cause ciguatera food poisoning.[15,16]

DIAGNOSTIC TESTING

Analytical methods to identify multiple ciguatoxins in moray eels include reverse-phase high performance liquid chromatography/mass spectrometry.[17]

TREATMENT

Because moray eels inflict deep puncture wounds, bites should be thoroughly evaluated for tendon, nerve, fascia, ligament, and vascular injures. All wounds should be copiously irrigated with normal saline after control of bleeding, evaluation of vital signs, and physical examination. The wound should be explored for foreign bodies (sand, teeth fragments) after radiographic evaluation for retained foreign bodies. Débridement may be necessary for crushed or devitalized tissue depending on the extent of injury and the presence of adjacent neurovascular structures. Wound closure should be loose because of the risk of infection, depending on physician judgment. Abrasions and superficial lacerations in victims with normal host defenses probably do not require prophylactic antibiotics. Although there are few clinical data, anecdotal evidence suggests that victims with deep wounds should receive prophylactic antibiotics, particularly when the wound may contain a retained foreign body. There are few clinical data on the effectiveness of antibiotics for the treatment of infections associated with moray eel bites. Most *Vibrio* species are sensitive to ciprofloxacin, cefuroxime, trimethoprim-sulfamethoxazole, and tetracycline.[18] *Vibrio* species and other Gram-negative bacteria are frequently resistant to penicillin and first-generation cephalosporins. The long, fanged teeth of the moray eel penetrate deep into soft tissue; therefore, victims of moray eel bites should be followed closely for the development of closed-space infections in the affected extremity.

V Fish

Chapter 183

BONY FISH
(Class: Osteichthyes)

LIONFISH, SCORPIONFISH, and STONEFISH

IDENTIFYING CHARACTERISTICS

The Scorpaenidae family contains venomous species of the genera *Pterois* (lionfish), *Scorpaena* (scorpionfish, sculpin), and *Synanceia* (stonefish). This family consists of 70 genera and about 350 species; venomous species from the family Scorpaenidae are some of the most venomous bony fish species. Approximately 80 of the 350 species are venomous. Venomous species of this family include the South Australian cobbler or soldierfish (*Gymnapistes marmoratus* Cuvier), lionfish (*Dendrochirus* species), sculpin (*Scorpaena* species), and fortescue (*Centropogon australis* White). Classification of these fish is based on the morphology of the venom apparatus. The bony plate that covers the facial region from the eyes to the gill helps identify this diverse family (i.e., "mail-cheeked" fish). Stonefish species (*Synanceia* spp.) include the common or estuarine stonefish (*S. horrida* L.), the reef stonefish (*S. verrucosa* Bloch & Schneider), the dwarf stonefish (*Synanceia nana* Eschmeyer & Rama-Rao), the Indian stonefish (*S. horrida* L.), and the pitted stonefish (*Synanceia erosa* Cuvier or *Erosa erosa*). The bullrout (*Notesthes robusta* Günther) is a venomous member of the Tetrarogidae family.

Common Name: Lionfish, Zebrafish, Red Lionfish, Butterfly Cod, Lion Fish, Ornate Butterfly-Cod, Peacock Lionfish, Red Firefish, Scorpion Volitans, Turkey Fish, and Turkeyfish

Scientific Name: *Pterois* spp. (*P. volitans* L., *P. radiata* Cuvier, *P. antennata* Bloch)

Physical Description: This group of colorful, graceful fish has fan-like fins. The length of this beautiful Asian tropical fish is about 30–38 cm (~12–15 in.) with vertical, dark stripes and long slender dorsal and ventral spines. Although coloration is highly variable, these fish are frequently zebra-banded in red and white. There are numerous spiny projections and fleshy tabs on the head. The eyes protrude dorsally over a large mouth that has numerous skin appendages. Figure 183.1 displays a specimen of the lionfish (*Pterois volitans* L.).

Common Name: Sculpin

Scientific Name: *Scorpaena guttata* Girard

Physical Description: The sculpin has a stocky, slightly compressed body with a large head, protruding eyes, and a large mouth and pectoral fins. The color is red to brown with dark patches over the body and fins. Most sculpins are small (<6 in./<15 cm), but the cabezon (*Scorpaenichthys marmoratus* Ayres) reaches 39 in. (~100 cm) in length.

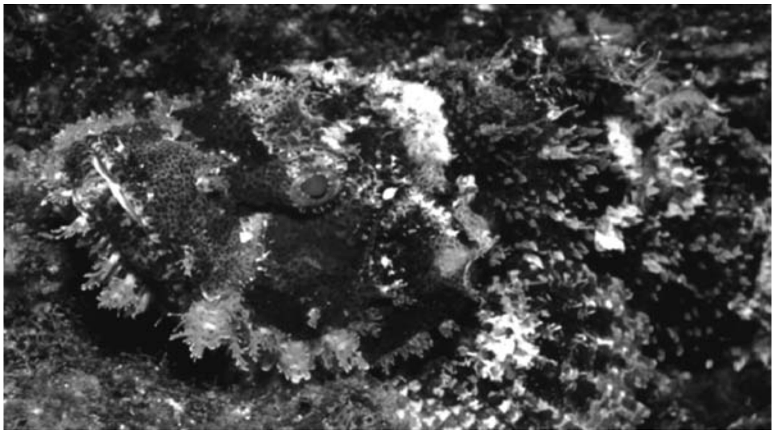

FIGURE 183.2. Spotted scorpionfish (*Scorpaena plumieri* Bloch). Photograph courtesy of Paul Auerbach, MD. See color insert.

Common Name: Spotted Scorpionfish

Scientific Name: *Scorpaena plumieri* Bloch

Physical Description: This common scorpionfish grows up to 45 cm (~18 in.) with fleshy plumes (cirri) over the eyes and characteristic skin flaps on the head. Distinctive features include three bars on the tail and white spots on the dark background of the inside of the pectoral fins. These spots are visible only when threatened or while swimming. Figure 183.2 displays a specimen of the spotted scorpionfish.

Common Name: Stonefish, Australian Stonefish, Estuarine Stonefish

Scientific Name: *Synanceia horrida* L. (*Synanceia trachynis* Richardson)

Physical Description: This well-camouflaged bottom-dwelling fish has a tough, uneven skin that is often covered with slime and wart-like bumps. This bulky, compact fish blends easily in the background with a color that resembles the surrounding environment (e.g., dark, mottled green-brown). The adult fish is about 20–30 cm (~8–12 in.) in length with elevated, dorsally positioned eyes.[1] Figure 183.3 displays a specimen of the estuarine stonefish.

EXPOSURE

Geographic Distribution

Envenomations by species of the Scorpaenidae family are the most common fish envenomations excluding stingrays. Widely distributed, Scorpaenidae species generally inhabit sandy, rocky, or coral coastlines in shallow tropical and temperate waters. Stonefish inhabit the warm temperate and tropical waters of the Indian and

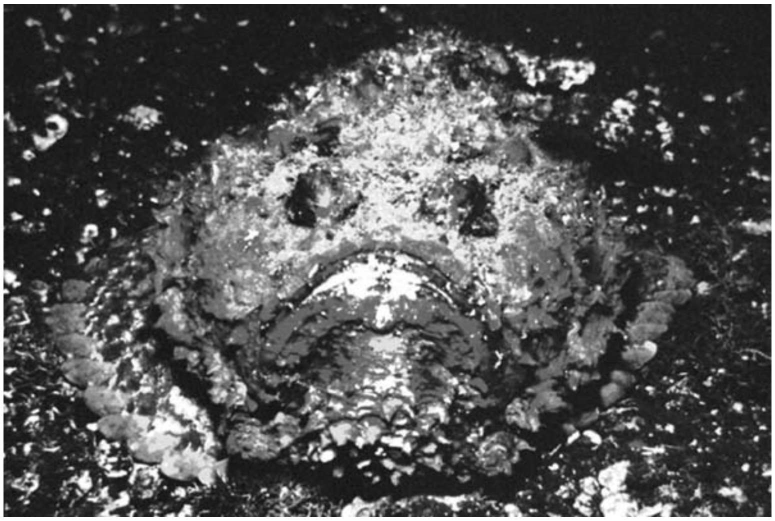

FIGURE 183.3. Australian or estuarine stonefish (*Synanceia horrida* L.). Photograph courtesy of Paul Auerbach, MD. See color insert.

Pacific Oceans north to China, east to Hawaii, west to the African coast, and south to Australia. Sculpin occur throughout marine waters, primarily in tropical and temperate oceans. The native distribution of the lionfish is the coral reefs of the Indo–Pacific Ocean. Lionfish (*Pterois volitans* L.) are frequently found in private aquariums. The bullrout (*Notesthes robusta* Günther) inhabits slow-moving streams and tidal waters along the eastern coast of Australia. Disturbance of this bottom-dwelling fish near rocks and weeds causes the erection of spines and the infliction of painful injuries similar to stonefish.[2]

Behavior

Lionfish

The most commonly encountered species in this genus is the lion fish (*Pterois volitans* L.). These fish respond aggressively to perceived threats by erecting venomous spines. Lionfish are solitary predators that feed on small fish, shrimp, and crab. They inhabit shallow coral and rocky reefs up to depths of 50 m (~160 ft). These fish prefer shelter under ledges or in caves or crevices during daylight hours. In these areas, the lionfish exhibit almost motionless posture with the head tilted slightly downward. Most lionfish envenomations occur while handling fish in an aquarium rather than in their natural habitat.[3]

Scorpionfish and Sculpin

Sculpin are bottom-dwelling fish that live in shallow waters off the coasts of California and Hawaii. These fish inhabit areas over hard, rocky bottoms at depths ranging from immediately below the surface to 600 ft (~180 m). Occasionally, these fish are present near sand or mud bottoms. This diverse group of stationary and slow-moving fish has differing habitats and camouflage abilities. Envenomation by the California scorpionfish or sculpin (*Scorpaena guttata* Girard) occurs following contact with the retractable spines during the removal of the fish from a net or a hook. Occasionally, envenomation occurs when humans pursue this slow-moving fish in open seas.

Stonefish

The stonefish (*Synanceia horrida* L.) lives in shallow coastal waters where the fish resembles a stone or dead coral in the crevices of coral reefs. Stonefish are sedentary fish that prefer the shallow waters of coral reefs, kelp beds, and rocky coastline, where inadvertent contact usually occurs when humans step on the camouflaged, bottom-dwelling fish. This fish feeds on small marine animals by sucking the prey into their mouth through rapidly opening and closing their mouth.

PRINCIPAL TOXINS

Venom Composition

Although comparison of venoms from these three families is difficult as a result of methodological differences, the venoms of most species of the Scorpaenidae demonstrate similar cardiovascular and neuromuscular effects.[4,5] The highly complex venom of these fish is heat-labile. The venom retains potency up to a few days after the death of the fish. Although potency between species is similar, the differences in amount and delivery mechanism between species cause a wide variation in symptoms following envenomation.

Scorpionfish

Scorpionfish venom (i.e., *Scorpaena plumieri* Bloch) contains a proteolytic enzyme (protease), which hydrolyzes casein and gelatin.[6]

Stonefish

Venoms from stonefish contain factors that affect the cardiovascular and neuromuscular systems including the development of increased vascular permeability and ventricular fibrillation in animal studies.[7] These venoms demonstrate hemolytic and hyaluronidase activity.[8] Stonustoxin (CAS RN: 137803-80-6) is a toxic protein isolated from the venom of *Synanceia horrida* L. In animal models, the administration of this toxin causes death following the development of endothelium-dependent vasodilation and rapid, irreversible hypotension.[9] This toxin also produces edema, increased vascular permeability, platelet aggregation, and hemolysis. Verrucotoxin is the major component of venom from the stonefish (*Synanceia verrucosa*).[10] *In vitro* studies suggest that verrucotoxin inhibits ATP-sensitive K^+ current through the muscarinic M_3 receptor-PKC pathway.[11]

Venom Apparatus

The venom apparatus of fish typically involves grooved spines containing glandular venom tissue surrounded by an integument or sheath. This apparatus is usually located near the oral pole. These fish have no voluntary control over envenomation other than the angulation of the spines.

Lionfish

The venom apparatus of the lionfish consists of long thin spines involving 12 or 13 dorsal spines, 3 anal spines and 3 pelvic spines associated with paired venom glands at the base of the spines. The pectoral spines do not have venom glands. A thin integumentary sheath covers the venomous spines, but there are no venom ducts. The venom diffuses into the wound when contact with the venomous spines tears the integumentary sheath over the venomous spine.

Scorpionfish

Scorpionfish have variable numbers of long, heavy dorsal, anal, and pelvic spines with moderate-sized venom glands. The dorsal and pelvic spines are covered by thick integumentary sheaths that produce envenomation following discharge into the wound. In contrast to stonefish, scorpionfish and lionfish have a poorly developed venom apparatus that lacks an excretory duct. The spines of scorpionfish are short and strong with the venom gland being more developed than the venom gland in lionfish.

Stonefish

The well-developed venom apparatus of the stonefish consists of short, thick spines, paired venom glands, and very thick sheaths on the dorsal spines. There are 13 dorsal spines, 2 pelvic spines, and 3 anal spines. A fibrous capsule covers the venom glands and divides the glandular tissue into many septa containing numerous nerves and blood vessels.[12] Inadvertent contact with the fish causes release of the venom from the dorsal spines into the wound. Mechanical pressure applied at the base of the venomous spines releases venom from the paired venom glands located in the two lateral grooves at the base of each spine. Regeneration of the venom gland and the venom around the spines requires about 3 weeks.[13]

Dose Response

There are inadequate data in humans to determine the dose response of stonefish venom or stonustoxin. Each spine has two venom glands, which contain about 5–10 mg of crude venom with an average venom yield of approximately 6 mg per spine.[14,15] In animal experiments, the LD_{50} of stonefish venom and snake venom is similar.[16] The estimated intravenous LD_{50} in mice is approximately 22 times greater for stonustoxin than for the crude venom.[17] The amount of venom injected during a stonefish bite is not well defined. The sting of a single stonefish spine on the knee of a 52-year-old woman was associated with intense pain that resolved over 14 hours.[18] She developed no systemic symptoms, and the only sign of envenomation was mild swelling around the area of the sting.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

These fish contain highly complex venom with enzymatic as well as pronounced cardiac and neuromuscular activity that results from increased intracellular calcium concentrations, possibly via the formation of pores.[19] A nondialyzable, high-molecular-weight, heat-labile protein component produces neuromuscular and cardiac effects including vasodilation, hypotension, muscular weakness, and respiratory paralysis.[20,21] Animal studies suggest that lionfish (*P. volitans*) venom produces cardiovascular effects primarily by acting on muscarinic cholinergic receptors and adrenoceptors.[20] Death from stonefish envenomation is attributed to respiratory

arrest secondary to skeletal muscle paralysis.[22] However, animal studies suggest that the venom from stonefish cause airway inflammation and acute lung injury.[23]

CLINICAL RESPONSE

Lionfish and Scorpionfish

The clinical manifestations of scorpion fish (*Scorpaena* spp.) and lionfish (*Pterois* spp.) are similar except the latter produces more severe local symptoms and the former produces more systemic symptoms. Typically, envenomations following contact with the dorsal or pelvic spines produce almost immediate, intense, pulsatile pain that may progress to involve the entire extremity within a few minutes. Symptoms range from erythema and ecchymosis to vesicle formation and local necrosis.[24] Substantial local swelling, hyperesthesias, hypesthesias, paresthesias, erythema, and pain may extend up the involved extremity.[3,25] Frequently, there is bluish discoloration around the puncture site. The maximum intensity of the pain occurs within approximately 1 hour, and the pain usually resolves within 8–12 hours (range: up to 1 day). Hypesthesia may persist along with necrosis when sloughing occurs at the site of envenomation.[26] Multiple stings may produce regional lymphadenopathy and local lymphadenitis. Occasionally, systemic effects of envenomation include nausea, vomiting, abdominal pain, headache, diaphoresis, generalized weakness, muscle cramps, tremulousness, dyspnea, tachycardia, chest pain, and mild hypotension.[27] Systemic symptoms are less common after lionfish envenomations than after sculpin envenomations.

Stonefish

Stonefish envenomation causes immediate, severe local pain that may progress proximally along with local edema, erythema, and bluish discoloration around the puncture wounds.[28] The pain typically peaks 1–2 hours after envenomation and resolves within 12 hours.[29] Vesicles can form in the immediate area of envenomation followed by sloughing of the tissue, cellulitis, and hyperesthesias. Local symptoms usually resolve within 1–2 weeks, but surgical débridement may be necessary for puncture wounds with retained spines or local necrosis.[1] Systemic effects include diaphoresis, nausea, and lightheadedness. Stonefish produce the most severe systemic effects following envenomations by species from the family Scorpaenidae with fatalities occurring rarely as a result of respiratory insufficiency.[30,31] Although uncommon, serious clinical features of stonefish envenomation include bradycardia, syncope, dysrhythmias, hypotension, convulsions, paralysis, and pulmonary edema.[32] Complications include localized necrosis and delayed healing,[33] secondary infection, cutaneous granulomas, and persistent paresthesias and hypesthesias. Extensive tissue necrosis suggests the presence of secondary infection.

DIAGNOSTIC TESTING

Clinically significant laboratory abnormalities do not usually occur following envenomation by these fish. There are no commercial analytical methods for the confirmation of envenomation by these fish.

TREATMENT

First Aid

First aid consists primarily of immersing the envenomated area with hot water, limiting movement, and referral to a health care facility if systemic symptoms develop. There are no specific substances that effectively neutralize the injected venom. Because the venom is heat labile, rapid hot water immersion for 30–60 minutes at 45 °C (113 °F) is usually the most effective first-aid measure.[3] Relief generally occurs soon after immersion, and the soaks may be stopped after complete relief. To prevent thermal injury, the temperature of the water should be tested by immersing the extremity opposite the envenomation into the water bath. After initial immersion of the envenomated extremity in hot water, the extremity should be removed every 15–20 minutes to determine if the pain continues. Narcotic analgesics should be withheld until the hot water immersion is completed to prevent scalding.

Antivenom

Most definite stonefish envenomations require antivenom (Commonwealth Serum Laboratories, Melbourne, Australia), which is an equine $F(ab)_2$ antivenom similar to snake antivenom. Indications for the administration of antivenom include severe pain unresponsive to analgesics, systemic effects (weakness, paralysis), or large stonefish envenomation (i.e., multiple puncture wounds). After skin testing and other precautions necessary for equine products, the usual dose of stonefish antivenom is 1 vial (2,000 Units) intramuscularly for definite clinical evidence of envenomation and the presence of one or two puncture wounds. There are few data on the intravenous administration of this antivenom, but 1 vial is typically diluted in 50–100 mL normal saline and infused slowly. Two milliliters of the antivenom neutralizes about 20 mg of stonefish venom *in vitro*.[14] Two to three vials may be necessary for larger envenomations

(i.e., more than 3–4 puncture wounds). Resources for antivenom include local regional poison centers and regional zoos. Currently, there are inadequate data to support the use of this antivenom for other venomous stings. However, envenomations by other members of the family Scorpaenidae do not usually require antivenin.

Supplemental Care

Local wound care includes irrigation, débridement as necessary, and tetanus prophylaxis as indicated. Visible foreign material, integument or spines should be removed with forceps to prevent the subsequent development of granulomas. Imaging studies may be necessary to exclude retained spines. Grossly contaminated wounds may require surgical therapy including the use of operating microscopes. Prophylactic antibiotics are not recommended, but the patient should be warned about signs and symptoms of infection. Magnesium sulfate (Epsom salts) soaks twice a day for several days may provide symptomatic relief for persistent symptoms. Treatment of systemic symptoms is supportive. Intravenous fluids may be necessary to correct hypotension. The administration of antihistamines, epinephrine, or corticosteroids does not alter the duration or intensity of the symptoms associated with envenomation.

WEEVER FISH

IDENTIFYING CHARACTERISTICS

There are four European species of weever fish (Family: Trachinidae) including the greater weever fish (*Trachinus draco* L.), the lesser weever fish (*Echiichthys vipera* Cuvier or *Trachinus vipera*), spotted weever fish (*Trachinus araneus* Cuvier), and the streaked weever fish (*Trachinus radiatus* Cuvier). The stargazer (*Uranoscopus* spp.) is a close relative of the weever fish with a more bulky body. Although this fish has pectoral spines capable of causing painful stings, these spines are not venomous.[34]

Common Name: Lesser Weever Fish

Scientific Name: *Echiichthys vipera* Cuvier (*Trachinus vipera*)

Physical Description: This short (<14 cm/6 in.), stout fish has a laterally flattened body with yellowish-brown coloration of the dorsal surface. There are dark spots on the head and back, whereas the dorsal fin is entirely black.

Common Name: Greater Weever Fish

Scientific Name: *Trachinus draco* L.

Physical Description: The grayish-yellow body of the greater weever fish is elongated and flattened laterally. The bottom surface of the fish is pale, and there are narrow diagonal stripes on the flanks and large black spots on the dorsal fin. Typically, the greater weever fish exceeds 40 cm (~16 in.) in length.

EXPOSURE

Geographic Distribution

Weever fish inhabit the Mediterranean Sea, the Atlantic coast of Europe, the Black Sea, and the Pacific coast of Chile, where these creatures are the most venomous fish in temperate waters. The lesser weever fish lives in the Mediterranean (Baltic to North Africa) and eastern Atlantic coastal waters, while the greater weever fish is also found in the North Sea.[35] In France, weever fish are a commercial delicacy. The spotted weever fish (*Trachinus araneus* Cuvier) inhabits shallow bottoms in Mediterranean coastal waters, whereas the streaked weever fish lives in the Mediterranean and eastern Atlantic coastal waters from Morocco to Senegal.

Behavior

The lesser weever fish prefers sand bottoms ranging from 1–50 m (~3–160 ft) in depth, where these partially submerged fish wait for prey (crab, shrimp). During the day, these fish lie motionless with only their eyes and dorsal fin exposed while waiting for prey. Envenomation usually occurs when bathers step on the partially submerged dorsal spines. Greater weever fish prefer sandy bottoms in water deeper than 100 m (325 ft). Envenomations primarily occur when fishermen attempt to remove the greater weever fish from their nets.

PRINCIPAL TOXINS

Venom Composition

The venom contains several heat-labile proteins, including a high-molecular-weight protein, a kinin or kininlike substance, and possibly serotonin as well as adrenaline, noradrenaline, and several enzymes.[36] Dracotoxin (CAS RN: 140609-96-7) is a protein isolated from the crude venom of the greater weever fish (*Trachinus draco* L.)

that possesses membrane depolarizing and hemolytic activities in animal models.[37] In animal studies, the crude venom did not possess any proteolytic or histamine-releasing activities, and the lethal activity was unstable at room temperature especially at low protein concentrations.[38] Purification the lethal extract from the lesser weever fish venom (*Echiichthys vipera* Cuvier) suggests that this toxin is comprised of four identical subunits with a total molecular weight of approximately 324 kDa.[39]

Venom Apparatus

Spines occur only on the dorsal fin and gill cover. The dorsal spines contain two grooves composed of holocrine glandular tissue. Like those of the lion fish, the spines are covered with a thin integument of stratified columnar epithelium that ruptures during contact with the victim and thus releases the venom.

Dose Response

There are few data on the dose response of active components in weever fish venom. Limited data suggests that there is substantial variation in the sensitivity of animal species to the venom from weever fish. In a study administering venom intraperitoneally or intravenously into a tail vein, guinea pigs and rabbits were 10 times and 25 times, respectively, more sensitive to the venom than mice based on the lethal dose on a weight basis.[40]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

In animal studies, the intravenous injection of weever fish venom causes necrosis of the ears and tip of the tail along with hair loss.[40] The venom of weever fish contains proteins that have antigenic properties.[41]

CLINICAL RESPONSE

Most weever fish stings cause mild to moderate symptoms without systemic complaints.[42] A burning, intense pain develops immediately after envenomation that may require narcotic analgesics. The pain occasionally radiates up the extremity and into the chest. Local symptoms include erythema, edema, pallor, ecchymosis, paraesthesias, and lymphadenitis that occur within several hours. The pain usually resolves within 24 hours, although slow recovery of a local inflammatory reaction may cause persistent limitation of motion, hyperesthesia, cold sensitivity, and pain.[43] The persistence of an inflammatory reaction requires consideration of the presence of a foreign body. Significant local trauma may occur because of the ability of the spines to penetrate protective clothing including leather shoes. Systemic symptoms are unusual.[35] Rare case reports associate systemic symptoms with weever fish envenomation including headache, delirium, nausea, vomiting, diaphoresis, syncope, and hypotension. Fatalities following weever fish envenomation are not well documented and deaths associated with stings from these fish probably resulted from sepsis.[44] A case report associated the death of an 18-year-old man with suspected envenomation by weever fish off the coast of Majorca (Spain).[45] He swam back to the boat after the envenomation, but was found in full cardiopulmonary arrest 1 hour later.

DIAGNOSTIC TESTING

The specific toxins associated with weever fish envenomation have not been identified, and there are no commercial biomarkers for the confirmation of envenomation by weever fish.

TREATMENT

Treatment is supportive. The best first-aid measure is immediate hot water immersion (110–115 °F/~43–46 °C) for 30–60 minutes until the pain resolves. The temperature of the water should be tested on the uninvolved extremity prior to hot water immersion. All wounds should be irrigated as soon as possible and all visible foreign bodies (spines, integumentary sheaths) removed. Local wound care requires irrigation, cleansing, and débridement with tetanus immunizations updated as needed. Secondary infections do not usually occur and prophylactic antibiotics are unnecessary.

CATFISH

IDENTIFYING CHARACTERISTICS

Catfish are members of the class Osteichthyes, order Siluriformes with about 1,000 species inhabiting primarily freshwater. North American families of catfish include Ictaluridae (freshwater) and Ariidae (saltwater). The characteristic perioral barbells do not produce envenomation. Table 183.1 outlines families of catfish involved with human envenomations.

TABLE 183.1. Catfish Associated with Human Envenomation

Family	Habitat	Distribution	Examples
Ariidae	Marine	Worldwide	Sea catfish (USA)
Bagridae	Freshwater	Asia	Akaza (Japan)
Clariidae	Freshwater	Indo-Pacific	Ikan Keli (Malaysia)
Doradidae	Freshwater	South America	Bagre (Amazon)
Heteropneustidae	Freshwater	Asia	Pla Cheet (Thailand)
Ictaluridae	Freshwater	North America	Madtom (USA)
Pimelodidae	Freshwater	South America	Bagre (Amazon)
Plotosidae	Marine	Indo-Pacific	Oriental catfish (USA)
Siluridae	Freshwater	Africa, Asia, Europe	European catfish

Source: Adapted from Ref 56.

EXPOSURE

Geographic Distribution

Although most of the 1,000 catfish species are freshwater, bottom-dwelling scavengers, a few species are found in salt water. Freshwater catfish in North America capable of causing envenomation include the brown bullhead (*Ameiurus nebulosus* Lesueur or *Ictalurus nebulosus*), white catfish (*Ameiurus catus* L. *or Ictalurus catus* L.), blue catfish (*I. furcatus* Valenciennes), channel catfish (*Ictalurus punctatus* Rafinesque), and Carolina mudtom (*Noturus furiosus* Jordan & Meek).[46] Stinging catfish in Asia include *Heteropneustes fossilis* Bloch, which are facultative air-breathers that inhabit swamps of Southeast Asia.[47]

Behavior

Freshwater catfish typically inhabit dirty, slow-moving waters, whereas the marine catfish (*Plotosus lineatus* Thunberg) live in kelp beds and travel extensively in large schools. Some unusual characteristics include the suctorial lips of a South American species that allows the catfish to climb cliffs, male catfish that incubate eggs in their mouths, Amazon catfish (e.g., *Plectrochilus diabolicus* Meyer or *Urinophilus diabolicus*) that lodge in the human urethra requiring endoscopic removal, and Egyptian catfish (*Malapterus* spp.) that possess electric plates capable of killing prey. Catfish envenomations occur when fishermen extricate the catfish or when bathers wade in shallow water.[48,49] As a defensive maneuver, catfish can lock the dorsal spines in an extended position.

PRINCIPAL TOXINS

Venom Composition

Animal studies indicate that some catfish venoms contain hemolysins, lethal factors, dermonecrotic fractions, and edema-producing substances, but the clinical relevance of these compounds is unclear.[50,51] The skin secretions of some catfish species also contain toxins. Analysis of crude skin toxin from the Suez Gulf oriental catfish (*Plotosus lineatus* Thunberg) demonstrated a variety of substances including hemolysin, hyaluronidase, and lipase along with smaller amounts of phospholipase A_2, cholinesterase, proteinase, and 5′-nucleotidase.[52] These substances (crinotoxins) may account for the pain associated with direct contact with the skin rather than the spines. Although mudtoms (*Noturus* spp.) appear most toxic to humans, studies in animals suggest that species differences do not entirely account for the wide variation in venom potency.[53]

Venom Apparatus

Catfish have a single spine on the dorsal fin and spines on each of the pectoral spines that are capable of causing trauma to human skin. Figure 183.4 demonstrates the dorsal spine of a typical catfish. The cartilaginous, serrated spines are held erect when the catfish is disturbed. In some catfish species, an integumentary sheath covers the spine. Penetration of the skin by the spine tears the integumentary sheath, exposes the venom gland, and releases venom into the wound. Many of the spines contain sharp, serrated teeth that inhibit removal of the spine from the surrounding area. These spines rest flat against the skin of the catfish until a stimulus causes the fish to erect the spines. The severity of an evenomation ranges from mild following exposure to fork-tailed catfish (family: Ariidae) to potentially serious envenomation by some marine catfish, such as the Oriental or striped catfish (*Plotosus lineatus* Thunberg) or the Arabian Gulf catfish (*Netuma thalassina* Rüppell).[54]

Dose Response

In mice, the intraperitoneal LD_{50} of whole skin crinotoxin from the oriental catfish (*Plotosus lineatus*) was 27.9 μg/g body weight, which is low compared with snake

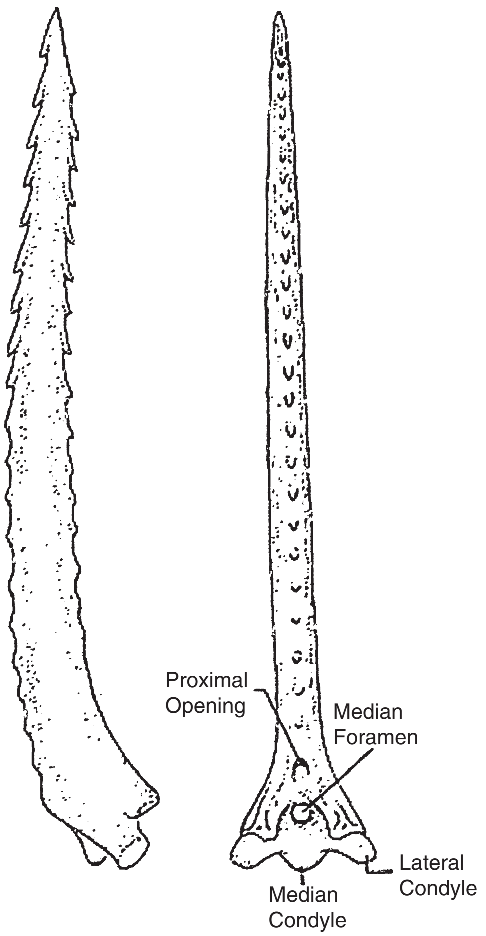

FIGURE 183.4. Dorsal spine of catfish (*Galeichthys felis*). From Blomkalns AL, et al. Catfish spine envenomation: a case report and literature review. Wilderness Environ Med 1999;10:245. Copyright Wilderness Medical Society. Reprinted with permission.

venom.[52] This crude venom has high hyaluronidase and lipase activities.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Catfish venom contains varying concentrations of dermonecrotic, inflammatory, hemolytic, and vasoconstrictive factors. Infections (e.g., *Vibrio* spp., *Aeromonas* spp.) may complicate catfish-induced wounds, particularly following retained spines. Chronic, indolent infections may result from the contamination of wounds by *Mycobacterium marinum*.[55]

CLINICAL RESPONSE

Envenomations by the spines of the catfish produce a wide range of symptoms from mild to severe pain.[56] Typically, contact with the venomous spines causes localized pain at the puncture site, occasionally with paresthesias and pain radiating up the extremity.[57] Symptoms usually resolve in 1–2 hours.[58] Significant edema, erythema along with some bleeding at the puncture site may occur following envenomation by some of the more venomous species (e.g., *Plotosus lineatus*). The pain associated with these envenomations may persist 24–48 hours. Edema and erythema may appear along with localized hypesthesias, regional lymphadenopathy, mild fever, and necrosis following more severe envenomations. Local spasm and muscle fasciculations occasionally occur.[49] Although most envenomations resolve without complications, occasionally dermal necrosis may occur that rarely is associated with gangrene.[59] Infection is the most serious common complication of contact with catfish spines, and serious infections (e.g., septic arthritis, acute tenosynovitis, large wound infections) may develop, particularly in immunocompromised patients or patients with chronic illnesses (e.g., liver disease). The microbiology of freshwater and marine catfish differ significantly with the most serious infections resulting from *Vibrio* species (marine) and *Aeromonas* species (freshwater).[56] Other sources of infection include *Klebsiella, Erysipelothrix, Nocardia, Mycobacterium, Actinomyces, Sporothrix, Enterobacteriaceae, Pseudomonas* species, and bacteria flora (*Streptococcus* spp., *Staphylococcus aureus*) of human skin.[60]

DIAGNOSTIC TESTING

Clinically significant laboratory abnormalities do not usually occur after envenomation by catfish. There are no commercial analytical methods to confirm envenomation by catfish.

TREATMENT

Management is supportive and similar to that for Scorpaenidae envenomations. However, catfish venom may not be as heat-labile as venom from other species of the family Scorpaenidae.[50] The wound should be carefully cleansed after the administration of sufficient local anesthetics to allow adequate cleansing of the wound. The affected extremity of symptomatic patients should be immersed in warm water (45 °C/113 °F) for 30–60 minutes depending on the amount of pain relief or the necessity of other procedures (radiography, wound cleansing). Although not all catfish spines are radiopaque, soft-tissue x-rays should be taken if there is a significant possibility of a retained foreign body. These films require careful examination to detect the presence of tiny serrations from catfish spines. If there is radio-

graphic evidence of foreign bodies, the wound should be explored, irrigated, and débrided. Removal of embedded spines may be difficult and require consultation with a surgical specialist. Although there are few data on the use of prophylactic antibiotics, patients with catfish envenomation frequently receive antibiotics (ciprofloxacin), particularly following the removal of foreign bodies, delayed presentation, or evidence of an immunocompromised host. *Aeromonas* species frequently are resistant to penicillin and cephalosporins.[61] Superficial abrasions or lacerations can be treated with local cleansing and topical antibiotics. Victims of catfish envenomation should be followed closely (24–48 hours) for the development of infection, particularly if prophylactic antibiotics are not administered.

RABBITFISH

This narrow, oval-shaped fish (Family: Siganidae) grows to about 30 cm (~1 ft) in length and inhabits coral reefs of the Indo-Pacific and the Mediterranean Sea. They possess numerous spines that contain venom glands along the lateral grooves. After penetration of the skin, the integumentary sheath ruptures and spreads venom in the victim. Immediate pain results from the envenomation, but the pain usually resolves soon after exposure. Rarely, case reports associate infectious complications including necrotizing fascitis with wounds caused by these fish.[62]

DOGFISH

These fish (Squalus spp.) are members of the order Squaliformes, and live throughout the temperate zones (tropics to sub-Antarctic seas). They prefer cool waters and protected bays, where they feed on a variety of vertebrate and invertebrate marine animals. Thick venomous spines protrude from the front of each dorsal fin; envenomation causes painful, erythematous, and edematous puncture wounds. Case reports associate local edema, erythema, and excruciating pain for 6 hours with contact with the anterior spine of a dogfish (*Squalus cubensis* Howell Rivero).[63] The local edema resolved after 2 weeks. Systemic symptoms are rare, but may be serious. Treatment is supportive.

TOADFISH

Toadfish (*Thalassophryne* spp., Family: Batrachoididae) inhabit shallow areas near the Atlantic Coast from Massachusetts to Central America, particularly in river mouths and estuaries. Other toadfish live in the Red Sea and Indo-Pacific (*Allenbatrachus grunniens* L. or *Batrachoides grunniens, Thalassothia cirrhosa* Klunzinger or *Barchatus cirrhosus*) and in the Mediterranean Sea (*Halobatrachus didactylus* Bloch & Schneider or *Batrachoides didactylus*). They are bottom-dwelling fish with large mouths and flat heads; they often hide in sand, rocks, or kelp beds. Two hallow spines with large venom glands at the base project from the dorsal fin, and envenomation by these spines causes local pain and swelling. Systemic symptoms do not usually develop after envenomation. The niquim (*Thalassophryne nattereri* Steindachner) is a venomous toadfish found in estuaries of the western Atlantic from Tobago to San Salvador and Brazil. This marine fish measures up to 14 cm (~5 in.). A substantial number of envenomations in fishermen from northeastern Brazil is attributed to the niquim.[64] Envenomation results from contact with venomous spines located near the opercular and dorsal fins that inject a protease with tissue-kallikrein-like activity.[65,66] The contamination of wounds with skin secretions from toadfish may contribute to the toxic effects of the envenomation.[34] Clinical features of envenomation include intense local pain, mild erythema, severe edema, and necrosis.[67] Complications include local necrosis and wound infections. Systemic symptoms do not usually develop after envenomation. Treatment is supportive.

PORCUPINE FISH

Porcupine fish (*Diodon Hystrix* L.) are widely distributed in marine environments from temperate to tropical waters. In the eastern Pacific, this fish ranges from southern California to Chile including the Galapagos Islands (Ecuador). The porcupine fish is the only member of the *Diodon* genus (order: Tetraodontiformes) found in the Mediterranean Sea. These fish are members of the puffer fish family (Diodontidae). Porcupine fish also live in the western Atlantic from Massachusetts and Bermuda to the northern Gulf of Mexico, south to Brazil. These shy inhabitants of warm coral reefs and shoals range in size between 20–50 cm (~8–20 in.). They are nocturnal, solitary creatures with approximately 20 spines in a row between the snout and dorsal fin that become erect

during defensive maneuvers. Otherwise, these spines are kept close to their bodies. The secretions of the skin of the porcupine fish contain tetrodotoxin as well as other thermolabile neurotoxins.[68] Four minor puncture wounds on the left middle finger after contact with a dead porcupine fish caused the onset of paresthesias and numbness within 1½ hours after envenomation. Over the next 2 hours, paresthesias and paresis of the left arm with lightheadedness developed.[69] No respiratory insufficiency occurred and symptoms (numbness, headache) resolved within 3 days. There were no laboratory abnormalities and the patient recovered without sequelae. Treatment is supportive with normal wound care procedures for minor puncture wounds and observation for respiratory insufficiency.

ICHTHYOTOXIC ACUTE RENAL FAILURE

In rural Asian populations, the ingestion of raw freshwater fish gallbladders is a traditional treatment for reduced visual acuity, arthritis, and impotence. Case reports associate the development of acute renal failure with the ingestion of raw gallbladders from freshwater fish. Fish species associated with this syndrome include the common carp (*Cyprinus carpio* L.), grass carp (*Ctenopharyngodon idella* Valenciennes), silver carp (*Hypophthalmichthys molitrix* Valenciennes), black carp (*Mylopharyngodon piceus* Richardson), bighead carp (*Aristichthys nobilis* Richardson), roho labeo (*Labeo rohita* Hamilton), blackshark minnow (*Labeo chrysophekadion* Bleeker), and the bony-lipped barb fish (*Osteochilus vittatus* Valenciennes).[70] Animal studies suggest that the C27 bile salt, 5-α-cyprinol, may contribute to the renal toxicity associated with the consumption of raw freshwater fish gallbladder,[71] but the exact nephrotoxin has not been identified. Renal biopsies from these patients are consistent with acute tubular necrosis. Some hepatotoxicity also occurs, primarily in fulminant cases. Clinical features typically involve the early onset of gastrointestinal distress (abdominal cramps, vomiting, diarrhea) followed in a few days by renal dysfunction. The gastrointestinal symptoms start from ½–12 hours (mean: ~4–5 hours) after ingestion followed by oliguria 48–72 hours after ingestion.[72] In a case series of 17 patients with this illness, the mean time to peak creatinine concentration was 8.6 ± 3.0 days. Rarely, fatal hepatorenal failure occurs.[73] Treatment is supportive with hemodialysis as needed.

Chapter 184

CARTILAGINOUS FISH
(Class: Chondrichthyes)

STINGRAY

IDENTIFYING CHARACTERISTICS

In contrast to reptiles, fish do not possess venom glands with muscles to inject venom into prey. Some bony and cartilaginous fish have sharp spines connected to a venom gland or spines covered with venom-producing epithelial tissue for defensive purposes rather than acquisition of prey. Relatively few fish species developed these spines covered with a sheath of venom-producing tissue. Most rays including the giant manta rays and devil rays from the Myliobatidae family do not possess venomous spines. However, stingrays have a long tail with venomous spines; these creatures constitute an important group of venomous marine animals. There are several families of marine stingrays and one family of freshwater stingrays.

Common Name: Stingrays

Scientific Name of Marine Families: Dasyatidae (whip rays, stingrays), Gymnuridae (butterfly rays), Myliobatidae (devil rays, bat rays, eagle rays, cow-nose rays), and Urolophidae (round stingrays, stingarees)

Scientific Name of Freshwater Family: Potamotrygonidae (river rays)

Physical Description: The diameter of the stingrays ranges between a few inches to over 5 ft (~1.5 m) with a whip-like tail containing one to four spines. These creatures have flattened dorsal and ventral surfaces with enlarged pectoral fins and the absence of a dorsal fin. Two eyes protrude on the dorsal surface. The most common color of the body is gray.

EXPOSURE

Geographic Distribution

Marine stingrays inhabit shallow waters up to 50 m (~160 ft) in depth in temperate, subtropical, and tropical areas including brackish lagoons and river estuaries. There are at least 11 species in US coastal waters. The marine families of stingrays are distributed worldwide including Dasyatidae (whip rays, stingrays), Urolophidae (round stingrays, stingarees), and Myliobatidae (devil rays, bat rays, eagle rays, cow-nose rays), whereas neotropical freshwater species of the family Potamotrygonidae (river rays) live in the Amazon, the Paraná (South America), the Niger (Africa), and the Mekong (Laos, Vietnam) river basins. Some species in the family Potamotrygonidae prefer the most extreme freshwater conditions of Brazil and the Paraná River basin. The butterfly rays (Gymnuridae) live in American waters as well as other marine waters around the world.

Behavior

The favorite habitats of these passive, reclusive bottom-dwellers are sandy or muddy bottoms of sheltered lagoons and estuaries, where they feed on crustaceans

Medical Toxicology of Natural Substances, by Donald G. Barceloux, MD
Copyright © 2008 John Wiley & Sons, Inc.

and mollusks. Their excellent camouflage and habit of submerging in the bottom cause accidental contact with exposed human extremities. Pressure on the back causes the stingray to envenomate the victim. The weight of the foot stimulates the stingray to thrust its tail forward, driving the spine deep into the victim's foot or lower leg. Incidental contact with the wings of a ray also results in the thrusting of the tip of the tail into the victim. The entire tip of the spine may remain embedded in the victim. In a case series of stingray envenomations, the lower extremity was involved in over 75% of the envenomations.[1] Rarely, serious envenomation occurs on the chest or abdomen while a human is swimming.[2]

PRINCIPAL TOXINS

Venom Composition

Experimental studies indicate that stingray venom potentially contains cardiotoxins (atrioventricular block, QRS prolongation, hypotension, bradycardia, ST-T wave changes), respiratory depressants, and convulsants.[1] Other fractions include phosphodiesterase, 5′-nucleotidase, and serotonin.[5] In rodent studies, the venom from Brazilian *Potamotrygon* freshwater stingray venoms produced mild proteolytic activity, but no hemorrhagic activity.[3] The venom of the smooth back river stingray (*Potamotrygon orbignyi* Castelnau) contains a novel peptide, orpotrin, which is a strong vasoconstrictor in *in vitro* studies.[4]

Venom Apparatus

All stingrays possess one to four bony, reverse-serrated spines located on the dorsal surface of their powerful tail. The arrow-like tip has proximally directed, serrated spines that cause jagged, bleeding lacerations. A thin layer of skin (integumentary sheath) surrounds the elongated spine and covers two ventrolateral grooves that contain venom glands. The spine is usually covered with a film of mucus and venom. When the venom gland on the tail enters the skin, the integumentary sheath surrounding the spine ruptures. Venom then flows down two ventrolateral grooves of the spine into the victim's skin. The powerful tail and serrated spines also cause traumatic wounds, such as penetrating injuries to the abdomen, chest, or throat. Severe trauma (e.g., fatal evisceration wounds to the abdomen or heart) may occur in children or adults.[1] Different families of stingrays possess significant variation in the sophistication of the venom apparatus. For example, the family Gymnuridae (butterfly rays) possesses the least developed system, whereas stingrays from Urolophidae (round stingrays, stingarees) have a well-developed muscular apparatus. The Dasyatidae (devil rays, bat rays) possess a partially developed venom apparatus including the California bat stingray (*Myliobatis californicus* Gill) commonly found off the US coast. Many stingrays lose or tear their integumentary sheaths (45% in one study of 4,000),[1] so that stings often result in trauma without envenomation.

Dose Response

There are inadequate data on stingray venom to determine a dose-response effect for human evenomation. Serious injuries following stingray envenomations usually result from trauma as well as toxicity.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The wound by a stingray causes traumatic injuries and envenomation. Consequently, a stingray envenomation can produce a variety of complications including secondary infection, osteomyelitis, intraabdominal trauma and peritonitis, and intrathoracic injuries (e.g., cardiac tamponade, right ventricular perforation).[5,6]

CLINICAL RESPONSE

The clinical features of a marine and fresh water stingray envenomation usually involve only local signs and symptoms (local pain, erythema, edema, ecchymosis, pruritus).[7,8] Intense pain out of proportion to the degree of trauma typically begins within 10 minutes of the envenomation, and the presence of pain disproportional to the injury suggests a stingray envenomation.[9] Edema around the wound is a constant finding, but the extent of the edema is variable. Cyanosis or erythema may surround the wound edges. The wound may be contaminated with debris from the integumentary sheath or surrounding fluids; bleeding is often profuse. If untreated, the pain reaches peak intensity within 60–90 minutes and resolves over 6–48 hours. Systemic symptoms vary considerably in intensity, and these clinical effects include abdominal pain, nausea and vomiting, muscle cramps, diaphoresis, tachycardia, syncope, headache, and muscle fasciculations.[10] Cardiac dysrhythmias, hypotension, and convulsions may occur during severe envenomations, but fatalities are not well documented in the absence of severe trauma. A supraventricular bigeminy developed in a 44-year-old male diver about 30 minutes after being stung by a Japanese red stingray (*Dasyatis akajei* Müller & Henle).[11] His rhythm spontaneously converted to his preexisting incomplete right bundle branch block within a few minutes, and no complications occurred.

Complications of stingray attacks include vascular injury with tissue necrosis and pseudoaneurysm.[12] Case reports of traumatic injuries following stingray envenomations include puncture wounds of the liver, perforated bowel, cardiac tamponade, and exsanguination secondary to femoral artery injury.[2,5,13] Freshwater stingrays inflict painful stings that often develop cutaneous necrosis.[14] Secondary infections may frequently develop. Systemic symptoms include nausea, vomiting, sweating, and agitation, but serious cardiac complications do not usually occur without direct trauma to the heart.

DIAGNOSTIC TESTING

The spines of stingrays are usually radiopaque, and plain films will demonstrate retained foreign bodies from the sting.[15] Most stingray envenomations are not associated with laboratory abnormalities. Deaths typically result from thoracic or abdominal trauma with associated hemorrhage.

TREATMENT

Treatment depends on the severity of the envenomation, the size and depth of the wound, and the extent of systemic symptoms. Lacerations of major arteries or organs may result in life-threatening hemorrhage that requires aggressive fluid resuscitation and blood transfusions.[16] First-aid procedures involve washing the wound with water and removing the integumentary sheath from the wound, if possible. Primary treatment is hot water immersion at 45 °C (113 °F) for 30–60 minutes until the pain resolves. This treatment reduces the acute pain associated with stingray envenomations, but hot water immersion does not alter the skin necrosis associated with freshwater stingray envenomations.[14] After soaking, the wound should be thoroughly débrided and copiously irrigated with saline or a very dilute povidone-iodine (Betadine®, Purdue Pharma, Stamford, CT) solution. If a retained stingray spine is suspected, plain radiographs should be obtained. Local anesthetics (e.g., nerve blocks are preferable) and a bloodless field are usually necessary to adequately remove the remnants of the integumentary sheath and to excise devitalized tissue.[17] Standard prophylactic antibiotics may be necessary because of the common occurrence of wound infections, and tetanus immunization should be updated as required.[18] The wound should be followed closely for signs of infection. Grossly contaminated wounds or wounds older than 6 hours on the extremity may be best managed by delayed primary closure. Large, contaminated wounds probably require prophylactic antibiotics. Although there are few clinical data, choices for antibiotics for suspected *Vibrio* or *Aeromonas* species in these large wounds include a third-generation cephalosporin (e.g., ceftazidime) or the combination of a first-generation cephalosporin or penicillinase-resistant penicillin plus a quinolone (e.g., ciprofloxacin). Elevation of the extremity is strongly recommended. Systemic symptoms should respond to the usual supportive measures. There are no adequate clinical data to support the use of steroids, cryotherapy, potassium permanganate, ammonia, or antihistamines.

RATFISH

Ratfish (chimaeras, Family: Chimaeridae) have large heads and tapering bodies with a long, narrow tails. The spotted ratfish (*Hydrolagus colliei* Lay & Bennett) is a relative of stingrays and sharks that prefers the cool waters of the Pacific Ocean from Alaska to Baja California. The European ratfish (*Chimaera monstrosa* L.) and the small ratfish (*Hydrolagus affinis* Capello) inhabit the northern Atlantic Ocean with the latter also occurring in the Mediterranean Sea. The first dorsal fin contains a strong, serrated spine capable of delivering venom from a glandular epithelium surrounding the slightly grooved spine. This large venomous spine potentially can produce a painful sting, but clinical evidence of envenomation in humans is limited and controversial.[19] Reported clinical effects include localized pain and erythema that usually responds to the treatment measures described for stingray and scorpion fish envenomations. Other types of fish in the class Chondrichthyes capable of producing local, painful puncture wounds include spiny dogfish (*Squalus acanthias* L.) and horned sharks (*Heterodontus* spp.). Hot water immersion at 45 °C (113 °F) for 30–60 minutes, thorough irrigation, and removal of debris are the main elements of supportive care.

VI Mammals

Chapter 185

MAMMALS

Although there are numerous nonmammalian vertebrates with lethal venoms, few mammalian species are venomous. The best-known venomous mammals belong to the orders Monotremata (platypus, spiny anteaters) and Soricomorpha (shrews). Fossil records indicate that some extinct mammals (North American eutherian, *Bisonalveus browni* Gazin) evolved specialized teeth as salivary venom delivery systems distinctly different from the present-day platypus or shrew.[1] Genome analysis indicates that reptile and platypus venom proteins have been co-opted independently from the same gene families.[2] The monotremes have one opening for their reproductive, excretory, and digestive systems, and in contrast to all other mammals, the female monotremes lay eggs instead of giving live birth. The Australian spiny anteater (echidna) has venomous spines on its hind legs, but there are few data on envenomations by this mammal.

PLATYPUS

Platypuses (*Ornithorhynchus anatinus* Shaw) are furry, dark-brown creatures that inhabit fresh water streams along the eastern Australian coast, Tasmania, and New Guinea where they feed on insect larvae, crustaceans, and mollusks on the bottom of streams. While foraging for food, they dive many times (~75 dives) every hour, spending several seconds between dives on the surface.[3] The mature male platypus weighs about 2 kg (~4 lbs) and measures about 60 cm (~2 ft) in length including a 20 cm (~8 in.) beaver-like tail. The female lays two or three eggs, which hatch after a one-week incubation by the mother. The male Australian duckbilled platypus has venomous, erectile, keratinized spurs on each inner hind leg just above the webbed foot. This shy, stocky creature has venom glands under the dorsal thigh muscles that connect to the spur via a venom duct. During envenomation, the male platypus grabs the victim between his hind legs and then drives the spurs into the victim while squeezing his thighs (and venom gland). Platypus venom is a complex mixture containing several polypeptides and nonproteins including defensins-like peptides,[4] L-to-D-amino-acid-residue isomerases,[5] and C-type natriuretic peptide.[6] The latter compound is a 39-residue peptide that is structurally similar to mammalian C-type natriuretic peptides. These compounds promote mast cell histamine release as well as causing hypotension and vasodilation in animal models via an increase in smooth muscle cGMP.[7] The role of defensins-like peptides in platypus venom is unclear because animal studies indicate these polypeptides do not affect muscles or Na^+-channel currents.[8] Envenomation produces immediate, severe pain along with hyperalgias and edema that may cause functional impairment of the envenomated extremity.[9] Symptoms may persist for 2–3 weeks, and muscle wasting can occur. Systemic effects following envenomation do not usually occur.[10] Treatment is supportive including ice, elevation, splints, and analgesia (regional anesthetic blocks, narcotic as necessary) to relieve the pain. Heat does not usually relieve the pain associated with enven-

omation. There is no clinical data to support the use of steroids.

SHREWS

Shrews are insectivores that belong to the order Soricomorpha and the Soricidae family; these animals are the smallest mammals on earth. Fossil records of the extinct giant shrews from the Early Pleistocene era indicate that these mammals had a rudimentary envenomation apparatus, probably as a means to increase body mass and hunt larger-sized prey.[11] These animals have short, dense fur and a long, slender snout. They live in a variety of habitats including forests, river banks, deserts, and even human dwellings. Venomous shrews include the American short-tailed shrew (*Blarina brevicauda* Say), the Haitian solenodon (*Solenodon paradoxus* Brandt), the European water shrew (*Neomys fodiens* Pennant), and the Mediterranean shrew (*Neomys anomalus* Cabrera).[12] These mammals possess enlarged and granular submaxillary venom glands that potentially could cause poisoning, but human envenomation is not well described.[13] Some shrews probably do not cause envenomation, such as the Indian shrew (*Suncus murinus* L.).[14]

American Short-Tailed Shrew

Based on limited experimental data, the venom from *Blarina brevicauda* Say is more toxic than other shrews.[12] Blarina toxin is an *N*-linked glycoprotein with a tissue kallikrein-like activity isolated from the submaxillary and sublingual glands of the American short-tailed shrew.[15] This toxin produces neurotoxic effects in animal models including respiratory depression, paralysis, convulsions, and death following intraperitoneal injection in mice.[16] A 32-kDa *N*-glycosylated protease, blarinasin, is a kallikrein-like protease that accounts for 70–75% of the kallikrein-like enzymes in the salivary gland of this shrew based on comparative studies.[17] The effect of envenomation by this shrew is variable, partly as a result of the inefficient venom apparatus.[18] The clinical significance of this toxin to humans is unclear because of the absence of reports of human toxicity following contact with shrews other than reports of minor local effects.[19] These mammals are potential vectors for bacteria and parasites.

Haitian Solenodon

The Haitian insectivore *Solenodon paradoxus* Brandt secretes venom from a mandibular gland that connects via a groove to the second lower incisor. These grooved incisors are missing in the American short-tailed shrew and the European water shrew. *Solenodon paradoxus* Brandt comprises one of only two surviving species of West Indian insectivores.[20] Human envenomations are not well documented, in part because of the limited habitat (i.e., Haiti, Dominican Republic) of this mammal. Mammalian bite produces a variety of infectious complications as well as serious diseases (e.g., rabies), but the mechanism is infectious rather than toxic.
